Foreword

THIS PUBLICATION, *Paint and Coating Testing Manual: Fourteenth Edition of the Gardner-Sward Handbook*, was sponsored by Committee D-1 on Paint and Related Coatings, Materials, and Applications. The editor was Joseph V. Koleske. This is Manual 17 in ASTM's manual series.

Acknowledgments

ASTM WOULD LIKE TO EXPRESS its gratitude to the authors of the previous 13 editions of this publication. These publications made significant contributions to the technology; therefore, ASTM, in its goal to publish books of technical significance, called upon current experts in the field to revise and update this important publication to reflect the changes and advancements that have taken place since the last edition, which was published in 1972.

Contents

Preface xi

Introduction xiii

PART 1: REGULATIONS

Chapter 1—Regulation of Volatile Organic Compound Emissions from Paints and Coatings 3
by John J. Brezinski

PART 2: NATURALLY OCCURRING MATERIALS

Chapter 2—Bituminous Coatings 15
by Ben J. Carlozzo

Chapter 3—Cellulose Esters 23
by L. G. Curtis

Chapter 4—Drying Oils 26
by Joseph V. Koleske

Chapter 5—Driers and Metallic Soaps 30
by Marvin J. Schnall

PART 3: SYNTHETIC MATERIALS

Chapter 6—Acrylic Polymers as Coatings Binders 39
by John M. Friel

Chapter 7—Alkyd and Polyesters 53
by Al Heitkamp and Don Pellowe

Chapter 8—Amino Resins (Reaction Products of Melamine, Urea, etc. with Formaldehyde and Alcohols) 60
by J. Owen Santer

Chapter 9—Ceramic Coatings 68
by Richard A. Eppler

Chapter 10—Epoxy Resins in Coatings 74
by Ronald S. Bauer, Edward J. Marx, and Michael J. Watkins

Chapter 11—Phenolics 79
by John S. Fry

Chapter 12—Polyamides 85
by Robert W. Kight

Chapter 13—Polyurethane Coatings 89
by Joseph V. Koleske

Chapter 14—Silicone Coatings 95
by D. J. Petraitis

Chapter 15—Vinyl Resins for Coatings 99
by Richard J. Burns

Chapter 16—Miscellaneous Materials and Coatings 108
by Joseph V. Koleske

PART 4: PLASTICIZERS

Chapter 17—Plasticizers 115
by Peter Tan and Leonard G. Krauskopf

PART 5: SOLVENTS

Chapter 18—Solvents 125
by Stephen A. Yuhas, Jr.

PART 6: PIGMENTS

Chapter 19—White Pigments 159
by Juergen H. Braun

Chapter 20—Black Pigments 179
by Frank R. Spinelli

Chapter 21—Colored Organic Pigments 190
by Peter A. Lewis

Chapter 22—Inorganic Colored Pigments 209
by Peter A. Lewis

Chapter 23—Ceramic Pigments 214
by Richard A. Eppler

Chapter 24—Extender Pigments 217
by Henry P. Ralston

Chapter 25—Metallic Pigments 223
by Russell L. Ferguson

Chapter 26—Pearlescent Pigments 229
by Carl J. Rieger

Chapter 27—Inorganic Anti-Corrosive Pigments 238
by M. Jay Austin

Chapter 28—Oil Absorption of Pigments 252
by Joseph V. Koleske

PART 7: ADDITIVES

Chapter 29—Bactericides, Fungicides, and Algicides 261
by Vanja M. King

Chapter 30—Thickeners and Rheology Modifiers 268
by Gregory D. Shay

PART 8: PHYSICAL CHARACTERISTICS OF LIQUID PAINTS AND COATINGS

Chapter 31—Density and Specific Gravity 289
by Raymond D. Brockhaus

Chapter 32—Particle-Size Measurements 305
by George D. Mills

Chapter 33—Rheology and Viscometry 333
by Richard R. Eley

Chapter 34—Surface Energetics 369
by Gordon P. Bierwagen

Chapter 35—Solubility Parameters 383
by Charles M. Hansen

PART 9: FILMS FOR TESTING

Chapter 36—Cure: The Process and Its Measurement 407
by Thomas J. Miranda

Chapter 37—Film Preparation for Coating Tests 415
by Robert D. Athey, Jr.

Chapter 38—Measurement of Film Thickness 424
by C. M. Wenzler and J. F. Fletcher

Chapter 39—Drying Time 439
by Thomas J. Sliva

PART 10: OPTICAL PROPERTIES

Chapter 40—Color and Light 447
by Fred W. Billmeyer, Jr. and Harry K. Hammond III

Chapter 41—Gloss 470
by Harry K. Hammond III and Gabriele Kigle-Boeckler

Chapter 42—Hiding Power 481
by Leonard Schaeffer

Chapter 43—Mass Color and Tinting Strength of Pigments 507
by Julio I. Aviles

PART 11: PHYSICAL AND MECHANICAL PROPERTIES

Chapter 44—Adhesion 513
by Gordon L. Nelson

Chapter 45—Abrasion Resistance 525
by Mark P. Morse

Chapter 46—Dynamic Mechanical and Tensile Properties 534
by Loren W. Hill

Chapter 47—Flexibility and Toughness 547
by M. P. Morse

Chapter 48—Hardness 555
by Paul R. Guevin, Jr.

Chapter 49—Stress Phenomena in Organic Coatings 585
by Dan Y. Perera

Chapter 50—Slip Resistance 600
by Paul R. Guevin, Jr.

PART 12: ENVIRONMENTAL RESISTANCE

Chapter 51—Prevention of Metal Corrosion with Protective Overlays 609
by William H. Smyrl

Chapter 52—Natural Weathering 619
by Lon S. Hicks and Michael J. Crewdson

Chapter 53—Accelerated Weathering 643
by Valerie D. Sherbondy

Chapter 54—Biological Deterioration of Paint Films 654
by David L. Campbell

Chapter 55—Chemical Resistance 662
by Alan H. Brandau

Chapter 56—Testing Coatings for Heat Resistance and Flame Retardance 667
by Wayne Ellis

Chapter 57—Water-Resistance Testing of Coatings 677
by Wayne Ellis

PART 13: SPECIFIC PRODUCT TESTING

Chapter 58—Aerospace and Aircraft Coatings 683
by Charles R. Hegedus, Stephen J. Spadafora, David F. Pulley, Anthony T. Eng, and Donald J. Hirst

Chapter 59—Architectural Coatings 696
by Harry E. Ashton

Chapter 60—Artists' Paints 706
by Benjamin Gavett

Chapter 61—Automative Product Tests 711
by Rose A. Ryntz

Chapter 62—Can Coatings 717
by Martin B. Price

Chapter 63—Masonry 725
by Frances Gale and Thomas Sliva

Chapter 64—Pipeline Coatings 731
by Loren B. Odell and Al Siegmund

Chapter 65—Sealants 735
by Saul Spindel

Chapter 66—Traffic Marking Materials 741
by Larry R. Hacker

Chapter 67—Water-Repellent Coatings 748
by Victoria Scarborough and Thomas J. Sliva

PART 14: ANALYSIS OF PAINTS AND PAINT DEFECTS

Chapter 68—Analysis of Paint 753
by Darlene Brezinski

Chapter 69—The Analysis of Coatings Failures 767
by George D. Mills

PART 15: INSTRUMENTAL ANALYSIS

Chapter 70—Atomic Absorption, Emission, and Inductively Coupled Plasma Spectroscopy 783
by Dwight G. Weldon

Chapter 71—Chromatography 789
by Rolando C. Domingo

Chapter 72—Electron Microscopy 815
by John G. Sheehan

Chapter 73—Infrared Spectroscopy 826
by Jack H. Hartshorn

Chapter 74—Methods for Polymer Molecular Weight Measurement 835
by Thomas M. Schmitt

Chapter 75—Coatings Characterization by Thermal Analysis 841
by C. Michael Neag

Chapter 76—Ultraviolet/Visible Spectroscopy 865
by George D. Mills

Chapter 77—X-Ray Analysis 871
by A. Monroe Snider, Jr.

PART 16: SPECIFICATIONS

Chapter 78—Paint and Coatings Specifications and Other Standards 891
by Wayne Ellis

Appendix 895

Index 899

Preface

AT A JANUARY 1967 MEETING OF ASTM COMMITTEE D-1 held in Washington, DC, ASTM (American Society for Testing and Materials) accepted ownership of the *Gardner-Sward Handbook* from the Gardner Laboratory. It was through this laboratory that Dr. Henry A. Gardner published the previous twelve editions of the manual. Acceptance of this ownership gave ASTM an assumed responsibility for revising, editing, and publishing future editions of this well-known, respected manual. The undertaking was assigned to Committee D-1 on Paint and Related Coatings, Materials, and Applications. This committee established a permanent subcommittee, D01.19 on Gardner-Sward Handbook, chaired by John C. Weaver, to provide technical, editorial, and general policy guidance for preparation of the 13th and subsequent editions of the *Gardner-Sward Handbook*. The 13th edition was published in 1972 as the *Paint Testing Manual* (STP 500) with Mr. G. G. Sward as editor. The manual has served the industry well for the past two decades; it contains useful information that cannot be found elsewhere. However, the passage of more than 20 years since its publication is readily apparent in many and perhaps most chapters of the manual.

Although updating the manual was discussed through the years, a variety of reasons prevented this task from being accomplished. Feasibility of updating the manual was not realized until mid-1989 when Dr. John J. Brezinski, Union Carbide (retired), and Mrs. Kathleen A. Dernoga, Manager of Acquisitions and Review of ASTM Technical Books and Journals, discussed the matter and the 14th edition was conceived. Between then and the spring of 1990 an outline for the 14th edition was developed and was approved by members of Subcommittee D01.19. Almost five years later the manual was completed—no wonder such a long period elapsed between editions!

The scope of the new edition is in keeping with the stated scope of Subcommittee D01.19:

> "To provide technical, editorial, and general policy guidance for preparation of the Fourteenth and subsequent editions of the Gardner-Sward Handbook. The handbook is intended for review of both new and experienced paint technologists and the past, present, and foreseeable trends in all kinds of testing within the scope of Committee D-1. It supplements, but does not replace, the pertinent parts of the Society's Book of Standards. It describes briefly and critically all Test Methods believed to have significance in the world of paint technology, whether or not these tests have been adopted officially by the society."

In this new edition, ASTM standard methods are described by minimal detail with the various volumes of the *ASTM Book of Standards* remaining the primary source of such information. An effort was made to include references in the absence of ASTM information concerning industrial, other society, national, and international test methods. For the most part, the manual contains either new chapters or the old topics/chapters in rewritten form. In a few cases, the old manual was merely updated, attesting to either the quality of the earlier writing, the lack of development in the area, or the apparent waning of interest in the topic. A variety of modern topics has been included. Individual authors, experts in their various fields, were given a great deal of freedom in expressing information about their topics.

Many things have changed through the years. The chemical emphasis has shifted from natural products to synthetic products, so this edition of the manual contains chapters that deal with a large number of synthetic polymers used in the coating industry. Instrumentation has undergone a marked change with innovative electronics providing the key to many changes. An effort was made to include chapters dealing with a broad variety of instruments.

To the authors, a warm, heart-felt "thank you." You put your talents to work and sacrificed much personal time to make the manual a success. A "thank you" is also due the reviewers, who are a special lot. They must be critical, yet carry out their task in a constructive manner. Because of the customary anonymity accorded reviewers, they should know that some authors made a special effort to express their appreciation for the review comments that they felt strengthened their manuscripts. Those organizations who permitted authors' time, use of support staff, and supplies are truly appreciated. Works such as this manual could not be completed without their generosity—may they prosper. The staff at ASTM is distinctive—they were interested and smilingly helpful to the authors, reviewers, Subcommittee D01.19, and the editor as they guided us through the maze of the publication assembly process (though they may have gritted their teeth at times). A very special thanks to Monica Siperko of ASTM, who worked closely with the editor in dealing with authors, reviewers, ASTM staff, and manuscripts. Her invaluable, cheerful assistance is appreciated. And last, but certainly not least, the contributions of Maureen Quinn and David Jones of the ASTM editing staff are acknowledged. Their able assistance ensured that the manual was uniform in style and grammar.

Editor

Introduction

PAST TO PRESENT

More than a score of years has passed since the previous edition of this manual was published, and many changes have taken place in the coating industry and elsewhere since that time. In 1972, the previous publication date, over 90% of all industrial coatings were low-solids, solvent-borne coatings. Total solids ranged from about 5 to 20% by weight. In the early 1970s, solvents were inexpensive, convenient carriers for the binder polymers used in coatings, and there appeared to be little knowledge in the scientific community about the consequences of breathing them, absorbing them through the skin, or placing them either in the atmosphere or in the environment in general. There were exceptions, as when a particular compound was known to be highly toxic. The specific effect of certain solvents as well as other chemicals on certain segments of the population was unknown in the scientific community. Large quantities of solvent were needed to dilute the high-molecular-weight binders to an appropriate application viscosity. High-molecular-weight binders imparted high-quality characteristics to the final coating. In addition, very dilute solutions allowed application of very thin, but continuous, films. These factors coupled with the low cost of energy used to drive the large ovens associated with coating manufacture were major reasons that kept coating systems low in solids and solvent-borne in nature. Even a large percentage of architectual coatings was oil-based, solvent-borne formulations. In an overall sense, products of the coatings industry worked and did a satisfactory job.

However, new technologies were being talked about, worked on, and even commercialized, albeit in a small way. Terms such as "powder coatings," "radiation-cure coatings," and "water-borne coatings" were beginning to creep into the language of the coating industry. The technologies promised a great deal, were considered mainly by the innovative, and had many difficulties associated with their introduction. Abbreviations such as EPA, MSDS, OSHA, SARA, TSCA, and similar others that are familiar to us today weren't yet in the industry's jargon. In fact, less than two pages (pp. 418–419) in the previous edition of this manual were dedicated to the topic of atmospheric pollution, and therein basically only Rule 66 was briefly discussed. No criticism is meant—such was the nature of the topic in the pre-1972 world. As stated previously, "Times have changed," and this new edition devotes a significantly sized chapter to acquaint readers briefly with the topic of regulation of volatile organic compounds emitted from coatings. This topic and the related topics of health and safety are mentioned a number of times in the manual.

POWDER COATINGS

Changes other than those of regulation, though related, have taken place in our industry. In 1972, coating journals had discussions about the "powder explosion." Powder coatings were to take over the industry since they were clean, 100% solids systems that could be applied on any substrate that could be either heated for fluid-bed application or made conductive for electrostatic spray application. Although powder coatings had been used in Europe as early as the 1950s, not many powder-coating systems existed in the United States in the 1970s. There was little incentive for large-company, raw-material suppliers who sold solvents to get into the powder coating business. A prime obstacle was the fact that there was little one could do to alter a

powder coating once it was made. If a fully formulated product such as a powder coating were to be sold by a raw-material supplier, there was a feeling that customers for solvents and other raw materials would be alienated. Also, from the end-user point of view, conversion from in-place, existing application equipment to powder coating equipment required a capital expenditure. This is a factor that always was and still can be a hindrance to conversion from existing to new technology.

It did not take long for the fuse of the powder keg to fizzle—but, more importantly, it did not go out. Epoxide powders were in vogue for pipeline coatings and were used on the Alaskan pipeline. In the early days of powder coatings, small amounts of vinyl chloride homopolymer and copolymer, polyester, and nylon powders were used. Fluid-bed application methods were first to be commercialized. It was relatively easy to melt-mix and grind mixtures of polymers, pigments, plasticizers, and other formulating ingredients to obtain the relatively large particle-size powders used by this method. Electrostatic spray took longer to develop since procedures for manufacture of the fine particle-size powders as well as the sophisticated spray equipment needed for effectively and efficiently handling charged powder particles had to be developed.

Powder coatings not only had problems in manufacture and application, but also in other areas such as: changeover from one color, availability and storage of a number of colored powders, flow and leveling, in developing thermoset coatings that would flow and level before cross-linking at an elevated temperature, in blocking during storage and as the powder flowed through the spray-system hoses and gun, in cost coupled with concerns about handling overspray and recovery and disposal. But, something new had been born, and a new industry within the coating industry was going through the throes of growing up in a competitive environment. Today the powder industry segment is strong and is growing. It has developed to the point where it now has its own organization, The Powder Coating Institute, located in Alexandria, VA. Journals such as the *Journal of Coatings Technology*, *Industrial Paint and Powder*, etc. now devote entire issues to the topic. Local, national, and international meetings are held to discuss the topic. The biennial trade show Powder Coating '92, held in Cincinnati, attracted over 4000 people, and 163 companies displayed their products. Powder coatings probably will not take over the coating industry, but they now are and continue to be important factors in the industry for the foreseeable future.

RADIATION CURING

Another new technology born in the late 1960s was radiation curing. It also showed great early promise and many problems—there were even unrealized problems at the beginning since no one really understood that some of the chemicals used were human sensitizers and strong irritants. Lack of knowledge in the scientific community about the hazards of acrylates resulted in some people becoming sensitized to these compounds. However, the idea of taking a liquid, low-viscosity, coating formulation, applying it to a substrate with conventional equipment, and having the coating essentially instantly converted into a solid, cross-linked film with very little or nil loss to the atmosphere was attractive.

Radiation curing involved the use of electron-beam or ultraviolet-light radiation. Free radicals were generated with ultraviolet light (photocure), and electrons were generated with electron beams. Acrylates and maleate polyesters/styrene were very rapidly polymerized in the presence of these active species. Because the reaction took place in thin films, the heat of reaction was readily dissipated and was not a problem to the technology. In the mid-to-late 1970s it was felt that this technology might capture only a percentage or two of the industrial coatings market.

Proponents of these essentially 100% solids systems refined the technology. Adaptation of existing equipment to the technology involved relatively simple, low-cost improvement when ultraviolet-light radiation was involved, and many conventional application techniques could be used. Most potential users insisted on the formulated products having low viscosity so that conventional equipment could be used. Such users were the driving force toward low-molecular-weight, reactive products. Innovators developed products that were quite safe to handle. A new branch of the technology that involved cycloaliphatic epoxides and photoinitiators that generated cationic species when photolyzed was begun at the end of decade.

Today, radiation-cure technology is considered a growth technology that is well established. It has developed to the point where it has its own technical society, RadTech International, located in Northbrook, IL, with large numbers of members and attendees at its meetings and exhibitions, which are held in North America, Europe, and Japan. Again, various journals have issues dedicated to the technology, and meetings or segments of meetings are held in various countries throughout the world. Radiation curing is currently a strong force in the market, and it is widely used to provide coatings for flooring, beverage cans (nonfood contact), electronics, plastics, paper, etc. It surely will also be a force in the future for as far ahead as we can see.

HIGH SOLIDS COATINGS

A third technology with its inception in the 1970s is high solids. Three factors provided the impetus for this technology and certainly had an effect on powder and radiation-cure coatings. First, the oil embargo during the mid-1970s caused the price of raw materials—including solvents—to increase significantly, and this was coupled with a significant scarcity of both petroleum-derived chemicals and fuel for energy purposes. Second, there was the energy cost involved in operating the huge ovens required to volatilize safely the large amount of solvent removed during the drying of the coatings. Not only were gas and oil costly, they were not readily available. High-solids, low-energy systems were developed in a feverish manner. Popular words in the industry at this time were "high solids" and "low energy cure."

Slowly the coating industry was coming to the realization that it might have to change—willingly or otherwise—from low solids and relatively easy to formulate systems to something new, be it powder coatings, radiation-cure coatings, water-borne coatings, or some other new technology. The third factor was related to concern about people and the environment. Everyone was becoming more and more conscious about the environment: in the workplace and the home as well as in a national and global geophysical sense. There was an awareness that solvents were being released into the atmosphere and into other parts of our ecological system, and that those solvents, though certainly not the only nor most important culprits, could have a long-term, deleterious effect on our environment and quality of life.

In addition to these factors, and very importantly, the government became strongly involved in regulation of the industry through the Environmental Protection Agency (EPA). The EPA is an agency that administers federal laws concerned with activities that affect the environment (details about the EPA and similar agencies are dealt with elsewhere in the manual). Governmental requirements, naive as some of them may have been at the outset, were established for the coating industry. For example, coatings were to contain no more than 20% volatile organic solvent. An industry that had been using formulations containing about 80 to 90% organic solvent and about 10 to 20% coating polymer was being asked (told) to change in a "quantum leap" manner. The industry was to develop formulations that significantly reduced the amount of organic solvent used and, of course, maintain ease of application, good protection, and aesthetically pleasing appearance. To term such a requirement "naive" may have been an understatement. The difficulty and impracticality of the requirement were realized, and over the years the standard has been modified. High(er) solids systems that contain more than 1 pound of polymer per pound of solvent are routinely used. Of course, this results in a markedly reduced volume of solvent that enters the atmosphere. Nonetheless, the change has been made and today almost all coatings are of the higher solids or 100% solids variety. Here, too, the industry discusses advances each year at The Water Borne and Higher Solids Coatings Conference that is cosponsored by the University of Southern Mississippi and the Southern Society and is held in the late winter of each year.

OTHER NEW COATING TECHNOLOGIES

Adjuncts to high-solids coating technology are the water-borne systems (though they may have predated organic-based systems) that require minimal cosolvent to achieve good appearance and properties, two-package coating systems that have relatively short pot lives, and water-borne emulsion or latex systems. The latter coatings are important

to the architectural coatings market, and today oil-base paints represent only a small fraction of the huge market for these commodity items. Latex-based paints have increased their solids, decreased volatile organic components, and are formulated with new thickening agents that have excellent flow characteristics. Even when the paint is applied by amateurs, spattering is almost unknown. This industry segment also is included in the above-mentioned symposium as well as at Lehigh University, which is well known for its efforts in the field of water-borne coating technology.

SOLVENTS

The area of solvent technology has undergone a number of changes during the past quarter of a century. The changes for the most part are associated with reduction of their health-hazard profiles and characteristics. Knowledge was developed or "rediscovered" about many solvents since the previous edition was published. This knowledge has led either to the demise or to "sharply" curtailed or restricted usage of what had been many commonly used solvents.

This same information was also responsible for innovation and has played an important role in development of new solvents that are less harmful to humans, animals, and the environment. The abbreviation MSDS (Material Safety Data Sheet) became well known for solvents and for other chemicals. Today these information sheets with safety data about materials are not only required for chemicals, they are used by people in laboratories and plants. It goes without saying that they should be required reading for anyone handling chemical compounds.

OTHER INNOVATIONS

The advent of new technology to produce functional and decorative coatings involved more than innovative organic chemistry. It also required innovative physical chemistry, material science, polymer science, and engineering. In addition to new chemicals and ways to use them, development of new application equipment and cure equipment was required. Conventional suction-feed spray guns and roll coaters could not be used for many of the new technologies. Powder coatings required development of methods of manufacture, of handling systems that could be quickly cleaned during a color change-over, of methods for placing a charge on the powder, of understanding and elimination of cage effects, of getting good wrap-around on other than flat substrates, of ways to remove fused powder from hangers and conveyors, and so on. Radiation-cure coatings required development of electron beam systems with improved safety features, of efficient ultraviolet light systems that could cure in other than line of sight, of low-viscosity chemicals with improved safety and health characteristics, and more. Water-borne systems had to deal with flash rusting, with minimizing cosolvents, with developing latexes that would quickly dry and fuse while maintaining qualities such as hardness, high gloss, and toughness. High solids required balances between molecular-weight, functional groups and their effects and viscosity, as well as between reactivity and shelf or pot life. It also required coating scientists to obtain high-quality finishes from the small molecules needed to achieve the low viscosity used for reasonable application characteristics at high-solids content.

Electronics also played an important role in the changes in coating technology and in the testing of coatings. During the period we are discussing, there has been a "Buck Rogerish" explosion in this industry. Many concepts and products related to such concepts that were considered amazing and with little likelihood of success in 1970 are realities today. Miniaturization technology has made printed circuit assemblies and semiconductors possible. Today, hand-held calculators are almost as powerful as the room-filling computers were in the early 1970s. Personal computers weren't even thought about in 1972. Robots and various forms of robotics have become useful tools in the 1990s. Application of electronics technology to a host of instruments, some of which are described in this manual, has vastly improved our ability to probe and otherwise examine and understand materials that are currently used, new materials as they are being developed, and final coatings in both an as-made and an aged condition. Both reliability and precision of tesing have been improved through new instruments.

Yet within this array of new test equipment that has been enabled through electronics and that allows quantitative results to be obtained in a reliable manner, there is still room for and a need for some of the simple, homey tests used for many years. Tests that are easy to apply and that require no elegant or complicated equipment are still desirable. Quickly drawing a nickel over a coating while applying downward pressure to the stroke almost immediately gives one a feeling for how well the coating is adhering to the substrate and to its toughness and formability. Such a test can be performed "on line" and by essentially anyone. Even interpretation of results is not difficult and is largely intuitive. Pencil hardness testing may vary from operator to operator, but one does not need to be a coatings scientist to quickly grasp what the test is measuring and to have a "feel" for a coating's hardness from the test. Solvent double rubs are easy to do. While the exact number of double rubs obtained may vary from individual to individual, the test still gives a quick understanding of the coating's thermoset character as well as the degree of cross-linking. Sharp impacts on the face or reverse side of a coated metal panel can quickly give an understanding about the impact and adhesion characteristics of the coating. These are four simple tests, but they can yield a great deal of understanding about a particular coating in a very short time. Other simple tests also exist.

Lest one get the wrong impression from the last few sentences, while these tests are useful, they certainly do not lead to the fundamental understanding that is very important to development of knowledge so necessary for new products. Sophisticated testing puts numbers on test results, probes deep into molecular achitecture, and allows both comparison of competitive products and the development of improved products. Sophisticated analyses also provide the understanding necessary to develop new chemicals and technology that will lead to improvements in existing products and to new products.

SUMMARY

Within the changed environment that has been described, the 13th edition of the *Paint Testing Manual* has, for the most part, become outdated—as was expected when it was compiled. Many of the methods described have changed, and the needs of the industry have also changed. The 14th edition reflects these changes. Even its title has been changed—to *Paint and Coating Testing Manual.* The collective effort of the many authors has resulted in a manual that has deemphasized, though certainly not eliminated, natural products, that provides a description of the regulations currently in force for the industry, and that discusses the main polymeric species, colorants, special pigments, extenders, and additives used in the industry today. The manual also deals with the analyses used to dissect and analyze a coating, the instruments used in the industry, and the products of the industry as well as how they are used and tested. Testing procedures for the most part are not detailed in the manual. Rather, the manual is a guide that will lead a coatings scientist to more in-depth treatises about the various topics and to test methods, procedures, and standards of ASTM and other national and international organizations.

Part 1: Regulations

Regulation of Volatile Organic Compound Emissions from Paints and Coatings

1

by J. John Brezinski[1]

PRIOR TO THE 1960s the coatings industry enjoyed a somewhat predictable regulatory and economic environment. The paint formulator developing a solvent-based coating selected solvents on the basis of evaporation rate, solubility parameter, density, flammability, and, of course, cost. There was no apparent need to consider the relative photochemical reactivity of these materials, nor was there any appreciable incentive to reduce the solvent content of commercially acceptable coatings.

It was, of course, recognized that objectionable odors were released from some paints and coatings. Further, air emissions resulting from the evaporation of solvents during high-temperature processing of oils and resins caused occasional complaints from persons living near the coatings plant. The prevailing view of this period was summarized by Francis Scofield in his article in the 13th edition of the *Paint Testing Manual* entitled "Atmospheric Pollutants" [*1*].

> These "nuisance" types of pollution are a continuing problem but, in general, can be dealt with by dilution and dispersion of the objectionable materials to bring the concentration below a level that can be detected by the neighboring citizenry. Fortunately, most of the materials used by the paint industry are not toxic at concentrations significantly below the range at which they can be detected by the human nose, and sophisticated analytical procedures are rarely needed to deal with these "nuisance" problems.

Since the 1960s societal concern about health and the environment has increased appreciably. Actions taken by federal and state legislative bodies have resulted in a steady avalanche of new laws and associated regulations that affect virtually all industry. Among the new federal laws administered by the U.S. Environmental Protection Agency (EPA) that impact significantly on the coatings industry are those shown in Table 1. They are designed to control the emission of pollutants to air, to water, and to soil.

In addition, among the new federal standards administered by the Occupational Safety and Health Administration are those that require manufacturers—including those making paints and coatings—to evaluate the hazards of products they make and to provide appropriate safety information to employees and users through the Material Safety Data Sheet (MSDS) and product labels.

TABLE 1—Federal environmental laws administered by the U.S. Environmental protection agency.

Law	Abbreviation
Clean Air Act, 1970	CAA
Amendments of 1977	CAAA-77
Amendments of 1990	CAAA-90
Clean Water Act of 1972 Amendments of 1977	CWA
Safe Drinking Water Act, 1974	SDWA
Toxic Substances Control Act, 1975	TSCA
Resource Conservation and Recovery Act, 1980	RCRA
Comprehensive Environmental Response Compensation and Liability Act, 1980	CERCLA (Superfund)
Superfund Amendments and Reauthorization Act, 1986	SARA
Title III, Emergency Planning and Community Right-to-Know, 1986	SARA, Title III

The discussion in this section will focus on the Clean Air Act and its amendments that, in the author's opinion, have had (and will continue to have) the greatest impact on coatings.

THE CLEAN AIR ACT AND ITS AMENDMENTS

California Smog

A precipitating factor influencing the basis for selection of solvents for coatings in the 1960s and early 1970s was the recognition that the emission of solvents from coatings to the atmosphere contributed to the growing "smog" problem in Southern California. The frequency of smog conditions in this area had increased steadily during the 1950s and 1960s as the number of automobiles, trucks, buses, and airplanes increased and as industrial development expanded with the accompanying growth of petroleum and chemical processing and power plant utilization.

The smog problem was (and is) most acute in the Los Angeles air basin, an area uniquely situated in a series of plains that originate in the high mountains to the east. The basin enjoys predominantly sunny days with cool moist air flowing with a light westerly wind most of the year. These factors cause a nearly permanent temperature inversion layer, trapping air emissions that combine to produce a persistent eye-irritating smog in the basin.

Copyright© 1995 by ASTM International

In a presentation entitled "Solvent Restriction—Problem or Opportunity," Dr. John Gordon, then of the University of Missouri-Rolla, discussed the major sources of hydrocarbons and nitrogen oxides, which together in the presence of UV radiation react to produce oxidants and ozone, major components of smog [2].

$$HC + NO_x \frac{\text{Sunshine}}{\text{UV Radiation}} \text{Smog } (O_3)$$

Sources of NO_x: Flame of almost any kind, volcanoes, internal combustion engines, forest fires, cigarettes, boilers, space heaters.

Processes that Produce Hydrocarbons

- Petroleum production, refining, transport
- Internal combustion engines
- Natural processes—forests and plants (isoprene and terpenes)
- Surface coatings

A 1962 estimate of the contaminants discharged into the Los Angeles air during the summer period revealed that motor vehicles accounted for about 60%, while the use of organic solvents (for all purposes) accounted for about 18% of the organic gases. About one half of the organic solvent emitted was attributed to the coatings industry, chiefly to the use in paint and coatings. Approximately 66% of the NO_x released was assigned to gasoline (motor vehicle) combustion, while the combustion of fuels (energy supply) accounted for about 26% [1].

Based on the results of laboratory studies in "smog chambers," in which a mixture of a solvent and nitrogen oxide was exposed for 6 h to light approximately the intensity of noon sunlight, the solvents could be classified as "low" or "high" in photochemical reactivity related to the amount of peroxides and ozone produced. These studies formed the basis for the well-known Rule 66, an air pollution control regulation passed by the Los Angeles Air Pollution Control District. Rule 66 identifies an "approved" solvent as one that contains less than 20% by volume of specific chemicals and is further limited to certain combinations of these chemicals. Thus, approved solvents can contain no more than designated amounts of the combinations shown in Table 2.

In effect, Rule 66 promoted the use of specific solvents such as aliphatic and naphthenic hydrocarbons, alcohols, esters, normal ketones, chlorinated hydrocarbons (except trichloroethylene), and nitroparaffins. Rule 66, superseded in 1976 by Rule 442, Usage of Solvents, by the California South Coast Air Quality Management District, was subsequently adopted by various other state jurisdictions. Renewed interest has developed recently in the consideration of solvent photochemical reactivity in state, federal, and international programs related to air quality control.

*Calculated as the percent by volume of the total solvent.

VOC Definition

The United States Environmental Protection Agency (EPA) was created in 1970 by Congress as part of a plan to consolidate several federal environmental activities. Studies directed by the EPA laboratories in Research Triangle Park, NC of the photochemical reactivity of materials in a laboratory smog chamber revealed that when organic materials and nitrogen oxide were irradiated for periods of up to 36 h, even those solvents considered acceptable under Rule 66 reacted to form peroxides and ozone. Only a few materials showed negligible photochemical reactivity, among which were: methane, ethane, methylene chloride, 1,1,1-trichloroethane, and fluorinated compounds. These studies, which were prompted in part by the passage of the Clean Air Act of 1970, led to the conclusion that most organic compounds emitted to the atmosphere contribute to the formation of ozone. On this basis, EPA adopted as a regulatory objective the limit of essentially all volatile organic compounds emitted to the atmosphere from all sources, including paint and coatings applications [3].

Regulatory Definition of VOC

The regulatory definition of volatile organic compounds (VOC) was revised by EPA in 1992. A part of this definition is as follows:

Section 51.100 Definitions[2]

Volatile organic compounds (VOC) means any compound of carbon, excluding carbon monoxide, carbon dioxide, carbonic acid, metallic carbides or carbonates, and ammonium carbonate, which participates in atmospheric photochemical reactions.

(1) This includes any such organic compound other than the following, which have been determined to have negligible photochemical reactivity: methane; ethane; methylene chloride (dichloromethane); 1,1,1-trichloroethane (methyl chloroform); 1,1,1-trichloro-2,2,2-trifluoroethane (CFC-113); trichlorofluoromethane (CFC-11); dichlorodifluoromethane (CFC-12); chlorodifluoromethane (CFC-22); trifluoromethane (FC-23); 1,2-dichloro-1,1,2,2-tetrafluoroethane (CFC-114); chloropentafluoroethane (CFC-115); 1,1,1-trifluoro 2,2-dichloroethane (HCFC-123); 1,1,1,2-tetrafluoroethane (HF-134a); 1,1-dichloro 1-fluoroethane (HCFC-141b); 1-chloro 1,1-difluoroethane (HCFC-142b); 2-chloro-1,1,1,2-tetrafluoroethane (HCFC-124); pentafluoroethane (HFC-125); 1,1,2,2-tetrafluoroethane (HFC-134); 1,1,1-trifluoroethane (HFC-143a); 1,1-difluoroethane (HFC-152a); and perfluorocarbon compounds which fall into these classes:

(i) Cyclic, branched, or linear, completely fluorinated alkanes;

(ii) Cyclic, branched, or linear, completely fluorinated ethers with no unsaturations;

[2]40 Code of Federal Regulations (CFR) Part 51; Requirements for Preparation, Adoption and Submittal of Implementation Plans; Approval and Promulgation of Implementation Plans. *Federal Register*, Vol. 57, No. 22, 22 Feb. 1992, pp. 3941–3946.

(iii) Cyclic, branched, or linear, completely fluorinated tertiary amines with no unsaturations; and

(iv) Sulfur containing perfluorocarbons with no unsaturations and with sulfur bonds only to carbon and fluorine.

(2) For purposes of determining compliance with emissions limits. VOC will be measured by the test methods in the approved State implementation plan (SIP) or 40 CFR part 60, appendix A, as applicable. Where such a method also measures compounds with negligible photochemical reactivity, these neglibility-reactive compounds may be excluded as VOC if the amount of such compounds is accurately quantified and such exclusion is approved by the enforcement authority.

(3) As a precondition to excluding these compounds as VOC or at any time thereafter, the enforcement authority may require an owner or operator to provide monitoring or testing methods and results demonstrating, to the satisfaction of the enforcement authority, the amount of negligibly-reactive compounds in the source's emissions.

(4) For purposes of Federal enforcement for a specific source, the EPA will use the test methods specified in the applicable EPA-approved SIP in a permit issued pursuant to a program approved or promulgated under title V of the Act, or under 40 CFR part 51, subpart I or appendix S, or under 40 CFR parts 52 or 60. The EPA will not be bound by an State determination as to appropriate methods for testing or monitoring negligibly-reactive compounds if such determination is not reflected in any of the above provisions.

The Ozone Standard

The Clean Air Act of 1970 targeted six criteria pollutants for control: carbon monoxide, lead, nitrogen dioxide, ozone, particulates, and sulfur dioxide. Criteria pollutants are those for which criteria were issued by EPA. These documents include national ambient air quality standards (NAAQS)—levels that protect against adverse effects to health and to plants and materials [*4*]. Standards for ozone and nitrogen oxides are:

Ozone The ozone concentration in the atmosphere *cannot exceed 0.12 ppm as a daily maximum one-hour average more than once per year.*

Nitrogen Dioxide The nitrogen dioxide concentration in the atmosphere *cannot exceed 0.053 ppm as the annual arithmetic mean concentration.*

CONTROL OF VOC EMISSIONS FROM COATINGS

The Clean Air Act addressed air pollution eminating from both existing sources and that from future new plant construction or significant modification of existing sources. States with areas that did not comply with the ozone standard were given primary responsibility to develop appropriate regulations for existing sources to meet the time schedule for compliance specified by Congress. The Federal EPA was assigned oversight responsibility for the state programs that were described in "State Implementation Plans" (SIP).

Control Technique Guidelines

In 1977, the Agency issued the first of a series of guidance documents for the states related to various industrial coating operations or end-use categories. These documents, called "Control Technique Guidelines (CTG) Series, Control of Volatile Organic Emissions from Stationery Sources," include recommended VOC emission limits, based on EPA's assessment of Reasonably Available Control Technology (RACT): the limits are expressed as pounds of VOC per gallon of coating (minus water), as applied.

The Clean Air Act Amendments of 1977 directed that states had to revise their implementation plans for areas out of compliance with the national ozone standard. The revised SIPs were to include sufficient control of VOC emissions from stationery sources, such controls to incorporate the RACT limits for coatings operations for which a CTG was published.

The CTG documents relating to surface coatings operations issued through 1992 are shown in Table 3 with recommended limits for VOC content.

NEW SOURCE PERFORMANCE STANDARDS

The control of VOC emissions from new coatings plants and from significant modifications of existing plants was addressed by EPA in a series of New Source Performance Standards (NSPS), the first of which issued in 1980. These mandatory standards, which apply uniformly to all parts of the country, define the emission sources more narrowly and impose a tighter level of emission control than that for related existing sources. The VOC limits defined in the NSPS, expressed as kilograms of VOC per liter of applied solids, are based on the best demonstrated technology (BDT) for the specific coating operation.

The New Source Performance Standards for surface coatings operations issued through 1992 are shown in Table 4.

The emission limits in both the CTG and NSPS documents, in the majority of cases, focus on restricting the VOC content per unit of coating or of coating solids applied in the operation, rather than placing a ceiling on individual plant emissions. The responsibility for establishing emission limits for particular plants, if appropriate, was left to the states [*5*].

DETERMINATION OF VOC CONTENT

Federal Reference Method 24

The procedures specified by the federal EPA for testing paint products for compliance with VOC limits are described in Federal Reference Method 24 [*6*]. This standard employs several ASTM test standards, including those shown in Table 5.

Method D 2369 is a key procedure of Federal Method 24. Since 1980, several important revisions have been made in this standard to make it compatible with revisions in Method 24, including the addition in 1990 of instructions for testing multicomponent coatings and the deletion of sections dealing with testing at shorter times. The revised version of Federal

		Natural finish plywood: 12.0 lb/1000 sq. ft of surface coated		
		Class II finishes 10.0 lb/1000 sq. ft of surface coated		

NOTE: The information presented in this table is not complete. Persons subject to emission control for any of the operations are advised to consult the state/local regulations for details.

[a]CTG documents are available from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161.

[b]Reasonably available control technology (RACT) limits recommended in CTG and, in most cases, adopted in state/local regulations.

Reference Method 24 is also included in the *ASTM Manual on Determination of Volatile Organic Compound (VOC) Content in Paints, Inks, and Related Coating Products*, 2nd ed., 1993 [7].

Substantial revisions during 1989–1991 were also made in ASTM D 3960, Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings, a standard developed in ASTM Subcommittee D01.21 to provide a guide for the calculation of VOC and to establish a base for the investigation in ASTM of the precision of VOC content determination. The definitions and symbols used in D 3960 are those adopted by the EPA and included in the Agency document "Procedures for Certifying Quantity of Volatile Organic Compounds Emitted by Paint, Ink and Other Coatings" that was published in 1984 [8].

The general expression for calculating VOC content in grams per liter of coating less water and exempt solvent specified in the EPA Control Technique Guidelines issued through 1991 is:

$$\text{VOC} = \frac{\begin{pmatrix}\text{Weight \% total volatiles}\\ \text{less water less}\\ \text{exempt solvent}\end{pmatrix}(\text{Density of coating})}{100\% - \begin{pmatrix}\text{Volume \%}\\ \text{water}\end{pmatrix} - \begin{pmatrix}\text{Volume \%}\\ \text{exempt solvent}\end{pmatrix}}$$

or

$$\text{VOC} = \frac{(W_o)(D_c)}{100\% - V_w - V_{ex}} = \frac{(W_v - W_w - W_{ex})(D_c)}{100\% - (W_w)(D_c/D_w) - (W_{ex})(D_c/D_{ex})} \quad (1)$$

where

VOC = VOC content in g/L of coating less water and exempt solvent,

W_o = weight % of organic volatiles = $W_v - W_w - W_{ex}$,

W_v = weight % of total volatiles = (100% − weight % nonvolatiles), (ASTM D 2369),

W_w = weight % of water (ASTM D 3792 or ASTM D 4017),

W_{ex} = weight % of exempt solvent (ASTM D 4457),

TABLE 4—VOC limits in New Source Performance (NSPS) for surface coatings operations.

Coatings Operation	NSPS Date[a]	Allowable Limits[b] Lb VOC/Gal Applied Solids	Kg VOC/L Applied Solids

[a]NSPS documents are available from the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161.

[b]Best demonstrated technology (BDT) emission limits established as NSPS standards. In the NSPS, the limits are expressed as kilograms of VOC per liter of applied solids.

TABLE 5—ASTM standards referenced in Federal Reference Method 24.

ASTM Method	Test Method for—
D 2369-81	Volatile Content of Coatings
D 1475-60	Density of Paint, Varnish, Lacquer, and Related Products
D 3792-79	Water Content of Waterborne Paints by Direct Injection into a Gas Chromatograph
D 4017-81	Water in Paints and Paint Materials by Karl Fischer Method
D 4457-85	Analysis of Dichloromethane and 1,1,1-Trichloroethane in Paints and Coatings by Direct Injection into a Gas Chromatograph

V_w = volume % of water = $(W_w)(D_c/D_w)$,
V_{ex} = volume % of exempt solvent = $(W_{ex})(D_c/D_{ex})$,
D_c = density of coating at 25°C in g/L (ASTM D 1475),
D_w = density of water at 25°C in g/L = 0.997×10^3, and
D_{ex} = density of exempt solvent at 25°C in g/L (ASTM D 1475).

To convert from g/L to lb/gal, multiply the result (VOC content) by 8.345×10^{-3} (lb/gal)/g/L). To convert g/L to kg/L, divide the result by 10^3.

The general expression for VOC content defined in terms of the mass of VOC per unit volume of coating solids applied as specified in the EPA New Source Performance Standards is

$$\mathrm{VOC}_m = \frac{(W_v - W_w - W_{ex})D_c}{V_n} \tag{2}$$

where

VOC_m = VOC content in g/L of coating solids, and

V_n = Volume % nonvolatile content of the liquid coating, ASTM D 2697.[3]

The EPA would have preferred to limit volatile organic compound emissions in the Control Technique Guidelines on the basis of the unit volume of coating solids applied. The adoption in the 1970s of Eq 1, in which VOC content is defined as mass per unit volume of coating less water and less exempt solvents, was necessary as no acceptable consensus procedure was available for determining the volume percent nonvolatile content. In a presentation in Copenhagen in 1990, James C. Berry of U.S. EPA stated: "Though certainly less than ideal, the major attraction is that the expression permits the determination of compliance from the analysis of a coating sample obtained during a plant inspection. In the simplest case, these units require only one volumetric and one gravimetric measurement" [5].

Studies and discussions in ASTM Subcommittee D01.21 that led to the modification and improvements of ASTM standards referenced in Federal Method 24 and in ASTM Practice D 3960 were conducted with the cooperation of EPA personnel of the Office of Air Quality Standards Development at Research Triangle Park, NC.

OTHER VOC-RELATED METHODS AND STUDIES

ASTM development activity on other VOC-related standards has expanded significantly since 1980. Many of the standards listed in this section have not been approved by the Federal EPA for use in demonstration of compliance with VOC emission control regulations. Use of any of these standards to demonstrate compliance should be coordinated with appropriate regulatory agencies. Among the new standards developed or in process of development are the following:

Standards Specific to the Automobile Industry

- D 5087 Test Method for Determining the Amount of Volatile Organic Compounds (VOC) Released from Solvent-Borne Automotive Coatings and Available for Removal in a VOC Control Device (Abatement)
- D 5066 Practice for the Determination of the Transfer Efficiency Under Production Conditions for Spray Application of Automotive Paints—Weight Basis
- D 5009 Test Method for Evaluating and Comparing Transfer Efficiency Under Laboratory Conditions

These standards were developed with the cooperation of representatives from automotive coating suppliers and the Motor Vehicle Manufacturers Association. Method D 5009 was derived from a study of transfer efficiency conducted for the U.S. Environmental Protection Agency [9].

Masonry Treatments

- D 5095 Test Method for Determination of the Nonvolatile Content in Silanes, Siloxanes, and Silane-Siloxane Blends Used in Masonry Water-Repellent Treatments.[4]

In this standard, a catalyst is added prior to the bake cycle to simulate the catalytic effect provided by masonry during actual application of the water-repellent treatment.

Aerosol Spray Paints

- D 5200 Test Method for Determination of Weight Percent Volatile Content of Solvent-borne Paints in Aerosol Cans
- D 5325 Test Method for the Determination of Weight Percent Volatile Content of Water-borne Aerosol Paints

These standards were developed for potential use related to proposed regulations in California to limit the level of volatile organic material in aerosol paints.

General Application Standards

- D 5201 Practice for Calculating Formulation Physical Constants of Liquid Paints and Coatings

The calculation of various physical constants directly from the paint formulation is a common practice in industry. ASTM D 5201 describes procedures for the calculation of *formulation* weight solids, volume solids, solvent content, and density of liquid paint based on formulation data (not analytical laboratory determinations). The values obtained may not be acceptable for demonstrating regulatory compliance.

- D 5286 Test Method for Determination of Transfer Efficiency Under General Production Conditions for Spray Application of Paints

This standard, a modification of Practice D 5066 developed for use in the automobile industry, describes conditions for determining transfer efficiency under production conditions applicable to spray application of miscellaneous parts.

- D 5327 Practice for Evaluating and Comparing Transfer Efficiency under General Laboratory Conditions

Practice D 5327 provides a useful guide for general research studies related to transfer efficiency. The general approach employed is derived from that developed in Method D 5009 except that D 5327 employs a fixed rather than moving spray station.

- Revision of D 2697, Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings: Use of the Helium Gas Pycnometer (Under Study)

The use of the helium gas pycnometer provides a quick, reliable approach to the determination of the dry coating density, a critical parameter in the calculation of volume percent nonvolatile content.

- Direct Measurement of Volatile Organic Material in Water-Reducible Coatings (Under Study)

Federal EPA funds supported the preliminary investigation of this novel approach to the "direct" gravimetric determina-

[3]EPA Reference Method 24 does not include an analytical method for determining V_n, but states that the value be calculated from the coating manufacturer's formulation.

[4]This standard has been accepted by the Federal EPA for use in the determination of the VOC of silane- and siloxane-based coatings: Letter, Gary McAllister, EPA, to H. Smith, NJ Dept. of Environmental Protection, 25 March 1992.

tion of volatile organic content of waterborne coatings [*10*]. The method involves collecting, on activated charcoal in weighed tubes, the organic effluent evolved on heating a paint specimen for 1 h at 110°C while purging the reaction vessel with dry nitrogen. Methanol is not captured on the charcoal.

- D 5403 Test Method for Volatile Content of Radiation Curable Materials

The test methods in D 5403 determine the weight percent volatile content of paint, coatings, and inks that are designed to be cured by exposure to ultraviolet light or to a beam of accelerated electrons. After radiation cure, the specimens are baked at 110 ± 5°C for 60 min.

Inks

- D 5328 Volatile Organic Compound (VOC40) Content of Non-Heatset Paste Printing Ink Systems at 40°C

This standard is patterned, in part, after Method 30 of California's Bay Area Air Pollution Control District in which the specimen is baked for 1 h at 40°C. D 5328 is applicable to paste printing inks and vehicles that dry primarily by absorption, polymerization, or related means without the application of heat.

Supplementary Information

Further information about the development, significance, and limitations of these VOC-related ASTM standards as well as about the use of ASTM standards for the demonstration of compliance with VOC emission control regulations is available in the ASTM *Manual on Determination of Volatile Organic Compounds in Paints, Inks, and Related Coating Products* [*7*]. Attachments in the second edition of this manual include the 1992 revision of Federal Reference Number 24 and a publication from EPA's Emission Standards Division titled "Procedure for Certifying Quantity of Volatile Organic Compounds Emitted by Paint, Ink and Other Coatings" [*8*]. Included in the latter publication are "VOC Data Sheets" applicable to coatings "as supplied" by the manufacturer and for coatings "as applied" by the user. The form used for "as supplied" coatings is patterned after a recommendation of the National Paint and Coatings Association.

CLEAN AIR ACT AMENDMENTS OF 1990

The Clean Air Act Amendments of 1990 defined a comprehensive long-term approach "to achieve and maintain a healthy environment while supporting a strong and sustainable economic growth and sound energy policy."[5] A major impetus for these amendments was the continued inability of a number of heavily populated urban areas to meet the requirements of the national ambient air quality standards for ozone and carbon monoxide.

Among the specific issues addressed in the Act are: control of ozone in the atmosphere; control of hazardous air pollutants; reduction of acid rain; and the protection of ozone in the stratosphere.

Features of the Act that will impact most on the coatings industry include:

Title I—Ozone Control in the Atmosphere

Title I specifically directs EPA to develop control technique guidelines and maximum achievable control technology (MACT) standards for aerospace coatings and for shipbuilding coatings and repair. EPA was also directed to prepare new control technique guidelines for additional coatings uses that include:

- autobody refinishing
- plastic parts (business machines)
- plastic parts (others)
- offset lithography
- wood furniture

In addition, EPA plans to promulgate national rules to control VOC emissions from architectural and industrial maintenance coatings and from traffic paints. Solvent emission from consumer and commercial products, including that from aerosols, are currently under study, and regulation of this broad category of products is planned. In the development of these rules, negotiated rulemaking may be employed, a process bringing together representatives of EPA, industry, the states, and environmentalist groups to negotiate the content of a proposed rule.

In CAAA-90, ozone nonattainment areas are placed in five classifications based on the mid-1991 ozone level (Table 6), and compliance with the national ozone standard by specific years is mandated in the law.

Increasingly strict provisions, including further reduction of VOC emissions, will be imposed on areas, the magnitude to be related to the severity of the ozone problem. Depending on the area classification, several or all of the following will be required:

- Increased monitoring and more accurate VOC and NO_2 emission inventory
- Revision of state implementation plans to incorporate RACT limits from previous and future CTGs for all major stationery sources
- New source review and permits for new or modified stationery sources
- Reduced emission threshold levels for the definition of major stationery sources, ranging between 10 tons/year for severe classification areas to 100 for marginal or moderate areas

TABLE 6—Clean air act amendments—1990 ozone nonattainment area classifications.

Classification	Design Value (Ozone Level)	Years to Achieve Compliance, year
Marginal	0.121–0.138	3 (1993)
Moderate	0.138–0.160	6 (1996)
Serious	0.160–0.180	9 (1999)
Severe	0.180–0.280	15 (2005)
Extreme[a]	0.280 and above	20 (2010)

[a]Only the Los Angeles area is in this classification.

- Higher VOC emission offset requirements for new or modified sources

Title III—Air Toxics Program

Under Title III, EPA is directed to evaluate and control the emission of hazardous air pollutants (HAPS). 189 products are identified in the Act, and EPA has the authority to delete or add additional products to this list. Industry groups may petition EPA to delist products.

Among the materials included on the initial HAP list that are used in paints and coatings are those shown in Table 7.

The control of emissions of hazardous air pollutants is to be achieved through the promulgation of emission standards for source categories and subcategories that emit these products. The initial list of categories of sources published by EPA (57FR31576, 16 July 1992) included under *Surface Coating Processes* those processes for which a CTG or national rule has been issued or is planned. Also included is the *Manufacture of Paints, Coatings and Adhesives.* A draft timetable for regulating the categories of sources of hazardous air pollutants was published by EPA in 1992 (57FR44147, 24 Sept. 1992). By the end of 1994 emission standards were due for the following surface coating processes: magnetic tapes, printing/publishing, shipbuilding and ship repair, and wood furniture.

The Agency was required to publish emission limits based on maximum achievable control technology (MACT) for 40 of these categories by the end of 1992, with MACT limits to be identified for the remaining categories by 2000. The Act directs that the health impact and economic factors be considered in defining appropriate MACT limits. Further, by the end of 1995 sufficient categories and subcategories must be listed to ensure that 90% of the area sources that emit the 30 most hazardous air pollutants are subjected to regulation.

TABLE 7—Clean air act amendments—1990 selected hazardous air pollutants used in paints and coatings.

ORGANIC MATERIALS
Bis (2-ethylhexyl phthalate)
Dibutyl phthalate
Diethanolamine
Dimethyl formamide
Dimethyl phthalate
Ethylene glycol
Formaldehyde
Glycol ethers (ethylene oxide-based)
Methanol
1,1,1-trichloroethane (methyl chloroform)[a]
Methylene chloride[a]
Methyl ethyl ketone[a]
Methyl isobutyl ketone[a]
2-nitropropane
Styrene
Toluene[a]
Xylenes[a]
INORGANIC AND OTHER
Ammonia
Antimony compounds
Cadmium compounds[a]
Chromium compounds[a]
Cobalt compounds
Lead compounds[a]
Mercury compounds[a]

[a]Materials included in the EPA/Industry 33/50 Project, a voluntary industry initiative to reduce the total release and transfer of 17 targeted chemicals by one third by the end of 1992 and by one half by the end of 1995 (using 1988 as a baseline year).

Title V—State Operating Permit Program

The state operating permit program is considered by EPA as a cornerstone of the CAAA-90 amendments designed to ensure that the ozone nonattainment areas meet compliance deadlines. This program will impact on many previously unregulated coatings manufacturers and users. The final rule re the operating permit program was issued in 1992 (57FR32250, 21 July 1992).

The operating permit program has been called the "air pollution equivalent" of the NPDES permit program of the Clean Water Act, under which operating permits are required of sources that discharge pollutants to water. In the program under Title V, all federal and state air pollution rules and regulations will be consolidated under a single document wherein the states are given authority to monitor and enforce the regulations. Sufficient funds will be available to the states from a minimum annual fee of $25 per ton for each regulated pollutant emitted, the fee to be assessed against all major sources.

Major sources required to have state operating permits include those that emit 10 tons or more per year of a single regulated hazardous air pollutant or 25 tons per year of a combination of hazardous air pollutants. These pollutants include those materials for which a national emission standard (NESHAP) has been established. Under Title V of CAAA-90, and the final rule on operating permit programs, EPA is to approve (or disapprove) state permit programs within one year of receipt; the major sources must apply for the five-year permit within one year of the EPA's approval of the state program, and all permits must be issued and be legally binding by the end of 1997. Under the rule, states have the option of exempting all nonmajor sources, with some exceptions, from requiring a permit for five years after the state permit program is approved by EPA.

The characterization of a major source in ozone nonattainment areas is also based on the amount of volatile organic compounds emitted annually. The threshold amount is related to the area classification and sources in ozone nonattainment areas that emit above the designated amount of VOC shown in Table 8 are identified as major sources. These limits vary between 10 tons/year for the "extreme" classification to 100 tons/year for the "marginal or moderate" classification.

For ozone transport regions (e.g., one is established in the Northeast), a threshold limit of 50 tons/year of VOC emission applies.

TABLE 8—Clean air act amendments—1990 major source identification based on VOC emissions: limits for area classifications.

Ozone Nonattainment Area Classification	VOC Emission Limit, tons/year
Marginal or moderate	100
Serious	50
Severe	25
Extreme	10

Title VI—Stratospheric Ozone Protection

The most significant feature of the program to protect ozone in the stratosphere is the staged phaseout of 1,1,1-trichloroethane, a material widely used in coatings and classified as a "VOC-exempt" solvent by the EPA. Production (and use) will be reduced in increments (from the 1989 amount) beginning in 1993 to a 50% level for the period 1996–1999, then to the 20% level for the period 2000–2001, after which the use of the material will be prohibited.

Title VII—Enforcement

EPA is granted broad new authority to impose penalties and substantial fines for various actions including: violations of the State Implementation Plan; violation of some of the operating permit provisions; and false statements in records, monitoring data, and reports. Also included are provisions for field citations by inspectors.

Scenario for the 1990s

CAAA-90 and the myriad of new federal and state regulations associated with implementation of this comprehensive law that will issue during the 1990s will have a major impact on the coatings industry. Among the many uncertainties are the nature and level of MACT limits to be defined for essentially all coating operations; the level of new or stricter VOC

emission limits for coating operations; and the time, manpower, and cost associated with complying with the many new regulations associated with the amendments.

As did the decades of the 1970s and 1980s, the 1990s will pose a continuing challenge to raw material suppliers to develop and provide environmentally acceptable materials as well as to paint formulators to develop new or modified coatings with reduced VOC content. Additionally, increased attention to the improvement of coating processes and to the use of abatement equipment for emission control during the application of coatings is expected.

REGULATION INFORMATION

Published Sources

Federal environmental regulations, including those promulgated under the Clean Air Act, are published in the *Code of Federal Regulations* (CFR), a series of books that are generally available in major libraries and law libraries. These regulations as well as those of related state and local codes are also obtainable from the associated regulatory offices.

Regulations of particular interest to the coatings industry can be found in subchapters of the *Code of Federal Regulations* (Table 9).

The Federal Control Technique Guidelines for coating operations are not included in the CFR, but are available from the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161. CTG documents through 1991 are included in the EPA publications listed in Table 10.

Proposed regulations are published by the EPA in the *Federal Register.* Typically, a public (written) comment period of 30 to 90 days on the proposals is allowed, and often a public hearing is scheduled at which oral comments can be presented. The comments received are considered by the Agency in the development of a final regulation that is published in the *Federal Register* together with the regulation compliance date.

Information Sources

Questions relating to the interpretation, applicability, and compliance to air quality regulations may be addressed to the U.S. EPA regional offices or to the specific state regulating body responsible for air quality control.

The U.S. Environmental Protection Agency has established ten regional offices, each responsible for several states (Table 11).

Among the industry organizations that provide information to their membership about pending regulations and guidance on compliance with finalized regulations are Chemical Manufacturers Association (CMA), National Paint and Coatings Association (NPCA), Dry Colour Manufacturer's Association (DCMA), and Chemical Specialty Manufacturers Association (CSMA). Several coatings journals publish excerpts from regulations and summary reviews.

Part 2: Naturally Occurring Materials

2

Bituminous Coatings

by Ben J. Carlozzo[1]

INTRODUCTION

General Overview

IN THE UNITED STATES, the terms "bituminous" and "asphaltic" are often used interchangeably. In Europe, bitumen refers to the mixture of heavy hydrocarbons, free of inorganic impurities. Asphalt is often considered the impure form of the generic material [*1*]. For our purposes, the ASTM definitions will be used.

ASTM Definitions of Terms Relating to Roofing, Waterproofing, and Bituminous Materials (D 1079-87a) [*2*] defines bitumen as either ". . .(1) a class of amorphous black or dark colored (solid, semi-solid, or viscous) cementitious substances, natural or manufactured, composed principally of high molecular weight hydrocarbons, soluble in carbon disulfide, and found in asphalts, tars, pitches and asphaltites; or, (2) a generic term used to denote any material composed principally of bitumen."

Asphalt is similarly defined as ". . .a dark brown to black cementitious material in which the predominating constituents are bitumens which occur in nature or are obtained in petroleum processing." While the term has historically implied the natural deposits (the Trinidad Lake asphalts on the Island of Trinidad or the Bermudez Lake, Venezuela asphalts), most asphalt used in the United States today for coatings applications is from petroleum processing [*3*].

History and Background of Bitumens

As one of man's oldest engineering materials, the adhesive and waterproofing properties of bitumen have been known since the earliest days of civilization. The area between the Tigris and Euphrates rivers in Iraq, long believed to be "the cradle of civilization," contains the earliest deposits of asphalt and heavy liquid petroleum. Early historical and biblical accounts tell of the use of asphalt in shipbuilding and foundation mortars. The Egyptians were known to have used asphalt in the mummification process; in fact, the part-Persian word for asphalt, "mumiya," is where our word "mummy" is derived [*4*].

The first asphalts produced in the United States were derived from California crude oils in the late 19th century. A straight run distillation, often without steam, was able to produce a good-quality material suitable for paving work. Most of this material was competing with foreign imports from the Lake Trinidad region on the Isle of Trinidad off the north coast of South America. In the early 20th century, Mexican asphalt obtained from Mexican crude oil was used extensively in the eastern United States and gained a reputation as a high-grade standard paving bitumen.

Today, asphalts are found throughout the world in several natural deposits of soft bituminous material or as hard, glassy, black bitumen associated with certain rock formations or impregnating various limestone or sandstone-type formations. Additionally, asphalts are derived from colloidally dispersed asphalt hydrocarbons in crude petroleum. This leads to the classification of bitumens into two classes: (1) natural asphalts (bitumens) and (2) artificial or oil asphalts (petroleum asphalts).

The purity of bituminous materials is generally related to the degree that they are soluble in certain organic solvents. For years, the degree of solubility in carbon disulfide (CS_2) has been a typical method for determining the purity of natural asphalts. ASTM Test Method for Bitumen Content (D 4-86) formalizes this procedure with CS_2 solubility as the primary screening test. Most oil asphalts are generally greater than 99% soluble in CS_2.

The natural asphalts can be further classified by the geographical region of their origin, as well as the extent to which impurities are present, for example, Trinidad, refined, of approximately 50 to 57% bitumen; Cuban, refined, of 80 to 90% purity; Bermudez, refined, of 85 to 92% purity; and various rock asphalts, i.e., limestone, sandstone, tar sands, etc., with varying degrees of bitumen content.

A separate class of natural bitumens are the asphaltites. These are also called the solid bitumens and are asphalts without impurities (silts, clays, salts, etc.), although their degree of CS_2 solubility varies. Examples of these materials are Gilsonite, grahamite, glance pitch, or manjak, as well as harder materials that show no softening point, such as the pyrobitumens. The most important of these for coatings applications is Gilsonite.

Artificial bitumens have been classified into three major groups [*5*]:

1. Oil or petroleum asphalts are soft to hard asphalts of high solubility in carbon disulfide (more than 99%) and are classed as pure bitumens. They are obtained from the vacuum or steam distillation of crude oils containing high asphalt content. The distillation concentrates the colloidally dispersed asphalt into the "still bottoms" or "residuum" and is often a solid material.

[1]Mameco International, Inc., Cleveland, OH.

Copyright© 1995 by ASTM International

Precipitation methods are also used to recover asphalt from raw lubricating oils. This de-asphalting operation uses propane or other low-boiling hydrocarbons. The materials produced are the so-called asphaltic resins, with the hard, high asphaltene asphalts as the precipitate. Variations are made by controlling the propane stream.

Oxidized or "blown" asphalts are obtained by blowing air at high temperatures through soft or liquid petroleum residues. This procedure can take semi-asphaltic materials of low purity and produce considerable amounts of bitumen. The resulting material is harder, with a higher softening point.

2. "Cracked" asphalts are also petroleum derivatives, but are obtained from by-products in oil-cracking processes. Residues are distilled to produce asphalt. They are variable in composition and may contain a certain amount of uncracked paraffinic material. These materials represent asphaltic hydrocarbons approximately intermediate in aromaticity between oil asphalts and the completely aromatic, highly condensed bitumens found in coal tars, water-gas tars, coal carbonization tars, and their pitches.
3. Coal tar, water-gas tars, and their pitches are derived from tars. ASTM D 1079 defines tar as ". . .a brown or black bituminous material, liquid or semi-solid in consistency, in which the predominating constituents are bitumens obtained . . . from the processing of coal, petroleum, oil-shale, wood, or other organic materials." The "free carbon" content, or other benzene insoluble matter, distinguishes coal tar from the asphaltites and oil asphalts. The latter are devoid of free carbon. Coal tars and their products are not included in the category of asphalt.

In the early 1960s, approximately 70% of all oil asphalts were consumed by the road-paving industries with 20% used in roofing. The solid bitumens and asphaltites of natural origin found their greatest consumption in lacquer, paint, and electrical insulation. Today, the paving industry is still the largest user of these materials, but the scope and area of specialty coatings has broadened considerably. In recent years, asphalts and other bitumens have become increasingly important as the cost of other natural and synthetic binders has continued to escalate. Their ability to act as adhesives with excellent moisture vapor transmission (MVT) properties continues to result in new and varied uses.

Coating Types

The types of asphaltic or bituminous coatings available can be classified, in a large part, by the industry of use. Industries considered are:

1. The paints and coatings industry, where bituminous coatings have been used to protect metal from the effects of water and oxygen degradation.
2. The roofing industry, where asphalt coatings are used extensively to weatherproof buildings.
3. The construction industries, where concrete and mortar are waterproofed.
4. The paving industry, where the adhesive properties of asphalt as binder is put to good use in roads.

Specialty Paints and Coatings

Asphalt, coal tar, and other bitumens have been used in several specialty areas in the paint and coatings industry. The predominate use has been in the area of pipe coatings and automotive under-body coatings, although containment coatings are fast becoming a sizable market.

In pipe coatings, the base bitumen forms an inter-penetrating network with a thermosetting resin to form an impervious barrier to groundwater and the effects of catastrophic rusting. On deep buried pipes or those set in concrete, the cost associated with the use of an expensive binder is offset by the large replacement costs involved. The thermoset resins most frequently used have been the epoxides. The bitumens used in these coatings have generally been the coal tars and pitches. This was primarily due to the compatibility of these highly aromatic materials with epoxy resins, as well as the ease of working with a liquid material. The final film hardness is derived from the cross-linked epoxy network.

There has been a growing concern with the toxicity of highly aromatic systems. The result has been that trade sales and light industrial coatings have moved away from coal tar or its pitches. Recently, the asphaltites and oil asphalts have been used in these types of coatings. The trend has been to use softer asphalts. Some form of compatibilizer has also been necessary to make these lower aromatic-content systems stable.

In automotive under-body rustproofing, bituminous coatings have found extensive use. These materials are modified with rubbery materials to give flexible coatings with excellent adhesion to metal parts. Many years ago, the predominant bitumen in use had been coal tar. Today, with the move away from highly aromatic products, petroleum asphalts are generally used. To use the harder bitumens such as asphaltites and petroleum asphalts, plasticizers such as di-octyl phthalate or butyl benzyl phthalate are required to soften and liquify the bitumen. Aromatic processing oils have also been used for this purpose. Natural and synthetic waxes are added to prevent chipping from road debris.

Given the severe penalties associated with contamination of groundwater, chemical and moisture-resistant coatings for containment dikes are being used more and more in the chemical process industry. Most state and local regulations require the use of a containment wall around every storage tank that may potentially rupture and contaminate the water table.

Coatings for this application have included coal tar epoxies and coal tar resinous systems. Gilsonite-based resinous coatings have been widely used and, depending on the chemical nature of the contained material, petroleum asphalt urethanes and epoxides are available.

Additional areas where bitumens have shown applicability as specialty coatings have included the areas of sealing soil to minimize water penetration (pond liners, seepage control for levees and dams, and hazardous waste containment) as well as sound deadening on sheet metal and binding other bituminous materials such as coal or lignite for pelletization.

Roof Coatings

In roof coatings, bitumens have been important raw materials since the turn of the century. Today, many commercial roofing systems use some form of asphalt or chemically mod-

ified asphalt in their construction. The application of an asphalt or polymer-modified hot melt asphaltic material, followed by the application of a reinforcing membrane, is the basic construction of a modern built-up-roof (BUR).

In some markets, the current industry trend has been away from the use of hot melt coatings, where a roofing kettle that heats the materials up to 450°F (232°C) to reach their application viscosity is required, and toward cold-applied systems. Here, the asphalt is usually modified with solvents, fillers, and thixotropes as well as various additives to result in a formulation that can be applied at ambient temperatures with good flow properties and that which will subsequently dry or cure into a weatherproofing membrane.

In these coatings, volatile solvents are varied to control cure times. In general, the solvents are either mineral spirits or naphthas. While asbestos was long a preferred additive for thixotropy and reinforcement, the hazards of working with and removing old installations with asbestos-containing materials have driven the products toward asbestos-free roofing materials. This has led to the use of cellulose, synthetic, and glass fibers as a partial replacement for asbestos. Bentonite and attapulgite clays are then used to obtain the required thixotropy. Today, there are still a significant number of manufacturers that continue to use asbestos in their formulations.

The asphalt portion of these coatings usually consists of materials referred to as cutbacks. Various solvents are used to cut (solubilize) the asphalt, depending on the cure times required. The solvent predominantly used today is mineral spirits, with a flash point (tag closed cup) of 104°F (40°C). Faster evaporating versions of these cutbacks have been used as primers for better substrate adhesion. These materials generally use faster aromatic solvents, including toluene, xylene, and the aromatic naphthas. The asphalt content varies from 30 to 70% by weight.

The preceding materials, while they can, in the strictest sense, be considered coatings, are actually closer to adhesives in performance; that is, these coatings are applied to hold the reinforcing membranes together. Although the last coat applied may be a flood coat of the adhesive coating, the roof is usually not left this way. Weathering characteristics are significantly improved when these roofs are gravel surfaced. This graveled surface blocks harmful ultraviolet (UV) radiation and serves to improve the fire resistance. The most common roof gravels are river-washed gravel, crushed stone, granite, and blast-furnace slag recovered from the iron ore reduction process and composed of silicates and aluminosilicates of lime [*6*]. Other materials, also available for this purpose, include a variety of small, colored roofing granules, similar to those used on shingles.

From 400 to 600 lb (181 to 272 kg) of river-washed gravel per 100 ft^2 (9.29 m^2) of roof is used, or, if weight considerations are important, 50 to 60 lb (22.68 to 27.2 kg) of the smaller roofing granules can be used. The bituminous coating is then an adhesive for these gravels.

Due to weight limitations on existing roofs and costs associated with roof tear-offs and subsequent reroofing, current philosophy is to maintain the existing roof. When physically possible, restoration instead of replacement is very cost effective. This requires the use of coatings whose purpose is to repair damage to the roof and re-establish or maintain the weather-tight seal. After the repairs are complete, a reflective coating may be applied to act as an ultra-violet (UV) barrier and thermal reflector, or additional gravel added. Several different types of coatings have been available for each of these purposes.

Asphalt cutbacks and emulsions are the primary coating used for restoration. They are applied in heavy applications of 40 to 80 mil thick. This allows the coating to cover minor surface defects that are present on the old roof. Splits and cracks can be repaired by using these materials with either fiberglass or polyester reinforcements. A final application gives a reasonably water-tight monolithic appearance.

Asphalt emulsions consist of two types. In one, the water is dispersed in the asphalt external phase. In the other, the asphalt is dispersed in a water external phase. The first are called water-in-oil (W/O) emulsions. The later are oil-in-water (O/W) emulsions. Roofing emulsions are predominately water-in-oil emulsions. The oil-in-water emulsions are more widely used in the paving industry and will be discussed in more detail in that section.

The water-in-oil emulsions are produced from finely powdered clays, which can act as dispersants for the water. Dispersing agents of this type show some affinity for water or are sufficiently hygroscopic to hold water and bring it into dispersion in the asphalt. The bentonite clays form extremely colloidal gelatinous mixtures and pastes with water and result in asphalt dispersions of very small particle size. These smooth buttery emulsions are very stable and can be fibered for reinforcement and modified with latex resins to obtain a degree of elasticity. Most commercial products are unmodified and yield a final coating possessing all the properties of a gel asphalt after evaporation of the water. Several books are available which offer greater detail in the area of emulsion technology [*7–9*].

Asphalt emulsions can be left untop-coated, but are frequently coated with reflective topcoats to help control roof top temperatures. For several years, the major type of coatings for this application have been solvent-borne aluminum pigmented bituminous coatings. A wide variety of bitumens have been used, including asphalt, asphaltite, tar, and pitch. Their viscosity has generally been low with moderate levels of volatile solvents present. Most of the solvent-based aluminum bitumen paints in use today are asphalt vehicles made from petroleum asphalt cutbacks. The predominate solvent has been mineral spirits. The pigment used has generally been a leafing grade of aluminum paste. It is reported that some early formulations used cumerone indene resin to improve the leafing characteristics and act as an anti-bronzing agent. A level of 2 lb (0.91 kg) of aluminum paste per gallon of paint is typical in these coatings [*10*].

With the recent increase in environmental legislation and an increased awareness of health issues, alternatives to these solvent-borne coatings are beginning to find their place in the market. Specifically, asphalt emulsions of various solids are being used in conjunction with new aluminum pigment technology which allows the manufacture of relatively stable waterborne versions [*11,12*]. These materials generally consist of petroleum asphalt emulsions that use organophosphate-treated leafing-aluminum pastes. The phosphate passivates the aluminum, giving it more stability on storage. The solids of such coatings vary from 25 to 50% by weight. Additional

modification similar to other emulsion systems is also used in these coatings.

Newer technologies to stabilize aluminum pigments in water have recently been introduced. Chemically bound chrome is used to passivate the aluminum [*13*]. While quite expensive, these products are finding use in the automotive industry. As their cost decreases, perhaps they will be available for the waterborne bituminous aluminum market.

Other technologies exist that are nonbituminous in composition. These coatings include elastomeric acrylic latexes, solvent and waterborne urethanes, epoxides, and alkyds. These are usually pigmented with either titanium dioxide (TiO_2) or aluminum pastes to give thermally reflective coatings. These types of coatings will be discussed elsewhere in this manual.

Waterproofing Membranes

Bitumen-modified waterproofing membranes are used extensively in the construction industry. The most common substrate is poured or cast concrete or mortared "cinder block." Prestressed concrete in the foundations, walls, and roof decks of high-rise buildings is also a suitable candidate for these membranes. In the home construction and repair industries, cinder block foundations and concrete footers are commonly waterproofed with bitumen-modified polymeric coatings.

The bitumen of interest in these markets has predominately been coal tar pitch and petroleum asphalts. Waterproofing membranes are generally composed of bitumen in an elastomeric polymer matrix. The aromatic polyurethanes are frequently used for this purpose.

In coating structural steel and steel reinforcement bars, coal tar epoxies have been extensively used. Their composition and purpose is similar to that of pipe coatings used for the prevention of underground corrosion. Their composition can be modified to conform to a particular steel coatings application.

As in other markets, the use of aromatic coal tars is slowly being replaced by safer soft petroleum asphalts. Environmental issues aside, higher tech systems are beginning to be seen. Other types of coatings for rebar in the last five years have included fused epoxy powder coatings systems and polyethylene dip coated systems. While much more expensive than bitumen-modified systems, their improved performance have made them of interest.

Coatings for Paving

The paving industry is probably the oldest using bitumen and its coatings. Asphalt cutbacks have also been known as "road oils." For years these solvent cut materials were used to seal roads as well as coat aggregates for application to the road surface. Today, hot asphalt or cutback is used to prime new paving as well as to repair damaged or worn areas.

Today, most road coating uses asphalt emulsions. These are generally chemically stabilized emulsions. The emulsion is prepared beforehand and mixed with aggregate on site and is referred to as *chip* and *seal*. Hot asphalt is not required in this application, making it much easier than the use of hot mix paving, where the asphalt is heated to melting before application. In paving, oil-in-water emulsions predominate.

The oil-in-water emulsions are formed from the action of a chemical emulsifier, either anionic, cationic, or nonionic in nature. The anionic and cationic emulsifiers form an emulsion in which the dispersed phase shows a definite charge. These emulsions are said to "break" upon contact with a charged aggregate, yielding the exclusion of one phase from the other. The speed of break can be modified, yielding rapid, medium, or slow setting emulsions. The cationic versions are preferred because the coating formed does not re-emulsify. With anionic emulsifiers, break occurs when emulsions destabilize due to water loss on drying. One disadvantage of this is the possibility of re-emulsification in the early stages of cure. Once the coating has dried, water is no longer a problem.

Paving sealers are used to protect new or old asphalt driveways or parking lots. The sealers are generally coal tar in nature due to good resistance to gas and oil. Asphalt sealers can also be used, but they must be latex or polymer modified to improve solvent resistance.

Other types of bituminous coatings used in the paving industry include slurry seals and micro surfacing, which uses latex or polymer-modified asphalts with fine aggregate filler as a surface treatment for repair of minor damage to roads. Coal tar is not used in this application because the resulting coating is too slippery. Tack coats consisting of asphalt cutbacks are also used when one layer of asphalt needs to be adhered to another.

IDENTIFICATION OF BITUMINOUS MATERIALS

This section will catalogue several test methods currently available through ASTM for characterization of bituminous paints and coatings. Many of these methods are familiar to the coatings chemist as standard paint-related tests found in Volumes 6.01 through 6.04 of the *Annual Book of ASTM Standards*. Several others are under the jurisdiction of Committee D 8 on Roofing, Waterproofing, and Bituminous Materials. These methods appear in Volume 4.04 of the *Annual Book of ASTM Standards*.

Tests on Bituminous Materials

The following test methods are used to differentiate one type of bitumen from another. They also can distinguish mixtures of bitumens and their purity. As bitumens are considered pseudo-plastic materials, with no true melt point, softening point and penetration are the two major tests routinely performed to identify differences within grades of the different bitumen classes. Viscosities at elevated temperatures are also very important with several instruments and their methods listed.

In earlier editions of this manual, several tests were described that were in common use in 1972. Among the tests described were the solubility of bitumens in carbon disulfide (CS_2) to identify the purity of a bitumen sample, since by definition only CS_2 soluble matter is bitumen. Also listed were tests to determine the presence of asphalt and tar in suspected mixtures (the Oliensis Spot Test and the characteristics of bituminous samples dispersed in solvent). Today, these have been incorporated into the *Annual Book of ASTM Standards* and will not be described in detail.

On this note, it is important to point out that each industry that uses bitumens has tended to develop their own series of common pertinent tests over the years. Today most of the pertinent tests have been incorporated as ASTM standards. In addition to ASTM, other organizations have tried to compile these tests for their members' use. The Asphalt Institute, an international, nonprofit organization sponsored by members of the petroleum asphalt industry, also publishes a handbook that has evolved over the past 50 years as the standard reference work in the field of asphalt technology and construction, especially in the paving industry [*14*]. This reference book cites both ASTM test methods and, where applicable, American Association of State Highway and Transportation Officials (AASHTO) counterparts to these methods. A large part of the manual is devoted to practical how-to information about how to use asphalt, as well as comprehensive data on asphalt technology, and is highly recommended.

General

D 4-86 Test Method for Bitumen Content

D 5-86 Test Method for Penetration of Bituminous Materials

D 36-86 Test Method for Softening Point of Bitumen (Ring and-Ball apparatus)

D 70-82 Test Method for Specific Gravity and Density of Semi-Solid Bituminous Materials

D 88-81 Test Method For Saybolt Viscosity

D 92-90 Test Method For Flash and Fire Points by Cleveland Open Cup

D 95-83 Test Method for Water in Petroleum Products and Bituminous Materials by Distillation

D 140-88 Practice for Sampling Bituminous Materials

D 529-90 Test Method for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials

D 1079-87 Definitions of Terms Relating to Roofing, Waterproofing, and Bituminous Materials

D 1669-89 Method for Preparation of Test Panels for Accelerated and Outdoor Weathering of Bituminous Materials

D 1670-90 Test Method for Failure End Point in Accelerated and Outdoor Weathering of Bituminous Materials

D 4798-88 Test Method for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials (Xenon-Arc Method)

D 4799-88 Test Method for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials (Fluorescent UV and Condensation Method)

D 4989-90 Test Method for the Apparent Viscosity Flow of Roofing Bitumens Using the Parallel Plate Plastometer

E 96-90 Test Methods for Water Vapor Transmission of Materials

E 102-81 Test Method for Saybolt Furol Viscosity of Bituminous Materials at High Temperatures

E 108-90 Method for Fire tests of Roof Coverings

Specifications and Test Methods for Asphalt

D 71-84 Test Method for Relative Density of Solid Pitch and Asphalt

D 312-89 Specification for Asphalt Used in Roofing

D 449-89 Specification for Asphalt Used in Dampproofing and Waterproofing

D 1328-86 Test Method for Staining Properties of Asphalt

D 1370-84 Test Method for Contact Compatibility Between Asphaltic Materials (Oliensis Test)

D 1856-79 Test Method for Recovery of Asphalt from Solution by Abson Method

D 2042-81 Test Method for Solubility of Asphalt Materials in Trichloroethylene

D 2521-76 Specification for Asphalt Used in Canal, Ditch, and Pond Lining

D 3461-85 Test Method for Softening Point of Asphalts and Pitches (Mettler Cup-and-Ball Method)

D 4402-87 Test Method for Viscosity Determinations of Unfilled Asphalts Using the Brookfield Thermosel Apparatus

Specification and Test Methods for Coal Tar, Pitches, and Highly Cracked Petroleum Products

D 61-75 Test Method for Softening Point of Pitches (Cube-in-Water Method)

D 450-78 Specification for Coal Tar Pitch Used in Roofing, Dampproofing, and Waterproofing

D 2318-86 Test Method for Quinoline-Insoluble (QI) Content of Tar and Pitch

D 2319-76 Test Method for Softening Point of Pitch (Cube-in-Air Method)

D 2320-87 Test Method for Density (Specific Gravity) of Solid Pitch (Pycnometer Method)

D 2415-66 Test Method for Ash in Coal Tar and Pitch

D 2416-84 Test Method for Coking Value of Tar and Pitch (Modified Conradson)

D 2569-89 Test Method for Distillation of Pitch

D 2764-81 Test Method for Dimethylformamide-Insoluble (DMF-I) Content of Tar and Pitch

D 2962-71 Method for Calculating Volume-Temperature Correction for Coal-Tar Pitches

D 3104-87 Test Method for Softening Point of Pitches (Mettler Softening Point Method)

D 4072-81 Test Method for Toluene-Insoluble (TI) Content of Tar and Pitch

D 4312-89 Test Method for Toluene-Insoluble (TI) Content of Tar and Pitch (Short Method)

D 4616-87 Test Method for Microscopical Analysis by Reflected Light and Determination of Mesophase in a Pitch

D 4715-87 Test Method for Coking Value of Tar and Pitch (Alcan)

D 4746-87 Test Method for Determination of Quinoline Insoluble (QI) Content in Tar and Pitch by Pressure Filtration

D 4892-89 Test Method for Density of Solid Pitch (Helium Pycnometer Method)

D 4893-89 Test Method for Determination of Pitch Volatility

D 5018-89 Test Method for Shear Viscosity of Coal Tar and Petroleum Pitches

TESTS AND SPECIFICATIONS FOR COATINGS

General Tests for Coatings

Several of the test methods familiar to the industrial paints and coatings chemist can also be used to characterize the performance and physical properties of bituminous coatings. The following methods can all be found in Volumes 6.01 through 6.04 of the *Annual Book of ASTM Standards*.

Tests and Specifications

B 117-90 Method of Salt Spray (Fog) Testing

D 522-88 Test Methods for Mandrel Bend Test of Attached Organic Coatings

D 555-89 Guide for Testing Drying Oils

D 562-81 Test Method for Consistency of Paints Using the Stormer Viscometer

D 609-90 Practice for Preparation of Cold-Rolled Steel Panels for Testing Paint, Varnish, Conversion Coatings, and Related Coating Products

D 610-85 Method for Evaluating Degree of Rusting on Painted Steel Surfaces

D 662-85 Test Method for Evaluating Degree of Erosion of Exterior Paints

D 714-87 Method for Evaluating Degree of Blistering of Paints

D 1212-85 Test Methods for Measurement of Wet Film Thickness of Organic Coatings

D 1474-85 Test Methods for the Indentation Hardness of Organic Coatings

D 1475-90 Test Method for Density of Paint, Varnish, Lacquer, and Related Products

D 1540-82 Test Method for Effect of Chemical Agents on Organic Finishes Used in the Transportation Industry

D 1542-60 Test Method for Qualitative Detection of Rosin in Varnishes

D 1640-83 Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature

D 1644-88 Test Methods for Nonvolatile Content of Varnishes

D 1654-79 Method for Evaluation of Painted or Coated Specimens Subjected to Corrosive Environments

D 1849-80 Test Method for Package Stability of Paint

D 2243-90 Test Method for Freeze-Thaw Resistance of Water-Borne Paints

D 2247-87 Practice for Testing Water Resistance of Coatings in 100% Relative Humidity

D 2369-90 Test Methods for Volatile Content of Coatings

D 2370-82 Test Method for Tensile Properties of Organic Coatings

D 2832-83 Guide for Determining Volatile and Nonvolatile Content of Paint and Related Coatings

D 3170-87 Test Method for Chip Resistance of Coatings

D 3359-90 Test Methods for Measuring Adhesion by Tape Test

D 3960-90 Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings

G 6-88 Test Method for Abrasion Resistance of Pipeline Coatings

Solvent-Thinned or Cut-Back Coatings

General

D 255-70 Method for Steam Distillation of Bituminous Protective Coatings

D 402-76 Test Method for Distillation of Cut-Back Asphaltic (Bituminous) Products

D 529-90 Test Method for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials (Carbon-Arc Method)

D 3105-90 Index of Methods for Testing Elastomeric and Plastomeric Roofing and Waterproofing Materials

Roof Coatings

D 41-85 Specification for Asphalt Primer Used in Roofing and Waterproofing

D 43-73 Specification for Creosote Primer Used in Roofing, Dampproofing and Waterproofing

D 1227-87 Specification for Emulsified Asphalt Used as a Protective Coating For Built-Up Roofing

D 2823-90 Specification for Asphalt Roof Coatings

D 2824-85 Specification for Aluminum-Pigmented Asphalt Roof Coatings

D 3805-85 Practice for Application of Aluminum-Pigmented Asphalt Roof Coating

D 4479-85 Specification for Asphalt Roof Coatings—Asbestos Free

D 5076-90 Test Method for Measuring Voids in Roofing and Waterproofing Membranes

Waterproofing Membranes

D 41-85 Specification for Asphalt Primer Used in Roofing, Dampproofing and Waterproofing

D 43-73 Specification for Creosote Primer Used in Roofing, Dampproofing and Waterproofing

D 5076-90 Test Method for Measuring Voids in Roofing and Waterproofing Membranes

Paving Sealers

D 3320-90 Specification for Emulsified Coal Tar Pitch (Mineral Colloid Type)

Specialty Coatings

D 41-85 Specification for Asphalt Primer Used in Roofing and Waterproofing

D 43-73 Specification for Creosote Primer Used in Roofing, Dampproofing and Waterproofing

D 1187-82 Specification for Asphalt-Base Emulsions for Use as Protective Coatings for Metal

Emulsion Coatings

General

D 466-42 Method of Testing Films Deposited from Bituminous Emulsions

D 529-90 Practice for Accelerated Weathering Test Conditions and Procedures for Bituminous Materials (Carbon-Arc Method)

D 1187-82 Test Method for Asphalt-Base Emulsions for Use as Protective Coatings for Metal

D 2939-78 Method for Testing Emulsified Bitumens Used as Protective Coatings

Clay Stabilized Emulsions

D 1227-87 Specification for Emulsified Asphalt Used as a Protective Coating For Built-Up Roofing

D 2963-78 Test Method for Testing Flow Table Consistency of Clay-Stabilized Asphalt Emulsions

D 3320-90 Specification for Emulsified Coal Tar Pitch (Mineral Colloid Type)

Anionic Emulsions

D 1227-87 Specification for Emulsified Asphalt Used as a Protective Coating For Built-Up Roofing

Non-Ionic Emulsions

D 1227-87 Specification for Emulsified Asphalt Used as a Protective Coating For Built-Up Roofing

Cationic Emulsions

D 1227-87 Specification for Emulsified Asphalt Used as a Protective Coating For Built-Up Roofing

Resin Modified Bituminous Coatings

Synthetic Resins

D 3468-90 Specification for Liquid-Applied Neoprene and Chlorosulfonated Polyethylene used in Roofing and Waterproofing

CONCLUSION

Bituminous coatings are still used extensively today. The waterproofing and adhesive properties, coupled with the relatively inexpensive costs for most bituminous materials, continue to drive their use in many diverse industrial applications. The preceding information will give the reader an understanding of the chemistry and uses of bituminous coatings in industry and a realization that even several thousand years after their discovery and first use the usage of these bituminous raw materials as an engineering raw material is still growing.

Cellulose Esters

by L. G. Curtis[1]

CELLULOSE ESTERS ARE THE reaction product of combining organic acids and acid anhydrides with the hydroxyl groups found on the anhydroglucose repeating units of a cellulose molecule. The esterification of the cellulose with the acids and anhydrides occurs quite rapidly and if allowed to proceed to completion, forms a triester with each of the anhydroglucose units, which contain three hydroxyl groups. Because the triester is of little practical use, hydrolysis is necessary to restore desired levels of hydroxyl content, which affects various properties of the cellulose ester such as solubility and compatibility with other coating polymers.

PRODUCTION OF CELLULOSE ESTERS

For the production of coating-grade cellulose esters, three organic acids and anhydrides are used, either separately or in combination with each other. Cellulose acetate is the simplest cellulose ester since only acetic acid and acetic anhydride are used in the esterification reaction. If two different organic acids and anhydrides are used simultaneously, the resultant product is referred to as a mixed ester. Examples of mixed cellulose esters are cellulose acetate butyrate and cellulose acetate propionate.

In addition to esterification and hydrolysis, several subsequent processing steps are required in the manufacture of cellulose esters including filtration, precipitation, washing, dewatering, drying, and screening. The final product is a dry, free-flowing powder in most instances, although other physical forms can be produced. Unlike cellulose nitrate, organic esters of cellulose are low in flammability and present no handling hazards.

TYPES OF CELLULOSE ESTERS

Several types of cellulose esters are commercially available, including cellulose acetate, cellulose acetate propionate, and cellulose acetate butyrate. Other esters of lesser commercial value are produced, but are not suited for coating applications. Table 1 shows the types of cellulose esters commercially available. Cellulose acetate butyrate is the most commonly used organic cellulose ester for coating applications, and there is an almost infinite number of types that can be produced because of the acetylbutyryl combinations that are possible. Hydroxyl content and molecular weight possibilities expand this range even further.

FACTORS AFFECTING PERFORMANCE OF CELLULOSE ESTERS IN COATINGS

Performance properties of cellulose acetate buytrate are affected by the chemical composition and the viscosity of the ester. As butyryl increases, solubility, compatibility, flexibility, diluent tolerance, and moisture resistance are increased. Lower butyryl levels are associated with decreased water tolerance, grease resistance, hardness, and increased melting range. As the hydroxyl content of cellulose acetate butyrate varies, several characteristics are also affected. Below 1% hydroxyl, solubility in common coatings type solvents is limited but improves as the hydroxyl increases. At levels around 5%, solubility in lower molecular weight alcohols occurs. At higher hydroxyl levels, reactivity increases, providing cross-linking capability with amino and isocyanate resins. However, in noncross-linking systems, higher levels decrease moisture resistance due to increased hydrophilicity.

The viscosity of cellulose esters also influences physical properties of the ester as well as coatings formulated with them. Increasing the viscosity of a particular ester by increasing the molecular weight slightly lowers its solubility and compatibility with other resins, but does not affect hardness and density. Generally, toughness and flexibility are improved with increased molecular weight and viscosity.

APPLICATIONS FOR CELLULOSE ESTERS IN COATINGS

Protective and decorative coatings for various substrates can be formulated either as air-dry lacquer systems or as converting or curing types often referred to as cross-linked enamels. In many such coatings, cellulose esters are included as either a modifying resin to impart a specific property to the coating or to function as the primary film-forming resin in the formulation. Both types of coatings can be applied over a variety of substrates ranging from paper products to automobiles. Some areas in which cellulose esters are used include automotive OEM and refinish, wood furniture coatings, leather coatings, printing inks, plastic coatings, aircraft coatings, cable lacquers, and various fabric coatings. Cellulose esters are used in coatings to impart such properties as rapid-

[b]ASTM D 817.

drying, pigment control, viscosity control, film toughness, and polishability.

TESTING OF CELLULOSE ACETATE

Cellulose acetate is tested by the manufacturer in accordance with ASTM Test Methods for Cellulose Acetates (D 871), which covers color and haze, combined acetyl, free acidity, heat stability, hydroxyl content, intrinsic viscosity, moisture content, sulfur or sulfate content, and solution viscosity. Coatings manufacturers usually restrict their testing to viscosity of the ester, solubility and appearance, and color and haze.

Viscosity

Viscosity measurement of cellulose acetate is carried out in accordance with ASTM Test Methods for Viscosity of Cellulose Derivatives by Ball-Drop Method (D 1343) based on the ball drop or falling ball principle. A precision Hoeppler viscometer is used in most viscosity determinations with results reported in ASTM seconds. Formulations for viscosity determination are shown in Table 2.

Solubility and Appearance

The solubility and appearance test is performed to determine the possible presence of insoluble gel particles, fibers, flock, or other contaminants, using solutions prepared for viscosity testing. The material to be tested is added to 16 oz. (454 g) French square bottles and visually compared to a reference standard.

TABLE 2—Solutions for viscosity measurement of cellulose acetate, cellulose acetate propionate, and cellulose acetate butyrate.

Cellulose ester	20[a]	20[a]	20[b]	15[c]	20[a]	10[c]
Acetone[d]	70	80	...	...	...	...
Acetone/water, 96/94	...	...	...	...	80	...

Typical Solution Densities, g per mL at 25°C	0.85	0.86	1.25	1.23	0.86	1.24

[a]For cellulose acetate having a max of 40.5% acetyl and for most mixed esters having less than about 40% acetyl and more than about 8% propionyl or butyryl.
[b]For cellulose acetate having 40.5 to 42.7% acetyl and for most of the commercial cellulose acetate propionate and acetate butyrates.
[c]For cellulose acetate having 42.7 to 44.8% acetyl and for most of the commercial cellulose acetate propionate and acetate butyrates; particularly good for esters containing more than 40% acetyl.
[d]Acetone (99.4 ± 0.1%) containing 0.3 to 0.5% water and under 0.3% ethyl alcohol.
[e]Ethyl alcohol (95% by volume). Formulas 2B, 3A, or 3O denatured ethyl alcohol may be used.
[f]Methyl alcohol (sp gr 20/20°C = 0.785 to 0.795).
[g]Methylene chloride having a boiling range of 39.2 to 40.0°C and less than 0.001% acidity calculated as HCL.

Color and Haze

The same solutions used for ASTM viscosity and solubility and appearance testing are normally used for color and haze measurements. The solution is transferred to a special 33-mm-square cell, and the analysis is performed with a Gardner Model XL-385 colorimeter. Light passes through the solution, and the primary yellowness index and primary haze values are simultaneously displayed by the instrument. Secondary color, based on platinum/cobalt standards, and secondary haze, based on scattered light from a monodisperse

polystyrene latex suspension, are calculated. APHA color and ASTM haze are predicted from the secondary values.

TESTING OF CELLULOSE ACETATE PROPIONATE AND CELLULOSE ACETATE BUTYRATE

ASTM Test Method for Cellulose Acetate Propionate and Cellulose Acetate Butyrate (D 817) contains the following tests: acetyl and propionyl or butyryl contents; apparent acetyl content; free acidity; ash; color and haze, heat stability, hydroxyl content; moisture content; sulfur content; and viscosity. Usually color and haze and viscosity are the only tests run by the coatings manufacturer. The test methods are the same as those used in the testing of cellulose acetate.

Drying Oils

by Joseph V. Koleske[1]

DRYING OILS REPRESENT A SMALL PORTION of the huge fats and oils industry.[2] In 1987 there were 81 000 metric tons (~178 million pounds) of drying oils consumed in the United States [*1*]. With an expected annual average growth rate of 2.6%, there should have been 92 000 metric tons consumed in 1992. Such consumption represents about 3% of the total nonfood fats and oils market and about 1% of the combined food and nonfood fats and oils national market. The industry is very mature with relatively little growth expected. Within this industry, whose growth is about the same as the population growth of the United States, drying oil consumption, though relatively very small, has the highest expected growth rate over the above five-year period. The paint and coating industry's need for drying oils is in an overall decline along with other end use markets, such as binders for hardboard, sealants, plasticizers, linoleum, and core oils. Drying oils used in paints and coatings are being replaced with oil-free, synthetic, petroleum-derived oligomeric and polymeric binders carried in a variety of media or in a neat manner. The printing ink market is the only one expected to have small growth in the area of drying oils.

Usually in the fats and oils industry, products solid at room temperature are referred to as fats, and products liquid at room temperature are termed oils. Often times the terms "fats" and "oils" are used interchangeably within the industry. Drying oils, except for fish oil, are of vegetable origin.

Chemically, drying oils are water-insoluble, unsaturated glycerides of long chain fatty acids with the generalized structure

$$\begin{array}{l} CH_2{-}O{-}OC{-}R_a \\ | \\ CH{-}O{-}OC{-}R_b \\ | \\ CH_2{-}O{-}OC{-}R_c \end{array}$$

Generalized Triglyceride

where R_a, R_b, and R_c are the same or different and represent the hydrocarbon chain residues of fatty acids. In simple terms, this means that most oils are mixed triglycerides. The triglycerides are produced by the condensation reaction that occurs between a glycerol molecule and three fatty acid molecules:

$$\underset{\text{Glycerol}}{HOCH_2{-}CH(OH){-}CH_2OH} + \underset{\text{Fatty Acid}}{3\,R_xCOOH} \longrightarrow \underset{\text{Triglyceride or Drying Oil}}{R_xCOOCH_2{-}CH(OOCR_x){-}CH_2OOCR_x} + \underset{\text{Water}}{3\,H_2O}$$

where R_x is anyone of R_a, R_b, or R_c. This reaction is reversible and when the oils are heated they can transesterify with R_a, R_b, and R_c capable of changing their positions in an inter- and an intramolecular sense. Drying oils also contain saturated glycerides of fatty acids, but these are usually present at relatively low levels and they do not participate in drying or polymerization phenomenon. Hydrolysis of drying oils results in separation into glycerol and the fatty acid.

Drying oils can be classified in many ways, but one principle way is to divide them into drying, semidrying, and nondrying (an oxymoron term) oils in accordance with their iodine values, which is a measure of unsaturation content. Although such classification has been rather arbitrary, Rheineck and Austin [*2*] defined the classes as given in Table 1.

The main fatty acids found in drying oils and their chemical composition are given in Table 2. The unsaturated-component content of selected drying oils was given in Table 3. Stearic (18-carbon) and palmitic (16-carbon) acids are the most widely distributed saturated fatty acids found in drying oils. Except for cottonseed oil, which contains 29% palmitic acid, the drying oils listed in Table 3 contain less than about 10% of any particular saturated fatty acid residue. The degree of double bond unsaturation controls the drying rate. The higher the degree of unsaturation or iodine number (see below), the faster the drying or polymerization of the oil. Double bond position is also important because conjugated bonds, which is the term used to described two carbon-carbon double bonds separated by one carbon-carbon single bond, are more susceptible to autooxidation [*4*].

Physical characteristics of some typical commercial drying oils are given in Table 4. The oils are particularly characterized by their Iodine Value, which is a measure of the amount of unsaturation present, and Saponification Number, which is an indication of fatty-acid chain molecule weight. Selected property requirement ranges or minimum values for various

TABLE 2—Main unsaturated fatty acids found in drying oils.

Fatty Acid	No. Carbon Atoms	No. Double Bonds	Structural Formula
Linolenic	18	3	$HOOC(CH_2)_7CH{=}CHCH_2CH{=}CHCH_2CH{=}CHCH_2CH_3$
Linoleic	18	2	$HOOC(CH_2)_7CH{=}CHCH_2CH{=}CH(CH_2)_4CH_3$
Oleic	18	1	$HOOC(CH_2)_7CH{=}CH(CH_2)_7CH_3$
Eleostearic	18	3	$HOOC(CH_2)_7CH{=}CHCH{=}CHCH{=}CH(CH_2)_3CH_3$
Licanic	18	3	$HOOC(CH_2)_2CH(O)(CH_2)_4CH{=}CHCH{=}CHCH{=}CH(CH_2)_3CH_3$
Ricinoleic	18	1	$HOOC(CH_2)_7CH{=}CHCH_2CH(OH)(CH_2)_5CH_3$

drying oils and the ASTM method that contains other specification properties are delineated in Table 5. The ASTM methods cited in Table 5 contain references to other ASTM methods appropriate for obtaining the indicated properties and for other pertinent properties. The following drying oils are the most important members of this class of coating raw materials.

Castor oil is obtained from beans of the plant *Ricinus communis*. The oil differs from the other oils in that it is made up of a very high percentage of the hydroxyl-containing ricinoleic acid residue. Although the fatty acid residues in this oil contain on the average only a single double bond and for this reason castor oil is essentially a nondrying oil, it can be converted into a drying oil by a dehydration process in which its hydroxyl group and an adjacent hydrogen atom are removed as water to form a double bond conjugate to the previously existing double bond. The resultant product is known as dehydrated castor oil, which has good drying characteristics.

Cottonseed oil is obtained from the plant *Gossypium malvaceae*. Although it is a drying oil, cottonseed oil is seldom used as an oil in the paint and coating industry. Its main use is as a source of fatty acids that are used in the manufacture of alkyd resins.

Linseed oil, which is obtained from seed of the flax plant *Linum usitatissimum*, is the most common and widely used oil. It has a high degree of unsaturation, which imparts a short drying time, due to its large percentages of linolenic and linoleic triglycerides. It is marketed in a number of modifications including alkali-refined, acid-refined, boiled, blown, and polymerized linseed oil [2]. Polymerized linseed oils of various acid values and viscosities are available.

Oiticica oil is obtained from the nuts of the tree *Licana rigida*. It has a very high licanic acid content, and the three conjugated double bonds of this acid result in rapid drying characteristics. It is often used as an alternative or supplement to tung oil.

Safflower oil is obtained from seed of the plant *Carthamus tinctorius*. This semidrying oil has drying characteristics between those of linseed and soybean oils. Because of its low linolenic acid content, it has low residual unsaturation after cure and very good anti-yellowing characteristics.

Soybean oil is obtained from the seeds of the widely grown plant *Soja hispida*. Its main use is in the preparation of alkyds. It has a wide variety of uses other than as a drying oil. In an epoxidized form, this oil is widely used as a reactive plasticizer and as an acid scavenger. Both epoxidized soybean and linseed oil have been reacted with acrylic acid to form products with residual acrylate functionality and markedly higher viscosity. These acrylated oils have been used as components in radiation-cure coating systems that are initiated with free radicals.

Although tall oil is classified as a drying oil, it is not a triglyceride. The product is obtained as the major byproduct of sulfate or Kraft pulping of pine and certain other softwoods such as spruce and hemlock that are pulped in Scandinavian countries. Crude tall oil is an approximately 50/40/10 by weight mixture of fatty acids, rosin acids, and unsaponifiable compounds such as higher alcohols, waxes and other hydrocarbons, and sterols.

Tung oil is obtained from seeds of the trees *Aleurites fordii* and *Aleurites montana*. This relatively high viscosity and refractive index oil is rapid drying and is used in varnishes and alkyds where water resistance is of principal importance. This oil is also known as wood oil, Chinese wood oil, chinawood oil, and mu oil.

Fish oils are the only nonvegetable oils in the drying oil class. They are principally obtained from menhaden (Alosa menhaden). These oils are semidrying in nature and contain a significant amount of saturated fatty acid residues. In addition to 16 and 18-carbon fatty acid residues, fish oils contain

TABLE 3—Weight percentage of major unsaturated fatty acid residues in selected drying oils [2,3] (remainder of oils is essentially all saturated fatty acid residues).

Tall oil	...	133	196	194.0	...
Tung	0.915	170	192	0.2	1.517

30 to 40% of arachidonic (20-carbon with four double bonds), clupanodonic (22-carbon with five double bonds), and nisinic (24-carbon with five double bonds) acid residues. Because of the presence of acid residues with high degrees of unsaturation, fish oils have a strong tendency to yellow after cure due to residual unsaturation. Fish oils do represent a source of the very long chain fatty acids that are not present in vegetable oils. Currently, they are not widely used in the coatings' industry with use often dictated by relative price of linseed and soybean oils.

Although raw drying oils are used in coating formulations, the oils are often further processed before use. Such processing includes alkali refining, dehydration, drier addition, heat polymerization that involves heating an oil to selectively advance molecular weight and viscosity, and oxidation or blowing wherein air is bubbled into heated oil and oxygen is taken up with a resultant molecular weight increase. Drying oils are also modified by reaction with maleic anhydride, by copolymerizing with vinyl monomers such as styrene, and by epoxidation.

Reaction with oxygen is the most important reaction that drying oils undergo in the drying or polymerization process [6,7]. Oxidation can result in trans isomer formation, cleavage of the carbon-carbon chain along with formation of volatile byproducts, and polymerization. These reactions can be catalyzed with metallic salts such as cobalt napthenate (see next chapter) that promote free radical formation by reaction with hydroperoxides and other peroxides that are formed in the oxidation process [8]. Farmer and coworkers [9] were first to describe the mechanism of autooxidation wherein they found that four different monohydroperoxides were formed when oxygen was reacted with the methyl ester of oleic acid. A different reaction path was involved when linoleic esters were autooxidized since two monohydroperoxides and one cyclic diperoxide were formed. Polymerization is initiated by reaction of oxygen with an unsaturated fatty acid residue and free radical formation followed by chain propagation in which free radicals react with oxygen to form peroxy radicals which in turn react with other unsaturation sites [10]. The polymerization is terminated by combination of various free radicals that exist in the reaction mass. Availability of multiple double bonds in some of the molecules results in a crosslinked polymeric network.

Solidification or polymerization of a drying oil such as linseed oil can be thought of in the following manner. When the drying oil is exposed to air, there is an induction period during which oxygen is absorbed and it consumes antioxidants present in the system. In this step, there is very little apparent change in physical or chemical properties. This is followed by a period in which there is a marked oxygen uptake and an appearance of peroxides which decompose to form free radicals. The free radicals then initate an addition polymerization of the unsaturation and a crosslinked network results. During the reaction scheme, low molecular weight cleavage products including carbon dioxide and water are formed.

ASTM D 1640 Standard Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature has procedures recommended for determination of the stages and rates of film formation in the drying or curing of organic coatings that are to be used at room temperature. Included are methods for determining tack-free, dry-to-touch, dry-hard, dry-through, print-free, and dry-to recoat times. In one instance (Section 7.5.1) a particular procedure is specified for drying oils. ASTM Standard Test Method for Gel Time of Drying Oils (D 1955), deals with determination of the gel time of oiticiica and tung oil. This simple test method, which involves heating the oil in a test tube and observing the time required for the oil to congeal around glass rod relative to a standard of known behavior, can be used for other oils

TABLE 5—Selected property requirements for drying oils (indicated ASTM method has other requirements).

Oil	Specific Gravity, 25/25°C	Iodine Value, Wijs	Saponification Value	Acid Value, max	ASTM Method
Castor, raw	0.957–0.961	83–88	176–184	2.0	D 960
Dehydrated castor	0.926–0.937	125–145	188–195	6	D 961
Linseed, raw	0.926–0.931	177 (min)	189.0–195.0	4.0	D 234
Oiticica	0.972 (min)	135 (min)	None	8.0	D 601
Safflower	0.922–0.927	140–150	189–195	3.0	D 1392
Soybean, refined	0.917–0.924	126 (min)	189–195	0.3	D 1462
Tung, raw	0.933–0.938	163	189–195	5.0	D 12

that have conjugated double bond or other gelling characteristics. ASTM Standard Guide for Testing Drying Oils (D 555) is an overall guide to selection and use of procedures for testing drying oils that are commonly used in coatings.

Driers and Metallic Soaps

by Marvin J. Schnall[1]

METALLIC SOAPS ARE COMPOUNDS of alkaline metals or heavy metals and monobasic carboxylic acids containing from 7 to 22 carbon atoms. The water-insoluble metallic soaps are of particular interest to the coatings industry, although potassium and lithium soaps have limited water solubility.

The applications of metallic soaps in coatings include their use as driers, catalysts, stabilizers, biocides, bodying agents, and flatting agents. An overview of metallic soap applications is presented in Table 1. This chapter concentrates primarily on metallic soaps used as driers, although a brief review of bodying and flatting applications is included.

METALLIC SOAPS AS BODYING AND FLATTING AGENTS

Aluminum stearates, aluminum octoates, and calcium linoleate pulp were at one time widely used as bodying and pigment-suspending agents in solvent-based coatings. Their advantages include fairly high efficiency and ease of incorporation. However, they have a number of deficiencies, including sensitivity to variations in the formulation and in the processing of paints, as well as adverse effects on film hardness and resistance properties. As a result, they have been replaced to a considerable extent by the bentonite clay and organic wax derivatives [*2*].

Zinc and calcium stearates are used on occasion as flatting additives in clear solvent-based coatings. However, precipitated and fumed silicas are now more commonly used for this purpose. Zinc stearate is also used to facilitate sanding of primers and sealers for wood furniture finishing [*2*].

THEORY OF OXIDATIVE DRYING AND FUNCTION OF DRIERS [*1,5*]

It is generally accepted that vehicles based on unsaturated oils, including alkyd resins and oleoresinous varnishes, dry by oxidation according to the following steps:

1. Induction period.
2. Oxygen absorption.
3. Peroxide formation.
4. Peroxide decomposition to free radicals.
5. Free radicals promote cross-linking.

TABLE 1—Coatings applications of metallic soaps.

Applications	Metals	Acids
Driers	Cobalt, manganese, lead, iron, rare earth, cerium, zirconium, zinc, calcium, barium, bismuth, potassium, vanadium, aluminum	Tallates, octoates, naphthenates, neodecanoates, synthetic acids, linoleates, rosinates
Catalysts	Potassium, lithium, cobalt, copper, tin, zinc, manganese	Octoates, naphthenates, laurates, neodecanoates
Stabilizers	Barium, cadmium, tin, zinc, calcium, lead	Proprietary, sulfates, carbonates, stearates
Biocides	Copper, tin, zinc, mercury	Naphthenates, octoates, phenyl acetates, phenyl oleates, laurates, butyl oxides
Bodying agents	Aluminum, calcium	Stearates, octoates, linoleates
Flatting agents	Zinc, calcium	Stearates

The induction period occurs because most drying oils contain natural antioxidants, the effects of which must be overcome before the drying process can begin. Oxygen is then absorbed from the air at the unsaturated sites on the oil molecule, and, as the absorption continues, forms peroxides. These peroxides then decompose to form free radicals which act as catalysts to promote cross-linking of the oil or resin molecules at the unsaturated sites, resulting in dried films.

These steps will occur in the absence of driers, but driers accelerate the process by means of the following mechanisms [*1,5*]:

1. Removal of natural antioxidants.
2. Acceleration of oxygen absorption.
3. Acceleration of peroxide decomposition.

Naturally occurring antioxidants may be considered as negative catalysts for oxidation, whereas driers are positive catalysts, counteracting the effects of the antioxidants.

The multivalent nature of the drier metal is considered to be a key factor accelerating oxygen absorption in the film. The drier metal is initially in a divalent state and is converted to a trivalent state by the presence of oxygen in the film. The metal then releases the oxygen to the film and is converted back to the divalent form. This action accelerates the process

[1]Coatings consultant, 620 Airport Rd., Suite 304, Chapel Hill, NC 27514.

Copyright© 1995 by ASTM International

of oxygen absorption, peroxide formation, and peroxide decomposition, which is responsible for oxidative film drying.

DESCRIPTION OF DRIER METALS

The metals that act as catalysts to promote oxidation and which may be used in driers are indicated below:

Cobalt	Active	Lead	Auxiliary
Manganese		Calcium	
Vanadium		Zirconium	
		Zinc	
		Iron	
		Rare Earth	
		Cerium	
		Aluminum	

Cobalt and manganese, particularly cobalt, are the most active drier metals. Cobalt promotes surface drying of films, while manganese affects both surface and through drying. Vanadium has been mentioned in the literature as an active drier but is seldom used in coating formulations.

The auxiliary driers are seldom used alone, but rather in combination with cobalt and/or manganese. Their functions are to increase the efficiency of the active drier metals and to increase film hardness. In the past, lead was the most frequently employed auxiliary drier, but it is presently out of favor due to toxicity. Calcium and zirconium driers are most frequently used as lead replacements. Zinc is used primarily for improved film hardness and to prevent wrinkling of thick films. Iron driers are used mainly to improve drying of baking systems when their dark color can be tolerated. Rare earth and cerium driers are recommended occasionally for improved through drying and as oxidation catalysts for baking. Interest in aluminum compounds as auxiliary driers has increased recently with the advent of high-solids alkyd resins. Aluminum compounds are being recommended to improve film hardness with these resins but may at times adversely affect viscosity stability and promote gelation.

DESCRIPTION OF DRIER ACIDS

To perform their function, driers should be soluble in the vehicles to which they are added. Solubility is achieved by reacting the drier metals with organic acids to form metallic soaps. The most commonly employed acids are as follows:

- Linoleates
- Rosinates
- Tallates
- Naphthenates
- Octoates (2-ethyl hexanoates)
- Synthetic acids
- Neodecanoates

Chronologically, the linoleates, rosinates, and tallates were the first types developed, followed by the naphthenates and the octoates. A more recent development is the synthetic acid type, which is proprietary but closely related to the octoates. The synthetic acid and neodecanoate driers can be prepared at higher metal concentrations than the other types and are gradually replacing the older acids.

Water-dispersible driers may be prepared by adding nonionic surfactants to naphthenate or synthetic acid driers. However, proprietary cobalt and manganese drier compounds are available that are purported to be more suitable for water-based coatings.

Trade names of the various commercial drier types available are listed in Table 2.

MISCELLANEOUS DRIERS

Restrictions on solvent emissions have stimulated the development of both higher-solids and water-reducible coatings. In the process of formulating these coatings, chemists are experiencing difficulty obtaining satisfactory drying properties with the conventional metallic soap driers. Alternative drier compounds, including both organics and proprietary metallic complexes, are currently being offered [6]. Some typical examples are shown in Table 3. They are usually recommended in combination with conventional metallic soap driers for improved drying efficiency.

Another class of metallic compounds closely related to driers are loss of dry inhibitors or "feeder" driers. These are compounds designed to prevent loss of drying efficiency of paints on aging resulting from the adsorption of driers by pigments, particularly carbon black and organic red pigments. They function by dissolving gradually into the coating vehicle so that the metals are available over a period of time rather than immediately. In this manner, they replace the drier metals that have been adsorbed by the pigments,

Nutra LTD 18%	Huls America	proprietary metal complex

thereby maintaining satisfactory drying on prolonged storage. Lead compounds, including litharge, were used formerly but have been replaced by lead-free compounds based primarily on less soluble forms of cobalt and other drier metals.

Commercially available feeder driers are listed in Table 4. All are lead-free metal complexes except for the last item [*3*].

DRIER LEVELS IN COATINGS

Drier requirements for coatings are usually expressed in terms of percent drier metal based on oxidizable vehicle nonvolatile content. A typical calculation is as follows [*1*]:

Assume:

1. In a 1000-g paint formulation, there are 300 g of vehicle nonvolatile.
2. Cobalt drier used is 12% metal by weight.
3. Calcium drier used is 10% metal by weight.
4. Required for optimum drying: 0.05% cobalt plus 0.2% calcium (percent metal based on vehicle nonvolatile).

per 1000 g of paint:

$$\text{Cobalt metal required} = 0.0005 \times 300\text{ g} = 0.15\text{ g}$$
$$\text{Calcium metal required} = 0.002 \times 300\text{ g} = 0.6\text{ g}$$

$$(10\%\text{ calcium drier required}) = \frac{(0.6\text{ g calcium metal})}{(0.10\text{ g metal/g drier})} = (6\text{ g drier as supplied})$$

$$(12\%\text{ cobalt drier required}) = \frac{(0.15\text{ g cobalt metal})}{(0.12\text{ g metal/g drier})} = (1.25\text{ g drier as supplied})$$

The optimum levels of drier metal required will vary depending on the type of resin system employed and the conditions of drying. Typical metal concentrations for a number of common vehicles are indicated in Table 5.

Huls America	Nuact Paste (lead-based)

TESTING OF DRYING EFFICIENCY

The procedures used to determine the stages of film formation during the drying of coatings are described in ASTM Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature (D 1640) [*4*]. With coatings containing metallic driers, it is recommended that the paint samples age overnight following the drier additions before drying tests. The drying conditions, shown in Table 6, are usually specified but are subject to agreement between the purchaser and the seller.

The methods used to determine the various stages of drying may be summarized as follows:

1. *Set-To-Touch-Time*—no transfer of the coating upon lightly touching the film with the finger.
2. *Dust-Free-Time*—(a) cotton fibers dropped on the film can be removed by blowing lightly; (b) fine calcium carbonate extender dropped on the film can be completely removed by blowing gently and wiping with a cloth or brush.
3. *Tack-Free-Times*—a specified type of paper or aluminum foil will no longer adhere to the film when applied under specific conditions.
4. *Dry-To-Touch-Time*—the film no longer adheres to the finger when pressed firmly and does not rub up when rubbed lightly.
5. *Dry-Hard-Time*—a thumb print applied under specified conditions is completely removed from the film when polished lightly with a soft cloth.
6. *Dry-Through-Time*—the film is not distorted or detached when the thumb is applied to it in a specified manner and rotated through a 90° angle.
7. *Dry-To-Recoat*—a second coat or top coat can be applied without development of lifting or loss of adhesion of the first coat.
8. *Print-Free-Time*—army duck or cheesecloth applied at a pressure of 3.5 or 6.9 KPa no longer marks the film as determined by photographic standards shown in ASTM Test Method for Print Resistance of Lacquers (D 2091) [*4*].

In addition to the above subjective tests, a number of mechanical drying time recorders are available. The instrument referred to most frequently in recent literature is the Byk-Gardner Improved Circular Drying Time Recorder [*7*]. This functions by moving a Teflon stylus over the applied film in a circular path. The pattern left in the film by the stylus after a complete revolution is observed. Recorders are available which make complete revolutions in 1, 6, 12, or 24-h. With the use of a plastic template, set-to-touch, surface dry, and through-dry times may be noted.

Development of film hardness is also an important criterion of drier efficiency. Tests [*4*] used to measure hardness include:

1. *Test Method for Film Hardness by Pencil Test (D 3363)*—a series of pencils varying in lead hardness from 6B (softest) through 6H (hardest) are pushed into the film, and the hardest pencil that will not penetrate the film is noted.
2. *Test Method for Hardness of Organic Coatings by Pendulum Damping Tests (D 4366-87)*—either a Konig or a Persoz Pendulum Hardness Tester is employed with the time, in seconds, noted for the swing amplitude of the pendulum to

decrease by a specified degree when set into oscillation on the dried film.

3. *Test Methods for Indentation Hardness of Organic Coatings (D 1474)*—either a Knoop or a Pfund Indenter is applied to a film under a specified loading, and the depth of indentation is measured with the aid of a microscope. The depth is converted to either a Knoop or a Pfund Hardness Number using the equations in the standard.

TABLE 6—Standard drying conditions.

Condition	Typical Value
Ambient temperature	23 + 2°C
Relative humidity	50 + 5%
Film thickness (dry)	12.5 to 45 μm
Substrate	Clean glass
Lighting	No direct sunlight
Applicators	Doctor blades
Coating viscosity	Close to normal application

SPECIFICATIONS FOR LIQUID PAINT DRIER

Drier specifications as described in ASTM Specification for Liquid Paint Driers (D 600) involve the following classes:

Class A	2-ethyl hexanoic acids in petroleum spirits.
Class B	Naphthenic acids in petroleum spirits.
Class C	Neodecanoic acids in petroleum spirits.
Class D	Tall oil fatty acids in petroleum spirits.
Class E	Any of the above, plus additives to make the driers water dispersible.
Class F	Other unidentified acids and acid blends.

A comprehensive table of liquid paint driers of the above classes is given in ASTM D 600 [*4*]. The typical properties of the driers listed and reproduced in Table 7 include percent metal concentration, percent nonvolatile content, specific gravity, Gardner Color, and Gardner-Holdt viscosity.

TABLE 7—Typical requirements of liquid paint driers.[a]

TESTING OF LIQUID PAINT DRIERS

ASTM Test Method for Liquid Paint Driers (D 564) [*4*] outlines the test procedures employed, including both physical and chemical tests. The physical tests include:

1. *Appearance*—observations for clarity and cleanness in accordance with ASTM Test Method for Clarity and Cleanness of Paint Liquids (D 2090).
2. *Color*—according to ASTM D 1544, which employs the Gardner numerical color scale. However, a number of driers, including cobalt, manganese, nickel, and rare earth, do not fit into this scale and are reported descriptively.
3. *Nonvolatile Content*—According to ASTM D 1644, Method A or B. Method A involves heating samples at 105°C for 10 min, while Method B specifies 150°C for 10 min.
4. *Miscibility with Oil*—One volume of the drier sample is mixed with 19 volumes of raw linseed oil. The mixture is observed for any signs of separation or clouding over a 24-h period.
5. *Stability*—The drier sample is stored for 7 days at 25°C, −20°C, and 50°C and examined for indications of clotting, gelation, or precipitation.
6. *Drying power*—As described in the section entitled "Testing of Drying Efficiency."
7. *Viscosity*—According to ASTM Test Method for Viscosity of Transparent Liquid by Bubble Time Method (D 1545). This involves comparing the time of travel of bubbles in tubes of the sample versus Gardner-Holdt standard tubes. The standards were formerly designated by letter but are now indicated directly in stokes. A table in D 1545 indicates the conversion from letters to stokes.

Chemical analysis is used to determine the metal content of liquid paint driers. The EDTA method is used for most drier metals (Table 8). The liquid drier is dissolved or digested in solvents and then treated with an excess of standard EDTA solution (disodium salt of ethylenediamine tetracetic acid dihydrate). The excess of EDTA is then titrated to an end point determined by a specified indicator. This method is applicable to single metal driers only, not to drier blends. An EDTA method is not yet available for cerium, and an oxidimetric determination is specified [ASTM Test Method for Cerium in Paint Driers by Oxidimetric Determination (D 3970)]. Table 8 outlines the ASTM designations, indicators, and titrating solutions for analysis of drier metals by EDTA titration.

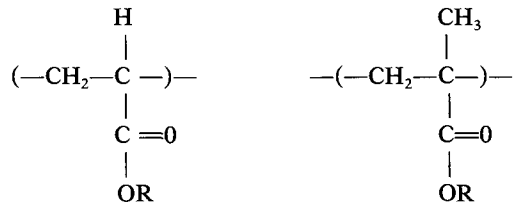
Acrylic Polymers as Coatings Binders

by John M. Friel[1]

ACRYLIC POLYMERS, WHICH ARE USED as coatings binders, are comprised chiefly of esters of acrylic and methacrylic acid that are polymerized by additional polymerization, usually using a free radical mechanism:



An acrylate A methacrylate

Interest in acrylic technology dates back to the 1920s when Dr. Otto Rohm developed a practical process for making acrylate esters from ethylene. Shortly afterwards, his associate, Otto Haas, established the first commercial production of methyl and ethyl acrylate in the United States [*1*]. The first commercial use of an acrylic polymer was as an adhesive-like interlayer for laminated safety glass. Probably the highest profile use of an acrylic began in 1936 with the introduction of thermoplastic, transparent methacrylate sheet. With the advent of World War II, methacrylate sheet became invaluable as a tough, weather-resistant glazing material for military aircraft. Since it could be formed easily and had excellent optical properties, the transparent plastic was used for aircraft canopies, bomber noses, and gun turrets [*2*].

Acrylic technology soon expanded into the coatings industry in the form of acrylic solution polymers, followed later by acrylic emulsions. The acrylics gained widespread market acceptance as coatings binders due to such outstanding properties as color stability, transparency, and resistance to weathering and aging. The good weathering resistance of acrylic polymers is primarily due to their resistance to hydrolysis and their lack of absorption of ultraviolet (UV) light, the high-energy portion of the light spectrum most responsible for degradation.

Acrylic solution polymers (often referred to as acrylic resins) are generally copolymers of acrylate and methacrylate esters prepared by direct solution polymerization in a solvent that has a solubility parameter similar to that of the polymer. Typical solvents include aromatics such as toluene and xylene, as well as ketones and esters. Acrylic resins are typically supplied at about 30 to 50% solids by weight, with viscosities ranging from a few hundred to a few thousand centipoise. In later years, 100% solid-grade versions became popular since they reduced the cost and safety concerns associated with shipping resins containing high solvent levels. The coatings manufacturer is then able to dissolve the solid-grade acrylic in a wide range of solvents, thereby having greater control over the formulation ingredients.

A wide range of properties can be built into an acrylic coatings binder by careful selection of the type and level of the acrylic monomers used. Some of the important properties for several acrylic homopolymers are shown in Table 1 [*3*]. Coatings for a wide range of applications can therefore be custom designed. Some of the principal applications for acrylic solution coatings include automotive finishing, factory, and farm implement coatings, general-purpose pigmented coatings, aerosol lacquers, and clear coatings for a multitude of substrates. There are two types of acrylic solution polymers: (1) thermoplastic polymers, which harden simply by loss of solvent through evaporation; and (2) thermosetting polymers, which contain functional groups that react with another functional material (i.e., melamine, epoxy, isocyanate, etc.) to form a cross-linked network. The advantages and disadvantages of each are discussed in detail later in this chapter.

Acrylic emulsion polymers (often referred to as acrylic latexes) have become one of the major binder types in use in the coatings industry today. To form an emulsion polymer, the acrylic monomers are emulsified and then polymerized as small droplets in a continuous water phase. The droplets are typically stabilized by surfactants, and usually no solvent is present. While acrylic emulsions are generally associated with quality architectural coatings, they are also used to formulate industrial coatings. In fact, the use of acrylic emulsions in industrial applications is expanding at the expense of

TABLE 1—Properties of polymethacrylates and polyacrylates [*3*].

Polymer Types	Tensile Strength, psi	Elongation, %
Polymethacrylate		
Methyl	9000	4
Ethyl	5000	7
Butyl	1000	230
Polyacrylates		
Methyl	1000	750
Ethyl	33	1800
Butyl	3	2000

solvent-based systems because of the industry's need to control organic emissions. Over the past 20 years, acrylic emulsion manufacturers have made great strides in improving the properties of acrylic emulsions so that they now offer performance similar to the solvent-based coatings they are replacing.

When the first acrylic emulsion designed for use in house paints was introduced in 1953, it had the low-odor, quick-drying, and easy cleanup features of its water-based competitors, styrene-butadiene and poly(vinyl acetate) emulsions; but, in addition, it offered excellent exterior durability that allowed use in exterior paints. During the past 40 years, it has been good exterior durability that enabled acrylic emulsions to replace solvent alkyds as the dominant binder in the exterior house paint market.

ACRYLIC SOLUTION POLYMERS

Thermoplastic Resins

Thermoplastic acrylic resins are acrylic polymers that are polymerized directly in a suitable solvent and form a film solely by evaporation of the solvent. They do not need to be oxidized or cross-linked to form a hard, resistant finish. They are fast-drying lacquer materials, but they remain permanently soluble.

Acrylic resins are usually supplied in strong solvents such as toluene, xylene, or methyl ethyl ketone. They are clear, colorless solutions and, if left unpigmented, will also dry down to clear, colorless films. They are often used in unpigmented form as protective finishes over vacuum metalized plastics and polished metals such as brass.

Acrylic resins generally make excellent grind media for dispersing pigments. No external pigment wetting agents are required to make finely dispersed pigment grinds for high-gloss lacquers. Also, thermoplastic acrylic polymers are quite unreactive and consequently are stable when mixed with pigments, extenders, and colors. They do not discolor powdered metals, such as aluminum.

Acrylics are a uniquely versatile family of polymers since an infinite array of properties can be achieved by carefully selecting combinations of the various acrylic monomers. Each acrylic monomer brings to the polymer its own individual performance characteristics based on its molecular structure. This is particularly true for polymer hardness as determined by the glass transition temperature (T_g) of the monomers that make up the homopolymer (only one monomer) or copolymer (two or more monomers). The T_g of a polymer is a softening point: it is actually a temperature range where the polymer undergoes a second-order transition. At temperatures below the T_g, the polymer is a glass, but above the T_g the polymer is a rubbery material. To approximate the T_g for a copolymer composition, it is useful to utilize the relationship proposed by Fox [4].

$$\frac{1}{T_g} = \frac{W_1}{T_{g1}} + \frac{W_2}{T_{g2}} \tag{1}$$

where

W_1 and W_2 = the weight ratios of Monomers 1 and 2, respectively,

T_{g1} and T_{g2} = the T_g's of the homopolymers of Monomers 1 and 2 in degrees absolute.

Since thermoplastic acrylics are not cross-linked to achieve a desired level of performance, the concept of T_g and the ability to manipulate T_g as a means to control properties is crucial in designing polymers that meet the needs of the coatings market. The marked difference in T_g's, and consequently polymer characteristics of the acrylics, can phenomenologically be explained by the free-volume theory proposed by Fox and Flory [5] and later refined by several others. The free-volume theory states that the T_g for any given polymer occurs at that temperature where the fractional free volume (i.e., unoccupied space contained within the polymer) reaches some universally constant value that remains unchanged as temperature decreases below T_g. Above this temperature, the free volume increases, permitting sufficient molecular motion so polymer flow can begin. In Fig. 1, Rogers and Mandelkern have plotted specific volume versus temperature for a series of methacrylates as a means of establishing the relationship of T_g to free volume [6]. The arrows (↑) in Fig. 1 indicate the temperature at which there is an inflection in the specific volume curve indicating a sudden increase in free volume (as temperature increases). This is the T_g. From the graph, it can be calculated that, at T_g, free volume accounts for 15% of the total polymer volume [6]. Simha and Boyer have independently calculated that at T_g, free volume accounts for 11% of a polymer's total volume [7].

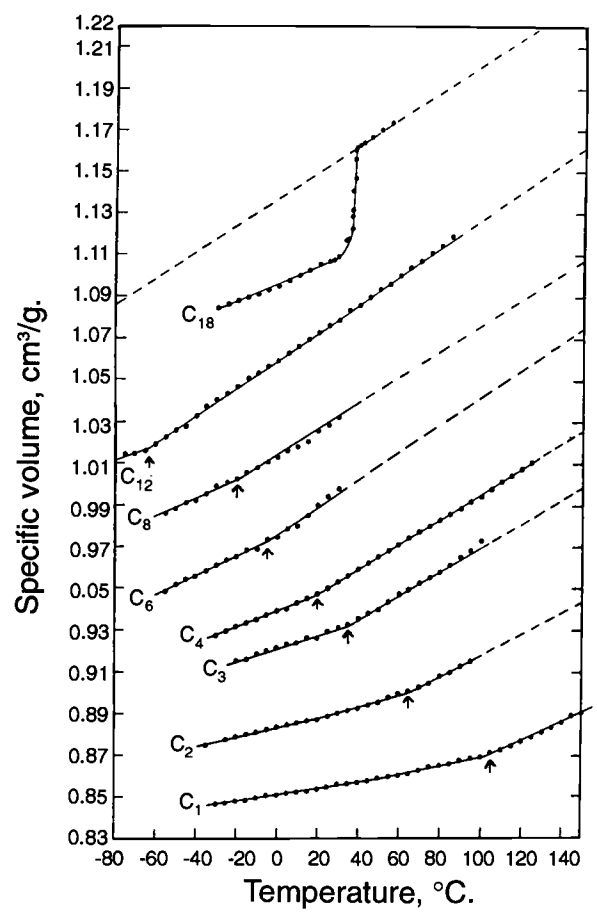

FIG. 1—Specific volume-temperature relations for the poly-(*n*-alkyl methacrylates). (Reprinted with permission from the American Chemical Society. Copyright 1957.)

On a molecular level, the T_g differences for the acrylic family of polymers can also be easily explained. The acrylates have an alpha-hydrogen atom next to the carbonyl group, giving them more rotational freedom and hence greater segmental chain motion than the methacrylates. The methacrylates have a bulky methyl group substituted for the alpha-hydrogen atom, which hinders molecular rotation, thereby increasing chain stiffness. The methacrylates are therefore higher in T_g, harder, higher in tensile strength, and lower in elongation than analogous acrylate polymers.

Equally important to T_g and polymer hardness is the length of the ester side chain of the monomer. As the alcohol moiety of the ester side chain becomes larger, the polymer chains are pushed further apart, creating additional free volume, thereby encouraging greater molecular rotation. Consequently, the polymers become increasingly soft (as the ester side chain becomes larger) until the effects of side-chain crystallization causes additional hardening effects. Table 2 demonstrates the large range of T_g's that exist for the acrylate and methacrylate family of homopolymers [8].

The second most important parameter governing the film properties of a thermoplastic acrylic polymer is molecular weight (MW). Most dry film properties for thermoplastic acrylics improve with increasing molecular weight up to a MW of about 100 000 and then tend to level off. Tensile strength, elongation, toughness, solvent resistance, and exterior durability are all dependent on molecular weight. This dependence of strength, elongation, and resistance of the acrylic polymer on molecular weight is primarily due to the greater number of chain entanglements (which act almost like cross-links), anchoring the polymer chains at higher molecular weight (i.e., longer chain length).

However, the viscosity of a solution polymer is proportional to the molecular weight of a polymer according to the Mark-Houwink equation [9].

$$\eta = K(\mathrm{MW})^a \qquad (2)$$

where

η = solution viscosity

K and a = constants derived experimentally for a specific polymer/solvent combination (for polymethyl methacrylate in toluene, $K \times 10^5 = 7.1$ and $a = 0.73$). The type molecular weight used in determining the constants should be specified.

As molecular weight increases, the solution viscosity also increases, thereby posing handling and application problems if the molecular weight becomes too high. For example, high spray solids are desirable for acrylic lacquers because of economy and emissions concerns. The lower the molecular weight of the polymer, the lower the viscosity at a given solids content, or conversely, the higher the spray solids at spray viscosity. Consequently, low molecular weight is beneficial to solids and application concerns, whereas high molecular weight is needed for good film properties.

The obvious answer to the viscosity versus film property dilemma is to reach an optimum balance by producing an intermediate molecular weight polymer. For this reason, most thermoplastic acrylic solution polymers have weight-average molecular weights in the 75 000 to 100 000 range. It is also helpful to narrow the molecular weight distribution, reducing the amount of low-molecular-weight fractions, which have a deleterious effect on resistance and strength properties, while also minimizing high-molecular-weight portions, which increase viscosity and cause application problems such as cobwebbing of spray-applied acrylic automotive lacquers.

Since the application and drying properties of an acrylic resin are largely controlled by the physical characteristics of the solvent contained in the resin, as well as by the interaction of the polymer and solvent, it is essential to carefully select

TABLE 2—T_g for methacrylate and acrylate homopolymers [8].

the solvent in which the acrylic is dissolved (see Chapter 18 entitled "Solvents"). To ensure good solubility of the polymer, it is important to match the solubility parameter of the solvent to that of the polymer. The solubility parameter is an estimation of the polarity of a solvent or polymer and is related to the intermolecular energy of the molecule (see Chapter 35 entitled "Solubility Parameters"). The solubility parameter concept was defined by Hildebrand [*10*] and applied to coatings by Burrell. Burrell has published the solubility parameters for an extensive list of solvents [*11*].

For polymers, the solubility parameter can be calculated by knowing the molecular structure of the repeating unit according to Small's method. Small has published a table of molar attraction constants used to calculate polymer solubility parameters [*12*].

Besides being helpful in estimating solubility, the solubility parameter concept is helpful in predicting the resistance of polymers to solvents or other organics. In general, the more polar acrylic polymers will have the best resistance to hydrophobic materials, such as gasoline, grease, or oil. More hydrophobic acrylics (with low δ values) will have better resistance to polar materials, such as water and alcohol.

The evaporation rate of the solvent or solvent mixture must also be carefully chosen to accommodate the expected application method and conditions. For spray application, moderately fast evaporating solvents are needed to avoid running and sagging of the low-viscosity paint. For roller coating, a much higher viscosity coating would be used; therefore, slower evaporating solvents are required to avoid skinning on the roller and to allow for flowout of roller pattern created during application of the paint. Since thermoplastic acrylics dry by evaporation of solvent alone, extremely slow-drying solvents, which retard development of properties, should be avoided.

The majority of thermoplastic acrylic solution polymers are designed for general-purpose industrial finishing (i.e., metal furniture and product finishing) and have a T_g of approximately 50°C. This T_g is generally obtained by copolymerizing combinations of methyl methacrylate (MMA), butyl methacrylate (BMA), ethyl acrylate (EA), butyl acrylate (BA), and ethylhexyl acrylate (EHA). While many other acrylate and methacrylate monomers exist, as indicated in Table 2, these few are the primary acrylic monomers that are commercially available and that are, therefore, the most economically feasible.

At a T_g of 50°C, these acrylic polymers are intermediate in hardness, having a Tukon hardness of about 11 to 12 [see ASTM Test Methods for Indentation Hardness of Organic Coatings (D 1474)]. They are hard enough to dry rapidly to a tack-free state that allows early handling of the coated product and also hard enough to resist marring, print [see ASTM Test Method for Print Resistance of Lacquers (D 2091)], block [see ASTM Test Method for Blocking Resistance of Architectural Paints (D 4946)], and dirt pickup. Yet, they retain enough flexibility and elongation to have some impact resistance [see ASTM Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact) (D 2794)], and some can even be post-fabricated, such as is done with coil coated stock to produce aluminum gutters, trim pieces, etc.

Up to the mid-1950s, nitrocellulose lacquers were the major automotive coating in use. Nitrocellulose finishes gave an excellent original appearance but had poor durability, particularly gloss retention, and required frequent polishing by the car owner for the finish to look good. This problem was eliminated in 1956 when General Motors adopted acrylic lacquers based on poly(methyl methacrylate). The acrylic lacquers gave significantly better durability and allowed for the use of the more modern eye-catching metallic pigments [*13*]. The acrylic lacquers generally contain external plasticizers, such as the phthalates, which contribute to improved chip resistance and cold crack resistance. No internal plasticizing monomer (i.e., acrylates) is generally contained in automotive acrylic lacquers, and consequently their T_g is approximately 105°C, with a Tukon hardness of about 22.

Since they are very hard and fairly high molecular weight (i.e., 100 000), the thermoplastic solution polymers designed for automotive use are not capable of the excellent molecular flow that would be expected of softer/lower-molecular-weight polymers. Consequently, the acrylic lacquers require factory buffing and or baking to obtain the kind of maximum gloss required for the new car showroom. This disadvantage was shared by the older nitrocellulose lacquers.

Also, because of hardness and high molecular weight, the spray solids percent is low. Since these lacquers are thermoplastic, they are permanently subject to softening by strong solvents, such as toluene or acetone, if for some reason they would contact the automotive finish. Conversely, however, the thermoplastic acrylic lacquers can be easily repaired by an additional coat of paint which "melts" into the original coat, leaving no "two-coat" effects or intercoat adhesion problems.

Thermosetting Acrylic Resins

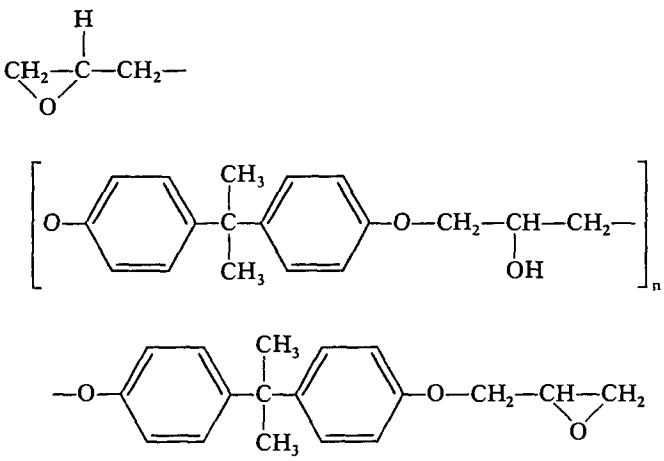
Thermosetting acrylic resins are compositionally very similar to the thermoplastic-type acrylics, with the exception that they contain functional groups, such as carboxyl or hydroxyl, that are capable of reacting with another polymeric or monomeric multifunctional material to produce a three-dimensional network structure. As has already been discussed, the mechanical properties of thermoplastic acrylic polymers for coatings are generally improved by increasing molecular weight, but polymers with overly high molecular weight produce solutions of unworkably high viscosity. An alternate route to improved film properties is to use a thermosetting acrylic polymer, converting linear, moderate-molecular-weight polymer chains to an infinite molecular weight structure. This cross-linking reaction takes place after the coating has been applied to the substrate, often by the application of heat, hence the term "thermosetting." To be truly cross-linked, one of the reactive species must have at least two reactive sites, while the other species has at least three reactive sites per molecule or chain.

Thermosetting acrylic polymers offer the following advantages over thermoplastic acrylics: (1) improved hardness and toughness, (2) better resistance to softening at elevated temperatures, (3) improved resistance to solvents, stains, and detergents, and (4) lower applied molecular weight, resulting in lower solution viscosity and consequently higher application solids.

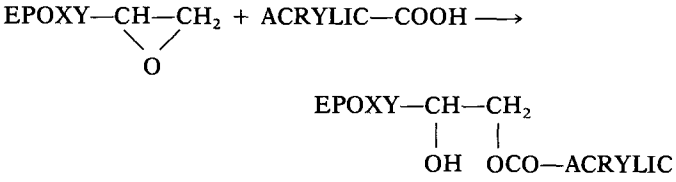
Over the years, numerous chemical reactions utilizing various functional groups have been devised as a means to cross-link acrylic polymers. However, we will elaborate on some of the more commercially significant thermosetting acrylics, namely those cross-linked with nitrogen resins, epoxies, and isocyanates.

Acid-Functional Acrylics Cross-Linked with Epoxy Resins

Possibly the most resistant acrylic enamels are based on thermosetting acrylic solution polymers that contain acid functionality and are reacted with an epoxy resin. Typically, the epoxy resin is a condensation product of Bisphenol A and epichlorohydrin (see Chapter 10 entitled, "Epoxy Resins in Coatings").



The acrylic solution polymer is made acid functional simply by incorporating acrylic or methacrylic acid into the backbone; when cured under suitable conditions, it reacts with the epoxide to form ester linkages between the two polymers:



An alternative reactant to epoxies based on Bisphenol A/epichlorohydrin is another acrylic polymer wherein epoxide sites have been incorporated by polymerizing glycidyl acrylate, glycidyl methacrylate, or allyl glycidyl ether into the acrylic backbone. This approach is limited in use, however, because both economics and performance favor the Bisphenol A type epoxides. Also, in recent years, epoxy manufacturers have developed many aliphatic epoxides in an attempt to mimic the benefits of the workhorse Bisphenol A based products (i.e., resistance properties) without the accompanying disadvantages (i.e., poor resistance to UV light).

The carboxyl-functional acrylic resins typically have a molecular weight in the 10 000 to 50 000 range and a carboxyl content of 5 to 20%. Some higher solids acrylics are lower in molecular weight with higher acid content. The acid content of the acrylic polymer determines the equivalent weight of epoxy resin required to react with the acrylic to achieve a thoroughly cross-linked system.

Styrene or vinyltoluene are often incorporated into the acrylic polymer as "honorary" acrylic monomers because their reaction kinetics with acrylic monomers are fairly good and because they often improve alkali resistance and are low in cost. The cross-linking reaction between the carboxyl group on the acrylic polymer and the epoxy resin is fairly sluggish and requires a base catalyst such as dodecyl trimethyl ammonium chloride, or tri(dimethylaminomethyl) phenol. In some instance, melamine-formaldehyde resins are sufficiently basic to be used as catalyst and have the additional advantage of entering into the cross-linking reaction [*13*]. For improved package stability, however, it is preferable to add the base catalyst to the other components just prior to use. Even with catalyst, the baking or stoving requirements for acid/epoxide systems are fairly high, with 15 to 30 min at 150 to 190°C being typical. Of course, the higher the bake temperature, the shorter the bake time required for cure. To determine the optimum conditions for a given system, it is best to cure that system at a variety of baking conditions and then measure properties to determine the temperature and time required for maximum performance.

The primary uses for acid-functional acrylics cross-linked with epoxy resin are as appliance enamels and coatings for interior metal furniture and equipment. Acrylic/epoxy enamels fill the needs of the appliance industry primarily because of their excellent alkali/detergent resistance [see ASTM Practice for Detergent Resistance of Organic Finishes (D 2248-89)], which is critical to the performance of washing machine coatings. Other properties that are important to the appliance industry include: hardness, scratch resistance, grease resistance, stain resistance, as well as flexibility, impact resistance, and adhesion to metal. Acrylic/epoxy enamels, on the whole, offer an excellent balance of these important properties. Typical properties for an enamel based on an acid-functional acrylic resin cross-linked with a Bisphenol A based epoxy are shown in Table 3.

The disadvantages associated with acrylic/epoxy coatings are usually concerns brought about by the aromatic nature of the Bisphenol A based epoxy cross-linker. Their most significant limitation is poor resistance to UV light, which restricts their use to interior applications. If used outside, the aromatic Bisphenol A portion of the epoxy would degrade rapidly, and early chalking would occur. In some of the newer high-solids acrylic/epoxies, the epoxy content is very high and can therefore cause discoloration problems even indoors due to UV light. Where this is a problem, an aliphatic epoxy can be substituted for at least some of the Bisphenol A based epoxy to reduce sensitivity to UV radiation (see Chapter 10 entitled "Epoxy Resins in Coatings").

Acrylic Polymers Cross-Linked with Amino Resins

Acrylic polymers containing acid or hydroxyl functionality can be cross-linked with amino resins such as: urea, melamine, and benzoguanamine formaldehyde condensates (see Chapter 8 entitled "Amino Resins") as follows:

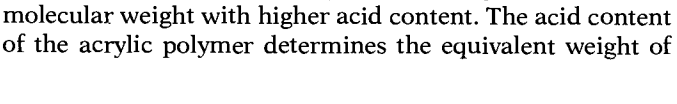


TABLE 3—Application properties for a white enamel based on an acid functional acrylic resin cross-linked with a Bisphenol A based epoxy [*14*] (baked 30 min at approximately 180°C).

Tukon hardness	16.2
Pencil hardness	2H
Solvent resistance, glass	
Cellosolve acetate, 15 min	6B
Cellosolve acetate, 60 min	6B
Xylol, 15 min	5B

[a]ASTM blister rating. A rating of 10 means no blistering, a rating of 0 means very large blisters, with intermediate ratings judged by ASTM photo standards.
[b]0 = no cracks; 9 = delamination.

$$\text{AMINO RESIN—NHCH}_2\text{OR} + \text{ACRYLIC—OH} \longrightarrow \text{AMINO RESIN—NHCH}_2\text{ O—ACRYLIC} + \text{ROH}$$

Reactions with amino resins containing an -NH-CH_2OH group are possible because this group differs from a simple alcohol in that it is far more acidic and reactive. Likewise, the methylol ether (when capped with alcohol) is more reactive than a conventional dialkyl ether. The curing condition required for acid functional acrylics cross-linked with amino resins is approximately 30 min at 150°C, while for an analogous hydroxyl functional acrylic, the reaction is more facile, requiring 30 min at 125°C with an acid catalyst [*15*]. Since the acid-methylol reaction is relatively slow, it allows significant self-condensation of the amino resin [*16*]. This detracts from the overall toughness and resistance properties.

The hydroxyl-functional acrylics are, therefore, favored over acid-functional polymers and are most often used in combination with a methylolated or butylated melamine-formaldehyde or benzoguanamine-formaldehyde condensate. Urea-formaldehyde condensates are less durable and have been found to have lower gloss and poorer chemical resistance. Hydroxyl functionality is incorporated into the acrylic polymer by copolymerizing monomers such as hydroxyethyl acrylate (HEA) or hydroxyethyl methacrylate (HEMA). This type of combination produces cross-linked acrylic/amino enamels with outstanding exterior durability, good hardness, and mar resistance, as well as excellent resistance to solvent attack. Acrylic/amino thermosetting enamels were, therefore, very successful in replacing the less durable alkyd/melamine systems in automotive topcoat applications, and general industrial finishing. Over the years, the automotive industry has relied heavily on this type of thermosetting acrylic because it offers the outstanding durability of acrylic lacquers but with better resistance to solvents and elevated temperatures. It also offers significantly higher application solids. Also, it does not require factory buffing to achieve high gloss as do the acrylic lacquer coatings.

Another reason that acrylic/amino resin technology became so popular is because of the versatility of the chemistry, whereby properties can be readily altered by varying acrylic T_g, acrylic monomers, acrylic functionality level, and cross-linker type and level. This is very important in general industrial finishing, where coatings often must be custom tailored to the specific end use. Table 4 briefly demonstrates the kinds of variation in performance which can be obtained by a few manipulations in composition [*17*].

An alternate approach to a thermosetting acrylic polymer is to prepare an acrylic polymer which contains functionality analogous to a melamine/formaldehyde condensate. Methylol or methylol ether groups can be attached to an acrylic backbone, and the resulting polymer can self-condensate, resulting in a cross-linked structure without the need for an external cross-linking agent. Initially, an acrylic polymer is made containing acrylamide (AM). The polymerization is usually a conventional free-radical, solution polymerization carried out in alcohol or a combination of alcohol and aromatic solvent. As in most thermosetting acrylic polymers, mercaptan is usually included to control molecular weight. After the polymerization is complete, the polymer is treated with formaldehyde to convert it to the methylol amide. An acid catalyst will bring about etherification with the alcohol present, usually butanol. The conversion proceeds as follows [*18*]:

$$\text{POLYMER—CO—NH}_2 + \text{HCHO} \longrightarrow \text{POLYMER—CO—NH—CH}_2\text{OH}$$

$$\text{POLYMER—CO—NH—CH}_2\text{OH} + \text{ROH} \longrightarrow \text{POLYMER—CO—NH—CH}_2\text{OR} + \text{H}_2\text{O}$$

As an alternative process, the AM monomer can be methylolated before being polymerized. The finalized methylolated amide acrylic polymers condense readily when acid catalyzed at bake conditions of 30 min at 150°C. The condensation process is a two-stage reaction [*19*]:

$$2\ \text{POLYMER—CO—NH—CH}_2\text{OH} \longrightarrow \text{POLYMER—CO—NH—CH}_2\text{—O—CH}_2\text{—NH—CO—POLYMER} + \text{H}_2\text{O}$$

TABLE 4—Compositions, viscosities, and film properties of HEMA-based copolymers containing a variety of other monomers[a] [17].

$$\text{POLYMER—CO—NH—CH}_2\text{—NH—CO—POLYMER} + \text{H}_2\text{O} \xrightarrow{\text{further heat}}$$

If the methylolated amide has been etherified by butanol capping, instead of water as a by-product, a mixture of butanol and dibutyl ether would be obtained. These types of self-condensing acrylic resins will also react with amino resins, but usually there is no justification for so doing (i.e., no improvements in performance). The strength of the methylol amide acrylics is that they have no glaring weaknesses and make very good general-purpose resins.

Isocyanate-Reactive Acrylics

Acrylic solution polymers that are cross-linked with isocyanates (often referred to as acrylic urethanes) are unique among the various cross-linking systems because they cure under ambient conditions—they don't require baking. The isocyanate group (—N=C=O) is extremely reactive and will cross-link with any type of functionality having a labile hydrogen atom. This includes amines, alcohols, ureas, urethanes, carboxylic acids, and amides. Acrylic polymers designed to be cross-linked with isocyanate resins generally contain hydroxyl functionality incorporated by polymerizing hydroxyethyl acrylate (HEA) or hydroxyethyl methacrylate (HEMA) into the acrylic backbone.

There are six basic types of curing mechanisms for urethane coatings [see ASTM Terminology Relating to Paint, Varnish, Lacquer, and Related Products (D 16-75)]. The two-package polyisocyanate/polyhydroxyl coatings make up "Type V." Of this class, acrylic urethanes based on weather-resistant hydroxyl functional acrylics predominate. The hydroxyl functional acrylic reacts with isocyanate resin as follows:

$$\text{ACRYLIC—OH} + \text{R—N=C=O} \longrightarrow \underset{\text{(a urethane)}}{\text{R—NH—COO—ACRYLIC}}$$

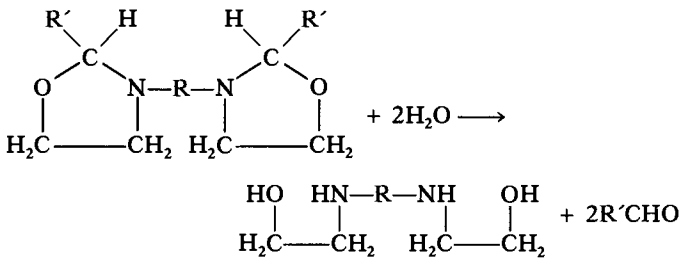
The preferred isocyanates are usually aliphatic, such as the adduct of hexamethylene diisocyanate (HMDI), because of the poorer color and exterior durability associated with the aromatic types of isocyanates. While the aromatic varieties of isocyanate react faster than the aliphatic types, a wide range of catalysts are available which can be used to speed up the cure of aliphatic isocyanates. A few such catalysts include triethylene diamine, zinc naphthenate, and dibutyl tin-dilaurate [20].

Acrylic solution polymers cross-linked with aliphatic isocyanates are ideal for applications where a durable, high-performance coating is required but where baking is not feasible because of the size or temperature sensitivity of the object to be coated. Acrylic urethanes are, therefore, invaluable in the transportation industry where high-quality coatings are needed for aircraft, railroad cars, trucks, buses, etc. Automobile refinishing, heavy equipment coatings, and high-performance maintenance coatings are also areas where acrylic urethanes are appropriate. The acrylic urethanes combine the inherent UV resistance and exterior durability of acrylics with the ambient cross-linking ability of aliphatic isocyanates to produce hard, tough, chemical-resistant, high-performance coatings. The major drawback of acrylic urethanes is that they are a two-package system and cannot be mixed until ready for application because they are so reactive and have a short "pot life."

Over the years, the hydroxyl-functional acrylics have been improving in performance, and now the emphasis is on higher solids content for lower VOCs. To meet more stringent VOC regulations, lower-molecular-weight, higher-solids hydroxyl functional acrylics have been developed. Increasing

the solids of the acrylic reduces solvent levels in the formulated coating. To compensate for lower molecular weight, one way to improve performance is to increase hydroxyl content, which in turn requires higher levels of isocyanate.

An alternative approach to reduced solvent or higher solids is to modify the acrylic urethane with a reactive diluent which is fluid and acts like a solvent but then reacts to form part of the cross-linked network [*21*]. One such diluent is a low-molecular-weight, difunctional oxazolidine which is non-reactive with isocyanates until ambient moisture opens the ring, releasing both hydroxyl and amine functionality [*22*].



This type of functionality has the advantage that it is one package stable with isocyanates as long as moisture is excluded from the paint. Because it has four reactive sites per molecule, it increases cross-link density for maximum performance, while it decreases solvent emissions.

ACRYLIC EMULSION POLYMERS

An acrylic emulsion is a two-phase system in which acrylic polymer droplets are dispersed in an external water phase, usually with the aid of an emulsifier (i.e., surfactant). Unlike some polymer emulsions, such as alkyds or epoxides, which are emulsified as preexisting resins, acrylic emulsions are made by an emulsion polymerization process wherein the monomer droplets are emulsified in water and then polymerized. A typical acrylic emulsion polymerization recipe is given in Table 5 [*23*].

The physical chemistry of acrylic emulsion polymers is much the same as for their solution polymer analogs, and the film properties of the emulsions can be controlled by manipulating polymer composition and molecular weight just as with acrylic solution polymers. However, the viscosity of an emulsion is unaffected by polymer molecular weight since solution principles do not pertain to emulsions (the polymer is insoluble in the continuous water phase). Therefore, for the best possible physical properties, the molecular weight of acrylic emulsions is generally higher than that of acrylic solution polymers: 100 000 to 1 000 000 for an emulsion versus 75 000 to 100 000 for a solution polymer.

The particle size of an emulsion is also very important in determining performance and must be carefully controlled. For example, the film-forming ability of an emulsion, as well as its pigment binding capability, is dependent on particle size, with smaller particle size being better than large particle size. Particle size does affect emulsion viscosity, with large particle size generally being associated with low viscosity.

TABLE 5—Copolymerization of ethyl acrylate, methyl methacrylate, and methacrylic acid [*23*].

Materials:

375.0 g	Deionized Water
5.1 g	Surfactant
100.0 g	Ethyl acrylate (15 ppm MEHQ)
100.0 g	Methyl methacrylate (25 ppm MEHQ)
4.0 g	Glacial methacrylic acid (100 ppm MEHQ)
4.0 mL	Ferrous sulfate solution (0.15%)
1.0 g	Ammonium persulfate in 5 mL of water
0.7 g	Sodium formaldehyde sulfoxylate in 5 mL of water
5 drops	t-butyl hydroperoxide (70%)

Procedure:

In a beaker, stir the surfactant with the water until dissolved and adjust the pH to 9.0 by adding 50% sodium hydroxide solution. Transfer this solution into the reaction flask, rinse the beaker with a small amount of deionized water, add the monomers and ferrous sulfate, and stir 15 min with flow of nitrogen before adding the initiators. The maximum temperature of 77°C is attained in 12 to 15 min. Stir 15 min after adding the initiators, then cool to room temperature, adjust to pH 9.5 with 28% aqueous ammonia, and filter; the gums amounted to 0.17%.

The free acid (unneutralized) surfactant can also be used as an emulsifier for the above copolymerization. In this case, the period of purging with nitrogen after charging the monomers should not exceed 15 min before the addition of initiators to avoid the formation of polymer emulsion product with excessive viscosity. Filtration of the finished emulsion gave only 0.05% gums. The properties of these emulsions were:

Surfactant Form	Sodium Salt	Free Acid
Solids Content, %—Calculated	35.0	36.0
—Found	34.3	35.6
pH at 25°C	5.6	1.8
Viscosity (Brookfield), cP	7.9[a]	10.5[a]
Particle size (light scattering), %	22.8[b]	12.3[c]
Minimum film-forming temperature, °C	22[a]	30[a]

[a]Emulsion adjusted to pH 9.5 before measurement.
[b]Measurement at 2% solids.
[c]Measurement at 0.4% solids.

Acrylic emulsion polymers (also known as acrylic latexes) have long been a mainstay of the architectural coatings market, particularly in exterior paints where their outstanding durability is so important. However, in recent years, clean air regulations have further strengthened the position of acrylic emulsions, usually at the expense of solvent alkyds. The use of acrylic emulsions in industrial coatings applications has also grown as a result of solvent emission restrictions. At the same time, the properties of acrylic emulsion polymers in the industrial coatings market has improved so that they now offer performance similar to their solvent-borne counterparts.

Acrylic Emulsions for Architectural Coatings

Architectural coatings are generally considered to be coatings intended for on-site application to residential, commercial, or institutional buildings; they are also known as trade sales coatings. Over the last 40 years, this market has evolved from an entirely oil-based market to one dominated by emulsions. There are three underlying reasons for the takeover of the architectural coatings market by emulsion polymers. The health, safety, air quality, and odor concerns associated with the solvents in oil-based paints have moved people towards

water-based latex paints whenever there is not a large penalty in performance. Also, latex paints are more tolerant of a wide variety of application conditions and can even be applied over damp substrates. Thirdly, emulsion polymers, particularly quality acrylic emulsions, have surpassed oil-based paints for long-term performance and protection in most applications.

Although acrylic emulsions generally provide a superior level of performance, their cost is somewhat higher than lower-performance emulsions such as vinyl acetates. Therefore, in segments of the architectural coatings market where performance is not critical, such as for interior flat paints, acrylic emulsions are not a dominant binder. However, in segments where performance and durability are essential, such as for exterior flat and gloss paints, acrylic emulsions control a very large portion of the market both in the United States and abroad.

Interior Coatings Applications

The high-volume, interior-flat market is dominated by vinyl acetate copolymers plasticized with a soft acrylate monomer, usually butyl acrylate at about the 15% weight level. Interior flat paints are aimed primarily at broadwall applications. Performance requirements for this market are fairly modest, with decorative features such as color, sheen level, and hiding being the more influential factors determining consumer preference. The one resistance property demanded in this market is scrub resistance; in this regard, vinyl/acrylics perform satisfactorily.

There is a small, premium segment of the interior flat market occupied by all acrylic latexes, and one of the key features which they offer is improved rheology and application characteristics resulting from the better interaction of acrylic latex particles with the new associative thickeners. Associative thickeners (also referred to as rheology modifiers) dramatically enhance flow, brushability, film build, and spatter resistance compared to conventional hydroxyethyl cellulose (HEC) thickeners.

Since interior flat paints contain a high pigment loading to increase hiding and reduce cost, the acrylic polymers used in this market tend to be fairly soft with good binding capacity. Typically, they are copolymers of a hard methacrylate monomer such as methyl methacrylate with a soft, commercially available acrylate monomer such as ethyl acrylate, butyl acrylate, or ethylhexyl acrylate. The T_g is generally around 10°C.

Interior gloss and semigloss paints have much more demanding requirements than flat paints since they are used for more diverse and challenging substrates such as windows, cabinets, and doors. Acrylic emulsions play a major role in this market, especially at the high-performance end. They are tailored to the specific needs of this market by optimizing the important variables contributing to performance: composition, hardness, molecular weight, and particle size.

Acrylic emulsions used in gloss and semigloss paints are copolymers of acrylate and methacrylate monomers and are usually harder than emulsions used in flat paints. They generally have a T_g in the range of 20 to 50°C. The harder polymers are necessary to build in block and print resistance, which are needed to keep doors and windows from sticking and to prevent marring and film damage associated with softer polymers. Since gloss and semigloss paints are formulated at low pigment volume concentration (PVC) to obtain gloss, the pigment does not contribute significantly to film hardness; it must all come from the polymer.

Since these gloss and semigloss latexes are often used over old oil-based enamels, adhesion to aged oil-based paints is required. This may be accomplished by copolymerizing adhesion promoting functional monomers into the acrylic polymer backbone. A major breakthrough in latex adhesion technology came about with the development of ureide functional acrylic monomers [*24*]. The adhesion promoter particularly is needed to improve adhesion and blister resistance when the paint film becomes wet, as it might in a bathroom. Since the gloss paints are often used in wet areas such as a bathroom, the water resistance of the dry film is also an important property. To ensure good water resistance, acrylic emulsions used in this market often contain hydrophobic monomers such as styrene.

Since interior trim paints are so highly visible, overall appearance properties are critical to the success of the paint job, and features such as flow and levelling, gloss, and film build are expected to be similar to oil-based enamels. This level of outstanding appearance has been possible in recent years with the introduction of associative thickeners. The traditional thickener for latex paints has been hydroxyethyl cellulose (HEC), which thickens by a flocculation mechanism and usually produces poor flow and gloss. Associative thickeners loosely bind to the surface of the latex particles through hydrophobic interactions, forming a network structure which accounts for their thickening action. The degree of interaction between the thickener and the latex particle is largely a result of the surface chemistry of the emulsion particles. Smaller particle-size emulsions have greater surface area and therefore have more interaction with associative thickeners. More hydrophobic latexes have stronger association with the new thickeners. Consequently, small-particle-size, hydrophobic acrylic emulsions have been designed specifically for use with associative thickeners. These newer acrylic emulsions optimize thickener interaction and produce exceptional flow and gloss. In fact, before these new emulsion/thickener systems, truly high-gloss latex paints were out of the question. They also improve brushability and film build, while eliminating the problem of roller spatter. Overall, the appearance properties of the newer small particle-size hydrophobic acrylics, when used in combination with associative thickeners, rivals that of oil-based enamels.

In an effort to further improve the performance of acrylic emulsions, the morphology of emulsion particles has become an additional important variable. In the past few years, new composite acrylic emulsions have been introduced, particularly into the interior gloss area, which are made up of two or more nonhomogeneous phases. They are prepared by a two-stage polymerization process sometimes referred to as a sequential emulsion polymerization that results in various types of core-shell structures. The goal of this type of polymerization is to incorporate the best characteristics of the different phases.

The hard acrylic emulsions typically used in interior gloss paints provide excellent performance but require considerable amounts of coalescent to achieve film formation (i.e., 10 to 20% by weight on polymer solids). This is undesirable both

from a cost and an organic emissions perspective. Using a two-stage polymerization, it is now possible to make hard, block-resistant acrylic emulsions that are also flexible and require lower coalescent levels. This type of polymerization can also be used to achieve a desired surface chemistry while not disturbing the bulk composition of the latex particle. This can be useful in optimizing rheology or improving adhesion characteristics of an acrylic latex.

Exterior Coatings Applications

By far the most challenging application for any coating is as an exterior paint required to protect a multitude of substrates in diverse and extreme weather conditions. It is in this demanding role that acrylic emulsions have met virtually all requirements and impressed the industry by their outstanding durability. One primary reason for their success, as mentioned earlier for solution acrylics, is their lack of absorption of ultraviolet light coupled with their inherent hydrolysis resistance. Over the years, acrylic emulsions have evolved from simple polymers troubled by shortcomings, such as poor adhesion or low film build, to sophisticated systems incorporating elements designed to address essentially every major challenge experienced by an exterior paint.

One of the toughest demands facing exterior flat house paints is the need to withstand the freeze-thaw type of expansion and contraction of dimensionally unstable substrates such as pine or other soft woods. To avoid the grain cracking that often occurs over this type of substrate, acrylic emulsions designed for flat house paints are fairly soft, with a T_g in the range of 10 to 15°C. A coalescing solvent is usually used in the formulation to assist film formation, particularly at lower temperatures. When the coalescent leaves, the acrylic paint film remains pliable and able to withstand substrate swelling and freezing, unlike oil-based house paints which become harder and embrittle on exposure as they continue to cross-link. The primary concern with making the acrylic polymer too soft is that dirt pickup would worsen. Since flat house paints contain a fairly high pigment content (i.e., PVC = 40 to 60%), dirt resistance is enhanced by the pigment loading. Experience over many years indicates that a T_g of 10 to 15°C is the optimum range to balance grain-crack resistance with dirt resistance.

For exterior flat house paints, the inclusion of an effective adhesion promoter in the acrylic backbone is crucial for good adhesion. The adhesion promoter greatly improves blister resistance. Furthermore, the improved adhesion enhances crack resistance over dimensionally unstable wood substrates. Painting over a degraded chalky surface is a common practice that can be a potential disaster if sufficient adhesion is not obtained. The chalk acts like a powdery barrier, preventing the emulsion binder from penetrating to the real substrate and establishing an adhesive bond. Studies have shown that smaller particle-size acrylic emulsions are much more effective than larger particle-size emulsions for filtering down through the chalk and obtaining adequate adhesion. For this reason, many exterior grade acrylic emulsions have been designed at a fairly small particle size of about 100 nm [*25*].

Small-particle-size, large-surface-area emulsions, when thickened with HEC, have poorer flow and film build than larger particle-size emulsions, which are less aggregated by the flocculating mechanism of HEC. Therefore, 100-nm emulsions that were designed to have improved chalk adhesion sacrificed some of the flow and film build of large particle-size (500-nm) emulsions. In an attempt to combine these seemingly mutually exclusive properties, particle-size distributions have been carefully controlled to ensure a tailored mixture of small particles that give good adhesion to chalky surfaces and large particles that help to improve flow in formulations thickened with HEC. An additional benefit of these polymers is their high supplied solids, which may be as high as 60% by weight compared to 40 to 50% for unimodal latexes.

Wide particle-size distribution acrylic emulsions do not significantly address the low film build associated with smaller particle-size emulsions when thickened with HEC. Film build is particularly important to an exterior paint because the durability of the film is usually proportional to the film thickness, i.e., how much paint is applied to the substrate. This was addressed in the 1980s by the Rohm and Haas Co. with the introduction of a Multilobe® acrylic emulsion, shown in Fig. 2 [*26*]. This type of polymer has a lobed morphology that is grown out during the polymerization process; it does not result from particle aggregation. The lobes of this polymer are about 350 nm, but it has an effective hydrodynamic volume of about 1000 nm and is, therefore, very effective at imparting high film build in paints thickened with HEC. It also reduces the level of thickener needed to achieve a given viscosity. Since in its commercial form this technology also contains small particles, good adhesion characteristics are retained while film build is optimized.

Other important aspects of weatherability are color retention and resistance to chalking. These properties are made worse by the catalytic degradation effects of TiO_2 on the binder, so that high PVC flat paints are generally poorer than low PVC gloss paints. However, the inherent durability of the binder is still a controlling factor, and acrylic polymers have excellent resistance to sunlight and erosion, which contribute to their very good chalk resistance and color retention. Among the common acrylic copolymer compositions in use commercially, MMA/BA polymers are better than MMA/EA polymers, and higher methacrylate containing binders are

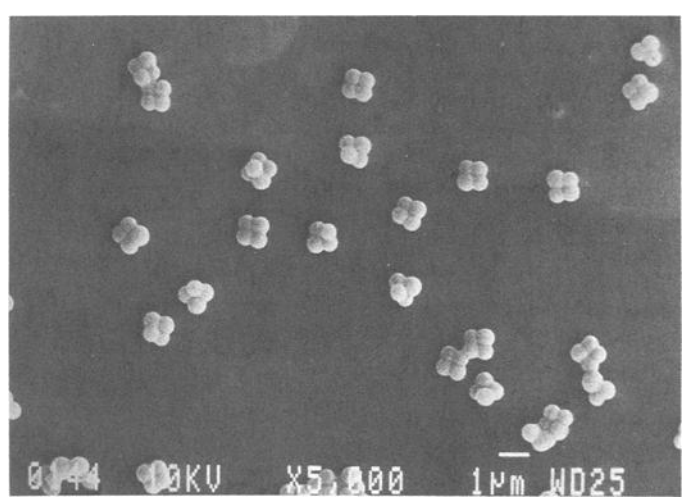


FIG. 2–Scanning electron micrograph of Multilobe® acrylic particles (courtesy of Rohm and Haas Co.).

better than acrylics containing higher levels of acrylate monomers. Of course, the methacrylate/acrylate levels are generally determined by the T_g required to achieve the desired balance of crack resistance and dirt pickup.

Exterior gloss and semigloss paints are required to withstand similar tortures as their flat paint counterparts and, in addition, must provide equally good dirt resistance at much lower pigment loadings. Acrylic emulsions have been designed that meet all of these challenges and perform very well in environments as diverse as the tropical regions of Asia and the Philippines to the Scandinavian regions of Europe. Since the acrylic emulsion engineered for interior gloss/semigloss paints are intended to be high-performance systems capable of good adhesion even in wet areas, they are often able to be used outside as well. Since exterior gloss paints must have good dirt resistance at low PVC, the acrylic emulsions used in these paints are harder than those used in flat paints and generally have a T_g in the area of 20 to 35°C. This T_g range can provide acceptable dirt resistance while still having good grain-crack resistance. The very hardest acrylic emulsions used for interior gloss paints (i.e., above T_g 35°C) would not be appropriate outside, at least in areas subject to freezing, because they would be more prone to grain crack.

Since brush marks are much more obvious in a gloss paint than in a flat paint, good flow and levelling is much more critical for a gloss paint than for a flat paint. Consequently, older acrylic emulsions intended for semigloss paints (there were no high-gloss latex paints until about 1980) are of large particle size to have the best possible flow with the prevailing thickener of the day, HEC. The flow of these systems could best be described as fair, but overall they have demonstrated an admirable balance of properties and are still popular today. However, newer acrylic emulsions intended for exterior gloss paint applications, particularly those generally referred to as acrylic enamel vehicles, are small in particle size (i.e., 100 nm) to take advantage of the excellent flow, gloss, and rheology available by using associative thickeners.

Over the past ten years, the decorative as well as protective capabilities of exterior gloss paints have improved significantly to the point where acrylic emulsions are rapidly replacing alkyd enamels as the preferred coating for exterior trim.

Acrylic Emulsion Maintenance Coatings

Maintenance coatings differ substantially from decorative coatings since they are used primarily for their protective features, which prevent substrate deterioration by corrosive elements. Maintenance coatings are generally used to protect metal surfaces such as bridges, storage tanks, and other industrial facilities, often in harsh chemical and corrosive environments. The first acrylic latex binders for corrosion-resistant maintenance coatings were introduced commercially in 1964. They are similar in hardness and composition to exterior flat house paint binders with the exception that they are formulated with reactive pigments and additives which help prevent rusting. The surfactants and other "salt and pepper" ingredients used in the polymerization of maintenance acrylic emulsions are carefully selected so as to not aggravate corrosion.

These acrylic latex maintenance coatings had the usual advantages in application of water-based paints over solvent alkyd paints along with expected advantages in chalk resistance, color retention, and other decorative qualities. However, to the surprise of some segments of the maintenance industry, acrylic maintenance emulsions often outperformed solvent alkyds for corrosion resistance and overall metal protection. This is partly because the alkyds continue to harden and eventually crack, leaving the substrate exposed and subject to the elements. Acrylic emulsions do not continue to harden once the paint film is dry, and they remain sufficiently pliable to expand and contract with the substrate.

The one weakness of the acrylic latexes in the area of maintenance coatings was their low T_g, which reflected a lower hardness than the alkyd paints. This limitation was removed by the development of aqueous gloss enamel binders. These hard latex binders used in interior and exterior gloss paints were fine tuned to maximize corrosion resistance and overall protection. Commercialized in the mid-1980s, this new generation of maintenance vehicles has proved very successful in extensive field tests, particularly on bridges in the southeastern United States. The small particle size of these binders fits perfectly with associative thickener technology to give tight water-resistant films, which are an improvement over HEC-thickened paints that can have microscopic defects as a result of the flocculating mechanism of HEC [27].

Acrylic Emulsions for Industrial Coatings

Nonreactive Emulsions

Industrial coatings users, who have traditionally applied solvent-based polymers, have recently been under pressure to reduce volatile organic emissions. This is particularly true in California, which has historically been at the forefront of clean air legislation. In many instances, these coatings users have complied with the stricter environmental legislation by switching over to water-based systems. Acrylic producers have responded to the needs of these coatings users by developing more sophisticated emulsions capable of meeting the demanding performance requirements of many different end users. Early emulsions aimed at industrial coatings applications were offshoots of architectural coatings technology and were often too soft for industrial coatings uses. Also, high gloss was not possible with these older emulsions. Like the newer gloss enamel emulsions for trade sales use, however, latexes aimed at industrial coatings applications have evolved into hard, resistant binders that match the performance of their solvent-based counterparts. Without this evolution in performance, it is unlikely that industrial coatings users would switch to latex coatings even with the more severe emissions regulations.

Thermoplastic acrylic emulsions designed for industrial coatings applications generally have to be harder and faster drying than architectural emulsions and have better corrosion and chemical resistance. The typical T_g range for such acrylics is about 30 to 70°C. The film formation problems usually associated with such hard emulsions are somewhat alleviated by the controlled application conditions in the factory, so that low-temperature film formation is generally not required. For general industrial finishing over metal substrates, industrial acrylic emulsions have borrowed technology from maintenance finishes and have optimized sur-

factants, additives, and compositions to improve rather than detract from corrosion resistance.

Newer heterogeneous acrylic emulsions comprised of two or more phases have recently become important in the industrial coatings industry. One such type of heteropolymer, the core-shell polymer, is being used to achieve rapid hardness development with improved block and print resistance at low VOC. These properties allow the manufacturer to stack, pack, and ship coated parts more quickly [*28*]. Using core-shell technology, acrylic emulsions have been able to rival the performance of traditional, high-solvent-content nitrocellulose lacquers in wood coatings and furniture finishes. The major deficiency of acrylic emulsions in these areas is the "warmth" of water-based coatings compared to solvent-based materials. "Warmth" is a quality which refers to the feel and appearance of the coated wood.

Thermosetting Emulsions

Just as is the case with solution acrylics, functional groups can be incorporated into the polymer backbone of an acrylic emulsion so that it can react with another functional material after application to the substrate, forming a cross-linked polymer. Typically hydroxyl or hydroxyl/acid functional acrylic emulsions are cross-linked with urea or melamine resins. Acid functional acrylic emulsions can be cross-linked with emulsified epoxy resins. The chemistry of these systems is identical to the cross-linking chemistry discussed earlier for solvent-based acrylic resins. After the emulsion is cross-linked, the infinite molecular weight provides for solvent and chemical resistance, along with hardness and toughness. By adjusting the level of functionality, the amount of cross-linker, and the T_g of the acrylic emulsion, a system can be custom designed for a specific application.

For many years, the construction industry has relied on hydroxyl functional acrylic emulsions reacted with urea or melamine to coat products such as hardboard, wood panels, shingles, and metal coil. In interior applications, such as over wood paneling, these emulsions offer comparable cure speed and performance to solvent-based alkyd/urea systems. In coil coating applications, the thermosetting acrylics offer high gloss, excellent durability, good corrosion protection, as well as good roll coatability. These emulsions have been applied at line speeds up to 137 m/min with good transfer, flow, and leveling. Usually these systems are catalyzed with an acid catalyst to achieve the fastest/lowest temperature cure. A very good property balance is demonstrated in Table 6 for an aqueous acrylic melamine coil coating enamel [*29*].

A recent development in cross-linking acrylic emulsion technology is an epoxy cross-linking, ambient cure system which has many applications but has been found to be particularly useful in maintenance coatings. Besides being ambient curing, an attractive feature of this system is its excellent early properties resulting from the high-molecular-weight acrylic emulsion, which provides ample resistance characteristics until the epoxy cross-linking is complete. This new acrylic/epoxy system is compared to an epoxy/polyamide

Alkyd and Polyesters

by Al Heitkamp[1] *and Don Pellowe*[2]

ALKYD RESINS, COMMONLY KNOWN AS "ALKYDS," are synthetic polymeric materials that have been used in the coating industry since the 1930s. Today they continue to be the "workhorse" polymers for the paint, coating, and printing ink industries. Alkyd and chemically modified alkyd polymers find use in most types of liquid organic coatings for architectural, air-dry, and baked industrial and maintenance coatings. Alkyds are a special class of polyesters that often have vegetable oil or fatty acids coreacted into the polyester, and these compounds provide the distinctive air-cure feature of many of these compounds.

Three major classifications of alkyds are those designed for conventional solids, higher solids, and water-borne coatings. Because there are a large variety of commercially available intermediates and chemical modifiers—i.e., monomers—for the preparation of alkyds, they continue to be the most versatile type of polymers for coatings and printing inks.

Most alkyds are film-forming polymers with a relatively low glass transition temperature (T_g), i.e., below 0°C. They are easily pigmented and readily accept additives to form coatings with a wide range of appearance, performance, and application characteristics. Alkyds are extensively used on wood, metal, plastic, composite, and other substrates such as primers, topcoats, maintenance paints, undercoatings, exterior trim paints, wall paints, and similar end uses.

Polyesters for coatings are based on a coreaction of polyhydric alcohols and polybasic acids. Such polyesters may be prepared from one or more polyhydric alcohols and polybasic acids to meet particular coating performance requirements.

HISTORY

Although condensation products of dihydric alcohols and dicarboxylic acids were known at the start of the 20th Century, alkyds modified with drying oils were developed in the late 1920s by Kienle et al. [*1–5*]. The early condensation products were not soluble in common solvents and did not air dry until monofunctional acid or fatty acids were incorporated into the polymeric material. Kienle coined the term "alkyd" from the alcohols ("al") and acids ("cid") used in their preparation. The early spelling of "alcid" was later changed to the current form, "alkyd." Air-dry films were the result of oxidative polymerization and cross-linking that took place through coreaction of oxygen and the carbon-carbon bond unsaturation part of the fatty acids. The use of vegetable oils and fatty acids as coreactants with the early developed polyesters was the technological breakthrough that led to alkyd resins being the predominate binder for organic coatings. Other developments contributed to the general interest in the products such as new techniques for the production of phthalic anhydride, synthetic glycerin, and other new, novel polyhydric alcohols.

Typically, an alkyd could be based on glycerin as the polyol, phthalic anhydride as the polybasic acid, and soya or linseed oil as the vegetable oil. These compounds are coreacted and then reduced with aliphatic or aromatic petroleum-based hydrocarbon solvents. Monofunctional fatty acids such as tall oil fatty acids or special blended fatty acids are commonly found in alkyds as alternatives to vegetable oils.

ALKYD SYNTHESIS, PROCESSING AND MANUFACTURE

Three major categories of chemical intermediates are utilized in the manufacture of alkyd resins:

- Polybasic organic acid/anhydride—example, phthalic anhydride
- Polyhydric alcohol—example, glycerin
- Monobasic fatty acid or triglyceride—example, soya fatty acids or soya oil

The stoichiometric proportions and the equivalent weight of these monomers lead to the desired physical properties and molecular weight distribution of the resulting alkyd. The solvent selection and quantities used influence the viscosity, nonvolatile content, and the solvent evaporation rate from coating films.

Alkyd processing is mainly a condensation reaction between hydroxyl and carboxyl groups of the chemical intermediates. The main by-product of the reaction is water, and it must be removed during the polymerization process or it will transesterify back into the alkyd and change characteristics. Other chemical reactions are possible during preparation, and these include dimerization of fatty acids or vegetable oils depending on their unsaturation and the alkyd processing temperature. Vegetable oils (triglycerides) are used for economical alkyd manufacture, whereas fatty acid blends are used in high-performance alkyds—particularly in higher solids and water-borne types.

Copyright© 1995 by ASTM International

An alkyd resin can be modified with a number of intermediates. Some of the more common types are:

- Acrylates
- Benzoic acid
- Epoxides
- Isocyanates
- Paramethyl styrene
- Phenolics
- Polyamides
- Rosin
- Silicone
- Styrene
- Vinyl toluene

More than one of the above compounds are often used to impart particular characteristics when an alkyd is modified.

There are two major methods of preparing or processing alkyds for both laboratory and production scale. These methods are the fusion and solvent reflux processes.

Fusion Process

In this method of manufacture, the alkyd intermediates are charged into the reaction vessel. Then an inert gas, such as dry nitrogen or carbon dioxide, is introduced to "blanket" the vapor space above at the top of the reaction vessel. The reaction mixture is heated from 350 to 500°F (175 to 260°C). The main polymerization occurring is by condensation to form ester groups. Water of condensation exits from the top opening of the reactor. Vigorous mixing and agitation are required throughout the process to insure uniformity of the final resin (Fig. 1). The product provided by this process depends greatly on the procedure conditions followed in temperature and timely removal of water-of-reaction by-product.

Solvent Reflux Process

In the solvent reflux process, an azeotropic solvent such as xylene is commonly used in the reaction. The purpose of the azeotropic solvent is to aid in removal of water formed during the condensation reaction. The reflux solvent and water volatilize together and liquefy in a condenser placed above the reaction vessel. A separator or Dean-Stark trap below the condenser collects this liquid mixture, and the azeotrope solvent is returned to the reaction vessel (Fig. 2). The choice of azeotrope solvent affects the temperatures maintained during the reaction.

In both fusion and solvent reflux processes, acid number and viscosity are measured until the final desired values are

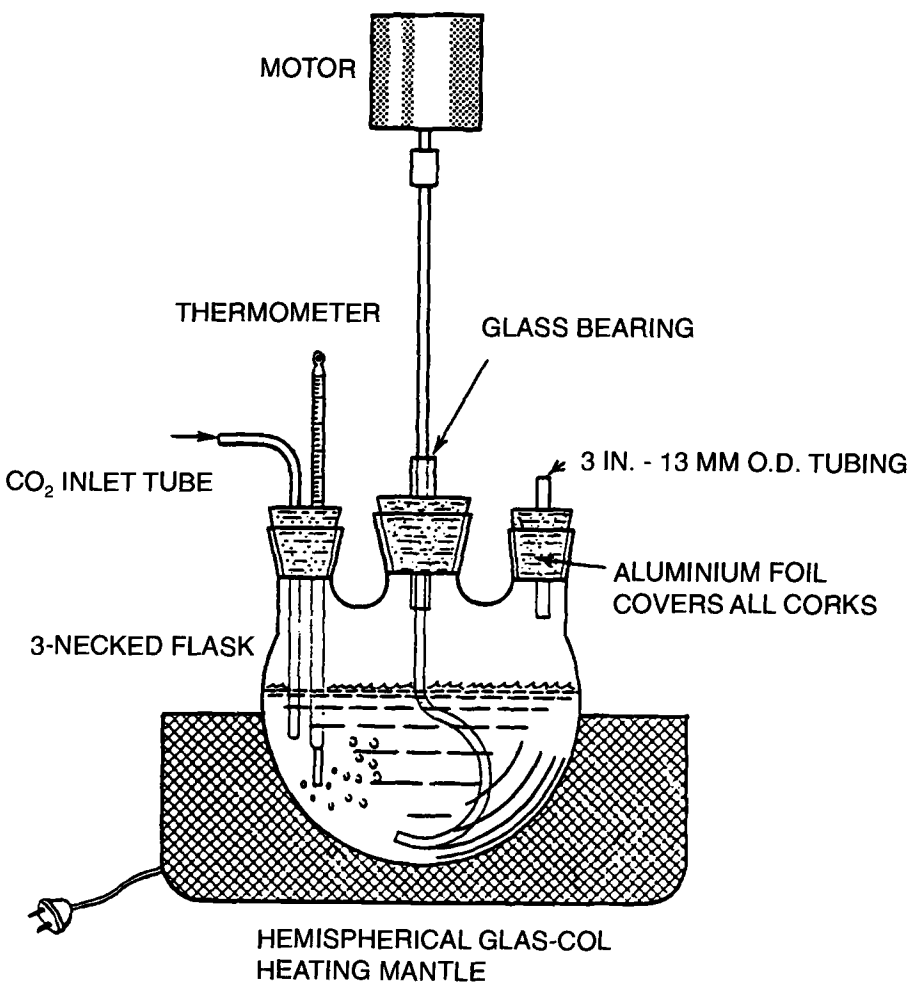

FIG. 1–Apparatus for fusion cooking of alkyds. (Diagram courtesy of ICI Hercules Alkyd Reports.)

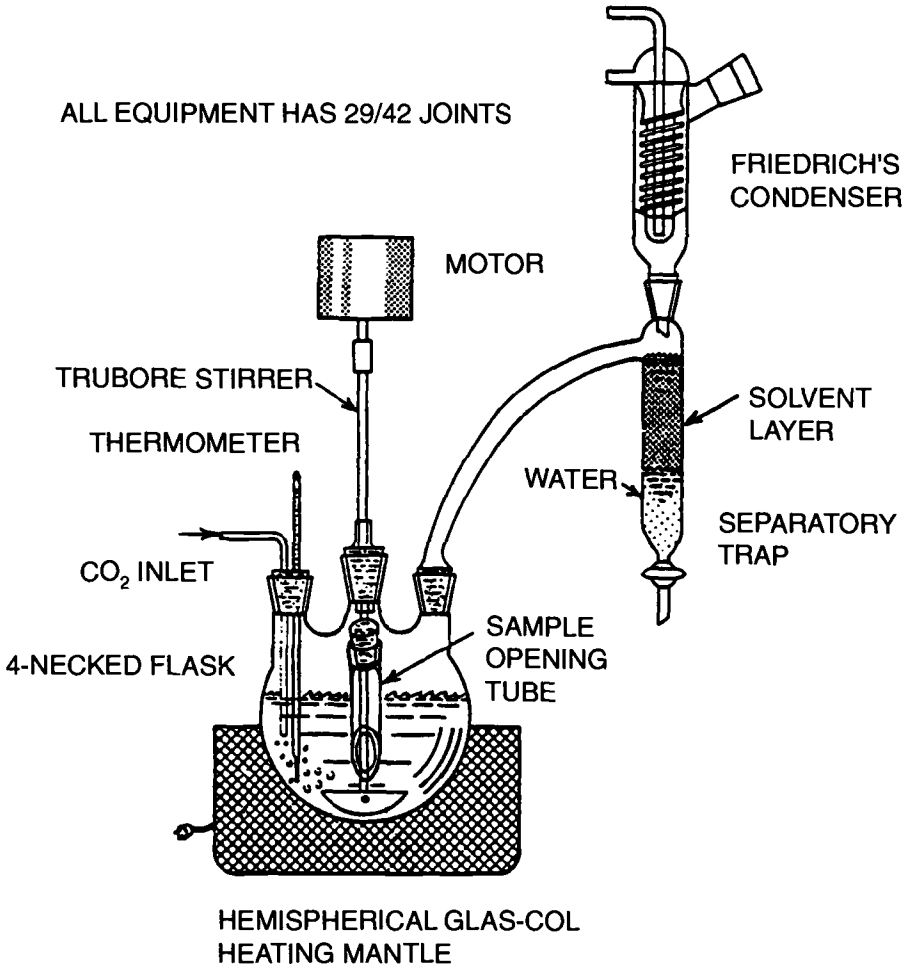

FIG. 2—Laboratory apparatus for solvent cooking of alkyds. (Diagram courtesy of ICI Hercules Alkyd Reports.)

reached. Then the alkyd is thinned with the desired type and amount of organic solvent. Only a small amount, usually less than 3% by typically 1% of the total weight, of the reflux or azeotrope solvent remains in the alkyd. The solvent reflux process advantages are less emission of by-products to the atmosphere and faster processing time. Also, a greater variety of alkyds can be made by this process. The final alkyd solution properties are measured at 25°C. Typical tests include color, acid number, hydroxyl number, hardness, viscosity, and percent nonvolatiles.

RAW MATERIALS (INTERMEDIATES) FOR ALKYD RESINS

Typical polybasic acids, polyhydric alcohols, and monobasic fatty acids or oils are given in Tables 1, 2, and 3. The numerous possible raw materials available and economic considerations of these lead to versatility of alkyds and to a wide range of commercially available products.

PHYSICAL PROPERTIES

The most common physical properties used to identify characteristics of alkyd resins are determined by ASTM methods.

Viscosity

The viscosity of alkyds covers a wide range and must be compared to the nonvolatile content and type organic solvent used, ASTM D 1545: Test Method for Viscosity of Transparent Liquids by Bubble Time Method [*6*]. The bubble tubes and measured times in seconds are easy to run with proper testing equipment and a constant temperature set at 25°C. Viscosity is important in reflecting alkyd molecular weight and the final coating application properties, thickness, and minimizing batch-to-batch variation of each specific alkyd. Relatively high-molecular-weight alkyds need to be reduced to application viscosity with a greater amount of solvent or solvent mixture or with solvents that have a particular solvency for the specific alkyd.

NONVOLATILE CONTENT

The nonvolatile content of alkyd solutions is determined with ASTM D 1259: Test Method for Nonvolatile Content of Resin Solutions. Alkyd specifications are designed to show a 1 or 2% variation from an agreed on nonvolatile by weight requirement. This method is sometimes varied to a higher oven temperature of 150°C and a shorter dwell time in resin processing use.

Alkyd resin solutions vary from 30% nonvolatile (flat wall, medium-oil alkyds) to 100% nonvolatile content by weight (very long oil alkyds for exterior paints, stains, latex modifiers, and similar products).

Color

The color of alkyd solutions is determined by comparison with a range of color standards referred to as the Gardner-Holdt color standards, ASTM D 1544: Test Method for Color of Transparent Liquids (Gardner-Holdt Scale) [*8*]. The color or degree of yellowness of the alkyd solution may or may not have an effect on the color of the final coating films.

Density

The density or specific gravity of alkyds is also referred to as the weight per gallon or density and can be determined by following ASTM D 1475: Test Method for Density of Paint, Varnish, Lacquer, and Related Products [*9*].

Flash Point

The flash point of alkyds is mainly of importance as it pertains to shipping the products and formulated paints, i.e., to bill of lading and other regulations. ASTM D 3278: Test Methods for Flash Point of Liquids by Setaflash-Closed-Cup Apparatus [*10*] is the most common test that will provide conformance with Department of Transportation regulations. However, other ASTM methods are utilized. The method utilized depends on flash cup availability and other specified requirements.

Neat alkyds have low vapor pressure. Therefore, the flash point of an alkyd solution reflects the flash point of the solvent used to dissolve the alkyd. It is recommended that flash points on alkyd solutions actually be measured by laboratory determination. The flash point of an alkyd solution is different from that of the actual solvent or solvents incorporated into the solution.

Drying Properties

The drying properties of alkyds are of importance when describing the product. Metallic driers are based on cobalt, manganese, iron, lead, calcium, and rare earths reacted with synthetic organic acids, such as vegetable fatty acids, to form soaps. When these driers are added to the alkyd-based coating, they act as catalysts and accelerate the rate of air drying and cross-linking. Driers are formulated in combinations or blends to maximize desired dry film surface and interior characteristics. In recent years, synthetic acid-based metallic driers have gained popularity for two main reasons: (1) higher metal concentration in the drier, and (2) greater uniformity of drier performance. Methods associated with determining drying are given in ASTM D 1640: Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature [*11*].

Acid Value

The free organic acid groups present in the nonvolatile portion of an alkyd resin is an important property for pigment wetting and performance properties of organic coatings. The acid value of alkyds is typically determined with ASTM D 1639: Test Method for Acid Value of Organic Coating Materials [*12*]. Reasonably accurate and consistent results can be obtained with this test procedure.

Hydroxyl Value

The hydroxyl value or number is a measurement of the free hydroxyl groups remaining in the alkyd that have not been reacted with carboxyl groups during the condensation stage of the alkyd resin preparation process. Hydroxyl value determinations are more difficult to perform than acid number determinations. There are several reasons for this. First, the hydroxyl group can be sterically hindered or less available within the polymer and thus difficult to reach with the reactants. Second, hydroxyl groups on primary carbon atoms are more reactive than those on secondary carbon atoms, and these are more reactive than those located on a tertiary carbon atom. Tertiary-positioned hydroxyl groups are the most difficult to esterify in this determination. Manufacturers can often specify methods that can be used for secondary hydroxyl groups.

Hydroxyl numbers are important in determining equivalent weight, which in turn is important to determining the amount of urea formaldehyde, melamine formaldehyde, or urethane prepolymer to react with the alkyd. In the case of oil-modified urethanes, also called uralkyds, the hydroxyl groups coreact with free isocyanate functionality. Although theoretical equivalency based on hydroxyl numbers is a good guideline to establishing performance characteristics, a ladder of co-reactant ratios is important to optimizing particular performance characteristics.

ALKYD RESIN CLASSIFICATION

Unmodified alkyds are classified into four types that depend on oil content—very long-oil, long-oil, medium, and short-oil alkyds. Properties such as speed of drying, ease of brushing, film flexibility, chemical resistance, and exterior gloss retention are all dependent on the oil content. These properties are summarized in Table 4.

A summary of alkyd resins comparing types of oil/fatty acids, nonvolatile, solvent, and typical application is given in Table 5.

TABLE 4—Alkyd resin properties related to oil length.

	Very Long Oil	Long Oil	Medium	Short Oil
Oil content	Highest	⟷		Lowest
Speed of drying	Slowest	⟷		Fastest
Ease of brushing	Best	⟷		Worst
Film flexibility	Highest	⟷		Lowest
Chemical resistance	Worst	⟷		Best
Exterior gloss retention	Worst	⟷		Best

HIGHER SOLIDS ALKYD RESINS

Higher solids alkyds have been developed to reduce organic solvent emissions in those applications under regulatory restrictive requirements. This is accomplished by the development of polymers with lower viscosities than so-called conventional alkyds. The design and processing of higher solids alkyds result in a lower average molecular weight than conventional alkyds. A narrower molecular weight range of the resin species is necessary to meet air-dry, nonvolatility, and performance properties of the coatings. Another important factor is solvent selection. Organic solvents with greater viscosity reduction of the base or neat alkyd are needed to lower coating hydrocarbon atmospheric emissions. The release of these solvents during coating film formation is an important consideration.

The higher solids alkyd resins are available in all classes of "conventional alkyds" such as those shown in Table 6.

Higher solids alkyds can replace their conventional solids counterparts in many coating applications, thus affording decreased atmospheric emissions. Such products are used in air-dry architectural enamels and both air-dry and baking industrial primers and topcoats.

WATER-BORNE ALKYD RESINS

Water-borne alkyds obtain their water reducibility by the use of coupling solvents and amine-neutralized carboxyl groups on the polymer. Typical coupling solvents are ethylene glycol monobutyether, propylene glycol monoethylether, propylene glycol monopropylether, and four-carbon alcohols such as s-butyl alcohol. Water-borne alkyds are available in most classes of "conventional alkyds" such as those shown in Table 7.

SATURATED POLYESTERS

Saturated polyesters are also called oil-free alkyds. The oil or fatty acid modification is zero percent, and this factor results in a polymer that cannot be air dried to a cross-linked coating. Rather, these polymers are formulated with a curing agent or cross-linker and baked. The curing agent can be a urea-formaldehyde or a melamine formaldehyde resin, both of which require baking. Polyurethane prepolymers can be coreacted with polyester resins for air-dry or low-bake coatings in two-component systems. In such systems, the saturated polyester provides the hydroxyl groups for cure with free isocyanate groups on the polyurethane prepolymer.

The physical properties of these coatings are outstanding due to the absence of fatty acids, and they afford coatings with excellent color retention, flexibility, exterior durability, and hardness.

The type of resins can be adapted to provide higher solids saturated polyesters by redesigning the polymer and using organic solvents with appropriate solvency rather than the customary blends of aromatic hydrocarbons with ketones, alcohols, and glycolethers.

Water-borne polyesters are available through design of polymers having acid numbers in the range of 40 to 60. When these products are neutralized with an amine, they become

TABLE 5—Description of unmodified alkyd resins.

Type Alkyd	Oil or Fatty Acid	Nonvolatiles	Solvent	Typical Applications
Very long	Linseed Soya Tall oil	85–100%	Aliphatic hydrocarbon	Exterior latex modifier House paint modifier Oil-based stain and ink vehicles and modifiers
Long	Linseed Safflower Soya Sunflower Tall oil acids	60–70%	Aliphatic hydrocarbon	Architectural coatings Maintenance coatings One-coat enamels Exterior enamels Primers Topcoats
Medium	Linseed Safflower Soya Sunflower Tall oil acids Blends	45–50%	Aliphatic hydrocarbon Aromatic hydrocarbon	Farm implements Railway equipment Maintenance
Short	Castor Dehydrated castor Coconut Linseed Soya Tall oil acids Blends	50%	Aromatic hydrocarbon or Rule 66-type solvent blend[a]	Industrial coatings

[a]A typical Rule 66 type solvent is isobutanol, VM&P naphtha, and xylene at 8% maximum volume solids. Rule 66 is a 1966 regulation from California's South Coast District that restricted the amount of aromatic hydrocarbon solvent in a coating formulation. In the 1960s, research indicated that these types of solvents contributed greatly to atmospheric ozone formation. Rule 66 legislation was adopted by many other local and state regulators.

soluble in blends of water and cosolvents and yield systems with low-volatile organic compound content. Formulation of a coating from these products involves the use of water-borne or water-tolerant ureas and melamines. The cured films offer excellent hardness, gloss, and flexibility.

TABLE 6—Higher solids alkyd resin types and end uses.

Type	Typical End Use
Long oil	Architectural enamels
Medium oil	Transportation enamels
Short oil	General industrial air-dry and bake enamels
Benzoic acid terminated	Implement enamels
Phenolic modified	Primers
Silicone modified	Maintenance topcoats
Copolymer	Aerosol enamels

TABLE 7—Waterborne alkyd resin types and end uses.

Type	Typical End Use
Long oil	Stains and enamels (limited package stability)
Medium oil	General industrial air-dry enamels
Short oil	General industrial baking enamels, automotive under the hood parts
Benzoic acid terminated	Implement enamels
Phenolic modified	Primers
Silicone modified	Maintenance topcoats

SILICONE-MODIFIED POLYESTERS

Conventional Types

Silicone modification of polyesters is accomplished by use of a silicone intermediate incorporated through reaction at a 30 and 50% level. The silicone intermediates are of either hydroxy or methoxy functionality, and when they are reacted with the polyester, water or methanol is eliminated. This modification improves the weatherability and/or heat resistance of the alkyd and resulting organic coating. The silicone-modified polyesters are available in both self-curing and baking (melamine formaldehyde resin cross-linked) types. They are used as coil coatings for prefabricated building panels, prefabricated architectural products, metal advertising sign stock, and other applications requiring excellent exterior durability and/or good heat resistance.

Higher Solids Types

Higher solids silicone-modified polyesters are made by lowering the polyester base molecular weight and/or using oxygenated solvents such as ketone and ester types as replacements for aromatic hydrocarbons. This substitution yields increased solvency, lower viscosities, lower solvent amounts, and higher nonvolatile content for the polyester solution. The end uses are similar to conventional solvent-borne silicone polyesters. However, the higher solids, silicone-modified polyester resins do not have the self-cross-link-

ing option available for conventional types and are always combined with a cross-linking agent.

Amino Resins (Reaction Products of Melamine, Urea, etc. with Formaldehyde and Alcohols)

8

by J. Owen Santer[1]

INTRODUCTION

Definition and Description

AMINO, OR AMINOPLAST, RESINS for coatings are the products of the reaction of either urea (Fig. 1) or melamine (Fig. 2) with formaldehyde and an alcohol. Besides urea and melamine, other compounds with similar functionality—such as benzoguanamine, glycoluril, etc.—are also used in specific applications where certain property advantages are required. However, use of these materials is quite limited, and sales of amino resins are dominated by those based on urea and melamine, with U.S. consumption of about 100 million lb (45×10^6 kg) per year.

As prepared, amino resins are usually water-white, viscous materials which may contain added solvent to reduce viscosity for ease of handling. Where a solvent is used, it is most often an alcohol such as *n*-butanol, iso-butanol, or iso-propanol, all of which are excellent solvents for amino resins. Mixed solvents, such as *n*- or iso-butanol with xylene are also used, especially for the higher-molecular-weight resins made with butanol as a co-reactant. Some amino resins are water soluble or water reducible with co-solvent.

Amino resins for coatings are grouped somewhat arbitrarily into two classes: (1) high solids resins, i.e., resin solutions at ≥80% solids (weight/weight), including resins which contain no solvent, and (2) conventional resins, i.e., resin solutions at <80% solids (weight/weight).

History

Historically, the first amino resins used in coatings were the reaction products of urea or melamine with formaldehyde and butanol (either *n*- or iso-). They were substantially polymeric and were formulated at about 50 to 60% solids in butanol/xylene mixtures. They have been commercially available for about 60 years. Parenthetically, it should be noted that resins made by reacting urea or melamine with formaldehyde without subsequent reaction with an alcohol have been available for 70 years or more. These resins are used as molding powders and adhesives and are generally unsuitable for coatings applications.

High-solids coating resins, usually made with higher ratios of reacted formaldehyde than the older, conventional resins, have been available for about 35 years. They are almost always made with methanol or combinations of methanol and butanol, although a small number of high-solids resins are available which are made exclusively with butanol.

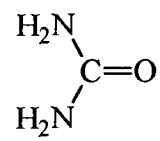

FIG. 1–Urea.

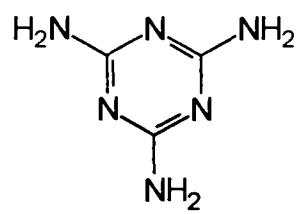

FIG. 2–Melamine.

Where Used

Amino resins are used in coatings to cross-link the primary film-former, usually an acrylic, polyester, or alkyd resin carrying primary or secondary hydroxyl groups. The cross-linking reaction ("cure") is principally one of trans-etherification between hydroxyl groups on the primary film-former and alkoxymethyl groups on the amino resin. In addition to the trans-etherification reaction, the amino resin almost always undergoes self-condensation reactions.

The major by-products of the cure reaction include methanol and/or butanol, formaldehyde, and water. Cure temperatures are in the range of 180 to 400°F (82 to 204°C) for times which vary from 20 to 30 min at the lower end of the temperature range to perhaps only 30 s at the upper end. An acid catalyst may be used to accelerate cure, depending on the cure temperature and the particular amino used. Claims have been made for amino resin formulations which cure at room temperature, but as far as is known, no such formulations are presently commercially available.

Urea resins are less expensive than melamine resins, which is understandable given that melamine is made from urea. Urea resins are also faster curing than melamine resins, but are moisture sensitive and therefore not suitable for use outdoors. They are used widely for wood finishing, e.g., furniture, kitchen cabinets, and in paper, film, and foil applica-

[1]Principal technologist, Monsanto Chemical Co., 730 Worcester Street, Springfield, MA 01151.

Copyright© 1995 by ASTM International

tions. Wood and paper applications capitalize on the relatively rapid cure of the urea resin since lower temperatures must be used to avoid damage to the substrate. In some wood applications, cure temperature is at or near ambient.

Melamine resins, on the other hand, find much broader application since they are not nearly as water sensitive as the ureas. Perhaps the largest single use for melamine resins is in automotive OEM (original equipment manufacture), where the finished paint must stand up to extremes of temperature, humidity, and the degradative effects of sunlight, etc. Melamine resins are used also in coil coatings, metal containers, etc. (see **End Uses of Amino Resins**).

SYNTHESIS OF AMINO RESINS

Reactions of Synthesis

The synthesis of amino resins for coatings is a two-step process. In the first step, the parent compound is reacted with formaldehyde (methylolation reaction); in the second, the methylolated intermediate is reacted with an alcohol (etherification reaction). Equations 1 through 4 exemplify the process, with urea as the parent compound. Reactions with melamine are analogous.

$$H_2NCONH_2 + CH_2O \longrightarrow \underset{\text{monomethylolurea}}{H_2NCONHCH_2OH} \quad (1)$$

$$H_2NCONHCH_2OH + CH_2O \longrightarrow \underset{\text{dimethylolurea}}{HOCH_2NHCONHCH_2OH} \quad (2)$$

$$HOCH_2NHCONHCH_2OH + ROH \longrightarrow HOCH_2NHCONHCH_2OR + H_2O \quad (3)$$

$$HOCH_2NHCONHCH_2OR + ROH \longrightarrow \underset{\text{bis(alkoxymethyl)urea}}{ROCH_2NHCONHCH_2OR} + H_2O \quad (4)$$

Reactions shown in Eqs 1 and 2 proceed quite rapidly when catalyzed by either acid or base. Reactions shown in Eqs 3 and 4 take place only under acid conditions, with the rate of reaction strongly pH dependent; the lower the pH, the faster the reaction. All four reactions are equilibrium reactions. Hence, the extent of the reaction is dependent on the charge ratios of the various reactants and on whether or not the reactions are driven by removal of by-products in order to shift the equilibrium.

The reactions of melamine are similar to those of urea with one exception. With urea, two of the four available hydrogens are readily reacted with formaldehyde (Eqs 1 and 2), while the remaining two hydrogens react more slowly and require an excess of formaldehyde to force the reaction. With melamine, on the other hand, all six hydrogen atoms may be reacted with relative ease to give hexa(methylol)melamine.

The kinetics of the methylolation reactions of urea and melamine have been studied extensively [*1-7*], but there is nothing in the literature on the kinetics of the etherification reaction. Although both of these reactions are superficially straightforward, a number of other reactions may take place which complicate the kinetics. These reactions are all self-condensation reactions in which two or more molecules of the parent species are joined together through either a $>NCH_2N<$ (methylene) or $>NCH_2OCH_2N<$ (methylene ether) bridge. The reactions leading to self-condensation may be written as follows:

$$>NCH_2OR + HN< \longrightarrow >NCH_2N< + ROH \quad (5)$$
$$R = H, \text{alkyl}$$

$$>NCH_2OH + HOCH_2N< \longrightarrow >NCH_2OCH_2N< + H_2O \quad (6)$$

The bridging groups in amino resins manufactured for coatings applications are predominantly methylene ether bridges. When formulated and cured, additional bridges of both types may be formed; how many of each will depend on factors such as the composition of the amino resin, cure temperature, and catalyst level.

It can be seen, then, that a variety of amino resins may be prepared, with properties which depend on such factors as the choice of starting material, i.e., urea, melamine, etc., the combining ratios of the various reactants, the choice of alcohol (or alcohols, if more than one is used), and the degree of polymerization of the resin. The principal manufacturers of amino resins for coatings typically offer a product line of 25 or more resins. A generalized composition of a typical melamine resin is shown in Fig. 3.

Structure/Property Variations

The difference between conventional solids and high-solids amino resins represents not so much a difference in solids content as it does a distinction between resin structures. The conventional solids (<80%) resins are made from melamine or urea reacted with relatively low levels of formaldehyde, typically 1.5 to 2.0 mol for urea resins and 2.5 to 3.5 mol for melamine resins, and etherified with either *n*- or iso-butanol. Because of these low reaction ratios, considerable self-condensation takes place during the synthesis, leading in the case of melamine resins to products with degrees of polymerization (DP) ≥3 and perhaps somewhat higher for the ureas. Because of the relatively high polymer content, these resins are viscous and must be reduced with solvent to less than 80% to obtain a manageable viscosity.

Another, possibly the major, contributor to high viscosity is the residual imino (>NH) and methylol ($>NCH_2OH$) groups on the amino resin, which can form strong hydrogen bonds with unshared electrons on nitrogen and oxygen.

The high-solids amino resins have much higher levels of combined formaldehyde than the conventional solids resins. Typical values for combined formaldehyde are in the range 2.0 to 2.7 for urea resins and 3.5 to 6.0 for melamine resins. The etherifying alcohol is most often methanol, although res-

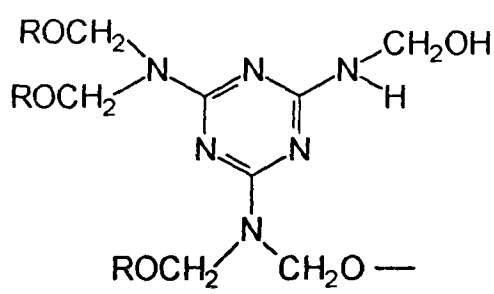

FIG. 3—Representative structure of a melamine resin.

ins made with both methanol and butanol or even butanol alone are also widely used. These resins are less polymeric, with DP <3, and usually more fully etherified and so less polar than the conventional resins. In some cases, these resins are sufficiently low in viscosity that no solvent is needed. Where solvent is required, it is usually either isopropanol or butanol (*n*- or iso-). Resins are also made which can be reduced with water.

Analysis/Analytical Methods

Structural analysis of amino resins has been reviewed by Christensen [*8*]. Methods discussed include ^{1}H NMR and ^{13}C NMR for determining levels of combined formaldehyde and alcohol, analysis of alkoxy groups by Zeisel cleavage, and by trans-etherification followed by gas chromatography. Christensen [*8*] and Kambanis and Rybicky [*9*] also describe nondestructive methods for removing solvent from amino resin solutions in order to determine nonvolatile content.

Classically, amino resins for coatings have been characterized by three test procedures. These procedures, which tell the coating formulator most of what he needs to know with regard to formulation and cure conditions, are measurement of (1) solids content, (2) viscosity, and (3) solvent tolerance. These are discussed below.

Solids Content

The most common methods used to determine solids content are gravimetric. Solvent is allowed to evaporate from a weighed sample under carefully controlled conditions of time and temperature. The sample is then reweighed. The loss in weight gives a measure of solvent content, and the solids content is obtained by difference. One difficulty with this test is the tendency of amino resins to deformylate and/or self-condense when heated, with evolution of formaldehyde, alcohol, and water. To the extent that this occurs, the measured solids content will be lower than the "true" value. Frequently, however, the paint formulator is interested in the "contributed solids," i.e., what fraction of the amino resin solution remains in the cured film. In that case, a solids test method which approximates the time and temperature of cure might be more appropriate.

For these reasons, solids test methods fall into two groups: (1) methods which reflect the solids content in the absence of self-condensation, etc., and (2) other methods, which reflect varying degrees of self-condensation in addition to loss of formaldehyde and solvent(s).

The most common of the first methods is the so-called foil solids test, which is used almost universally for high-solids amino resins. Essentially, a 1-g sample of resin solution is weighed onto a piece of preweighed aluminum foil. The foil is folded over on itself and the sample compressed between the two foil surfaces to provide a thin film about 3 to 4 in. (7 to 10 cm) in diameter. The foil is then opened up to give a thin film on each foil surface. The foil is placed in a 45°C oven for 45 min, at the end of which time it is removed, reweighed, and the solids content calculated. These conditions are known to be sufficiently mild that no resin condensation occurs; nor does the resin lose formaldehyde via demethylolation. Surprisingly, the foil solids test may on occasion overestimate the solids content, particularly when (1) the resin is relatively polar, i.e., carries appreciable >NH and $>NCH_2OH$ groups, and (2) the solvent is not low boiling. Apparently, the increase in viscosity as solvent evaporates slows the diffusion rate and effectively prevents complete removal of solvent within the time frame of the test. There may also be a hydrogen-bonding effect between solvent and resin which contributes to the retention of solvent.

Other test methods involve much higher temperatures, where resin condensation/degradation does occur. One standard method is the ASTM Test Methods for Volatile Content of Coatings (ASTM D 2369), where a small resin sample (0.3 to 0.5 g) is diluted with xylene and placed in a 110°C oven for 1 h. There are a number of other, similar tests.

Viscosity Measurement

Amino resin viscosities are most commonly measured by the Gardner bubble viscometer method. This method is similar to the Test Method for Viscosity of Transparent Liquids by Bubble Time Method (ASTM D 1545). A tube containing the resin under test is placed in a rack containing reference tubes of known viscosity. The tubes are equilibrated to 25°C in a constant temperature bath. The rack is quickly inverted, and the rate of rise of an air bubble in the sample tube is compared against similar bubbles in the reference tubes. The reference tubes are letter graded A through Z and Z1 through Z6.

Solvent Tolerance

There are a number of different solvent tolerance tests. All involve titrating a weighed sample of the amino resin with a standard reagent (solvent). The object of the test is to measure how much of the reagent the amino resin can accept before the solution turns cloudy/milky. Results are typically reported in milliliters of reagent per gram of sample. Typical reagents used include xylene, iso-octane, and the iso-octane/decahydronaphthalene/toluene mixture described in ASTM Test Method for Solvent Tolerance of Amine Resins (D 1198).

While the immediate objective of the solvent tolerance test is to determine the amount of reagent which the amino resin can accept before solution clouding occurs, the real purpose of the test is to gain insight into the structure and composition of the resin and hence have a better understanding of how it will perform in a given coating application. In general, amino resins of high molecular weight, or having high levels of polar functional groups, i.e., >NH, $>NCH_2OH$, will have limited compatibility with the typical hydrocarbons used and hence will give low tolerance test results. Experience shows that a low tolerance value means a faster curing resin and vice versa, especially in the absence of acid catalyst. However, although the tolerance test represents a quick and easy way to measure potential cure response, it does not uniquely define the resin structure. Thus, a low tolerance reading can be caused by either high polarity or high molecular weight or both.

Size Exclusion and High-Performance Liquid Chromatography

To obtain more detailed knowledge of resin structure, amino chemists now rely very heavily on gel permeation or size exclusion chromatography (SEC) and on high-performance liquid chromatography (HPLC). The size exclusion

chromatograph provides an excellent measure of number and weight-average molecular weight and molecular weight distribution (polydispersity), while HPLC, which fractionates the resin components primarily by functional groups, provides information on resin composition. The more polar species are eluted first, followed by the less polar fractions. Thus, taken together, SEC and HPLC provide detailed information on molecular weight and functionality which cannot be directly obtained or inferred from any of the various solvent tolerance tests. Size exclusion and liquid chromatograms for a representative commercial high-solids methylated melamine resin are shown in Figs. 4 and 5.

Combining Ratios

Amino resins may also be characterized by measurement of the amounts of formaldehyde and alcohol which have reacted. For example, see hexa(methoxymethyl)melamine (HMMM) (Fig. 6), which has exactly 6 mol each of combined formaldehyde and methanol per mole of melamine. Unlike HMMM, most resins are, of course, mixtures of products which are best described by an average composition. One of the most widely sold commercial high-solids methylated melamine resins has an average combining ratio melamine/formaldehyde/methanol of about 1/5.6/5.1. Because methanol reacts with an already-reacted formaldehyde molecule, a resin can never have combined methanol greater than the combined formaldehyde. The excess formaldehyde, 0.5 mol in the commercial example, represents formaldehyde which has not reacted with methanol and which must therefore be present as methylol ($>NCH_2OH$), bridging groups ($>NCH_2OCH_2N<$), and acetals ($>NCH_2OCH_2OCH_3$). Acetals are formed when an excess of formaldehyde is used in the

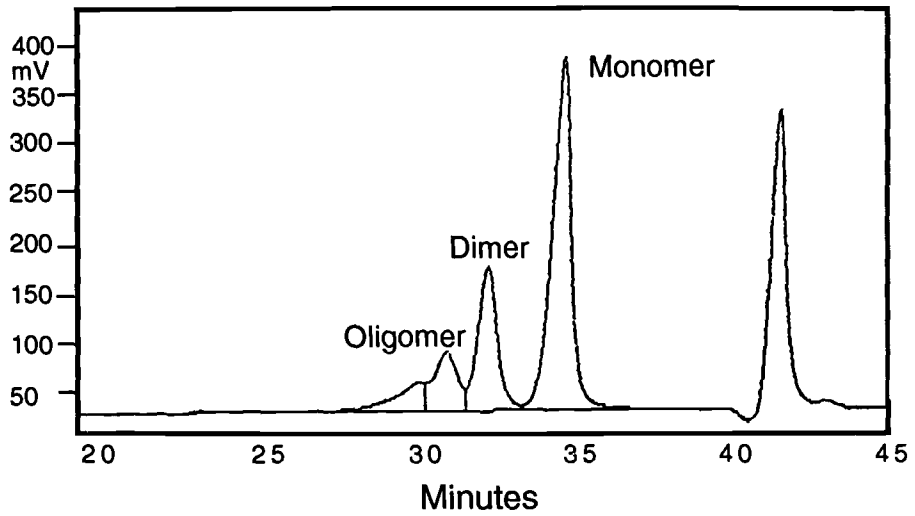

FIG. 4–Size exclusion chromatogram of a typical high-solids methylated melamine resin.

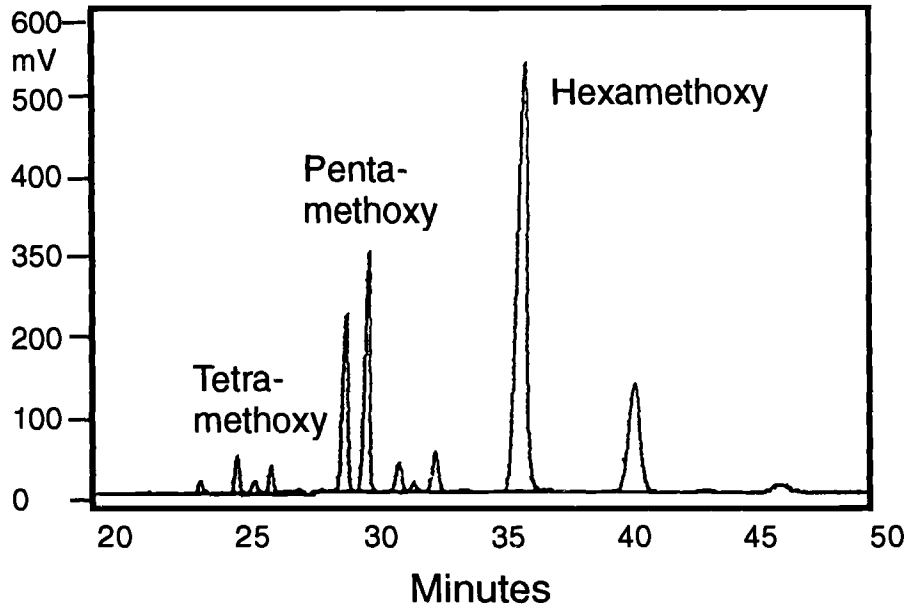

FIG. 5–High-performance liquid chromatogram of a typical high-solids methylated melamine resin.

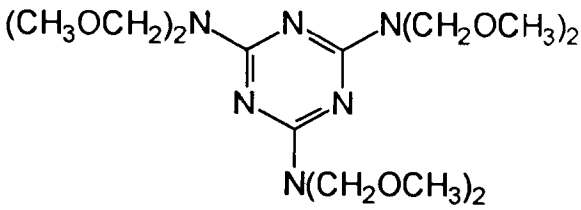

FIG. 6–Hexa(methoxymethyl)melamine.

synthesis. They are therefore present in many high-solids amino resins.

Determination of combining ratios may be done most easily by either ^{1}H or ^{13}C NMR techniques [8]. Older methods involve complete hydrolysis of the resin to the starting materials, followed by wet-chemical analysis for formaldehyde and gas chromatographic determination of alcohol (methanol or butanol).

Free Formaldehyde

Amino resins always contain some unreacted formaldehyde, usually referred to in product specifications as "free" formaldehyde. Free formaldehyde may be analyzed quantitatively by a number of methods. One of the most commonly used is the sodium sulfite method [10]. Formaldehyde reacts rapidly and completely with aqueous sodium sulfite to form a bisulfite addition complex. Sodium hydroxide is liberated quantitatively on a mole-for-mole basis

$$CH_2O + Na_2SO_3 + H_2O \longrightarrow NaOH + CH_2(OH)NaSO_3 \quad (7)$$

The NaOH is either titrated directly with a standard HCl solution, or neutralized with a known excess of standard HCl, which is then back-titrated with NaOH. Care must be taken to ensure that reacted formaldehyde, particularly methylol groups, is not analyzed as free formaldehyde. This can occur because of the following reaction, which can be minimized by performing the titration as rapidly as possible at cool temperatures, e.g., room temperature or lower.

$$>NCH_2OH \longrightarrow >NH + CH_2O \quad (8)$$

PHYSICAL PROPERTIES

General

Amino resins are typically viscous liquids, with an amine-like odor. Depending on composition, they may also smell of formaldehyde and/or solvent. They are readily soluble in alcohols, ketones, hydroxy-functional glycol ethers, esters, etc., but have limited solubility in hydrocarbons. Some resins, especially methylol-rich resins with low levels of both combined formaldehyde and combined methanol, are water soluble. Many more are water reducible in the presence of other solvents, e.g., alcohols and glycol ethers.

Because of their resinous nature, aminos have neither a well-defined freezing point nor boiling point. Uncured resins typically have glass transition temperatures around −40°C. When heated, they undergo decomposition, with release of formaldehyde and alcohol, at temperatures above about 140°C. This tendency to decompose causes difficulties in determining the solids content of resin solutions, as described in **Analysis/Analytical Methods**. The problem is particularly acute with resins having high methylol functionality.

Viscosity

The viscosity of an amino resin is a function of (1) polymer content (degree of polymerization) and (2) the nature of its functional groups. The latter may be a more important contributor to viscosity than the former.

Amino resins are not generally very polymeric, especially in comparison with other coating resins, e.g., polyesters, alkyds, and acrylics. Typically, average degrees of polymerization are in the range of 1 to 5. High-molecular-weight "tails" increase viscosity significantly.

Because of strong hydrogen bonding, resins carrying significant amounts of $>NH$ and $>NCH_2OH$ functionality are quite viscous, even though they may not be highly polymerized. There is a marked drop in viscosity when amino resins are diluted with solvent, largely due to breaking of hydrogen bonds. Good solvents (e.g., alcohols) are more effective at reducing viscosity than poor ones [11]. Methanol is probably the best, although it is not widely used because of its low boiling point. Isopropanol is almost as effective, and because it is somewhat higher boiling, represents a good compromise.

Surface Tension

The surface tension of amino resins is quite strongly related to the nature of the etherifying alcohol and is much less affected by the level of combined formaldehyde and alcohol. In the author's laboratory, surface tension measurements on high-solids, solvent-free resins using a DeNouy tensiometer have given values ranging from about 45 dynes/cm for methylated resins to about 28 dynes/cm for butylated resins. Mixed methyl/butyl resins give intermediate values, depending on the methyl and butyl content. The reduction in surface tension when butanol is the etherifying alcohol may be one reason that high-solids butyl and methyl/butyl resins provide improved flow and leveling in high-solids formulations compared to their fully methylated counterparts.

REACTIONS OF AMINOS IN COATINGS

Cure Reactions

Amino resins in coating formulations cure by reactions which are chemically and mechanistically similar to those which take place during synthesis of the resin. The principal reaction of cure is one of trans-etherification, wherein a hydroxyl group on the primary film-former (acrylic, polyester, or alkyd) reacts with an alkoxymethyl group on the amino resin

$$>NCH_2OR + HO{-}A \longrightarrow >NCH_2O{-}A + ROH \quad (9)$$

where

R = alkyl, and
A = primary film-former.

Additionally, direct etherification may take place, the end result being the same

$$>NCH_2OH + HO—A \longrightarrow >NCH_2O—A + H_2O \quad (10)$$

where

A = primary film-former.

These two reactions both result in chemical bond formation between the amino and the primary film-former (co-condensation). Two other reactions may also take place, both of which involve reaction of the amino resin with itself (self-condensation). These are

$$>NH + ROCH_2N< \longrightarrow >NCH_2N< + ROH \quad (11)$$

where

R = H, alkyl.

$$>NCH_2OH + HOCH_2N< \longrightarrow >NCH_2OCH_2N< + H_2O \quad (12)$$

Besides the co-condensation and self-condensation reactions, hydrolysis and deformylation reactions may also occur

$$>NCH_2OR + H_2O \longrightarrow >NCH_2OH + ROH \quad (13)$$

$$>NCH_2OCH_2OR + H_2O \longrightarrow >NCH_2OH + CH_2O + ROH \quad (14)$$

$$>NCH_2OH \longrightarrow >NH + CH_2O \quad (15)$$

The relative contributions to cure of the co-condensation and self-condensation reactions will depend on a variety of factors. These include:

1. The functionality of the amino resin, i.e., the relative proportions of $>NCH_2OR$, $>NCH_2OH$, and $>NH$ groups present initially, as well as those generated during formulation and/or cure.
2. The functionality (hydroxyl number) of the primary film-former (coreactant).
3. The amino/coreactant ratio.
4. The level and type of catalyst (weak acid/strong acid).
5. Cure time and temperature.

A coreactant resin with a low hydroxyl number is best if formulated with a "polar" amino (i.e., one rich in $>NH$ and/or $>NCH_2OH$) since these groups help build molecular weight during cure via self-condensation, particularly if little or no catalyst is present. Conversely, a high hydroxyl resin is best if matched with an alkoxymethyl-rich amino and cured with a strong acid catalyst. Where high cure temperatures are employed (e.g., can or coil coating operations), the choice of amino resin is less obvious, and, in practice, both polar and nonpolar aminos are used.

Acid catalysts are usually used as an aid in curing amino-based formulations. These catalysts include very strong acids such as *p*-toluenesulfonic acid (PTSA), dodecylbenzenesulfonic acid (DDBSA), dinonylnaphthalenedisulfonic acid (DNNDSA), etc., and weaker acids such as phenyl acid phosphate (PAP), butyl acid phosphate (BAP), etc. Amine blocking agents are sometimes used to help minimize resin advancement prior to cure. Some coatings, particularly those designed for high-bake temperatures, need no catalyst, relying instead on the combination of high temperature and perhaps carboxylic acid functionality on the primary film-former to bring about cure [*12*]. While all of the various reactions which take place during cure are accelerated by either acid or heat, it is fair to say that reactions of transetherification are most influenced by catalyst level and type, while reactions of self-condensation are most influenced by heat. The trans-etherification reaction takes place very rapidly under strong acid catalysis, even at low temperatures. This is especially true for aminos with a high level of alkoxymethyl substitution, i.e., a very low NH content, which tends to inhibit catalysis. Thus, most formulations involving resins with high alkoxymethyl ether content and designed for low-temperature cure (250°F or lower) will call for a sulfonic acid catalyst, either blocked or free.

Although the individual reactions of cure are reasonably well understood and have been described in numerous papers [*13-18*], there is still much to be learned about the overall behavior of amino resins during cure, in particular the relative contributions of each of the various reactions. One of the difficulties is, of course, that the coating becomes intractable as cure progresses. Hence, a majority of studies involve analysis of the by-products of cure [*13,17,30*]. Other methods, such as dynamic mechanical analysis [*19*], nuclear magnetic resonance [*20,21*], FTIR [*17*], ESCA, etc. investigate the structure of the cured film.

These techniques are useful not only for analyzing the freshly cured coating, but also as a means of following the coating through its lifetime, either natural or accelerated.

Degradation and Weathering

Amino-based cross-linked coatings exposed to the atmosphere are subject to both hydrolysis and UV-degradation.

The mechanisms by which melamine resins hydrolyze have been described in detail by Berge [*22–24*], who was the first to distinguish between mono- and di-substituted nitrogen with respect to their behavior towards acid or base hydrolysis. Thus, in an alkaline medium, hydrolysis of an alkoxymethyl group on a singly substituted nitrogen is initiated by removal by the base of the proton attached to nitrogen

$$—NHCH_2OR + B \longrightarrow —\tilde{N}CH_2OR + BH^+ \quad (16)$$

$$—\tilde{N}CH_2OR \longrightarrow —N = CH_2 + OR^- \quad (17)$$

$$—N = CH_2 + H_2O \longrightarrow —NHCH_2OH \quad (18)$$

$$OR^- + BH^+ \longrightarrow ROH + B \quad (19)$$

This mechanism is clearly not applicable to di-substituted nitrogen ($N(CH_2OR)_2$), and these groups are in fact extremely resistant to alkaline hydrolysis.

On the other hand, acid hydrolysis takes place readily for both mono- and di-substituted nitrogen. Berge proposed two mechanisms (a) specific acid catalysis

$$>NCH_2—OR + H^+ \longrightarrow >NCH_2OHR^+ \quad (20)$$

$$>NCH_2OHR^+ \longrightarrow >NCH_2^+ + ROH \quad (21)$$

$$>NCH_2^+ + H_2O \longrightarrow >NCH_2OH + H^+ \quad (22)$$

and (b) general acid catalysis

$$>NHCH_2OR + HA \longrightarrow >NCH_2OHR^+ + A^- \quad (23)$$

$$>NHCH_2OHR^+ + A^- \longrightarrow >N = CH_2 + ROH + HA \quad (24)$$

$$—N = CH_2 + H_2O \longrightarrow —NHCH_2OH \quad (25)$$

Berge's work with melamine resins is undoubtedly relevant to acid hydrolysis of paint films, which has been studied by a number of workers.

English et al. [*25,26*] found that coatings prepared from highly alkylated melamines underwent extensive hydrolysis of residual methoxy groups during two years exposure in Florida, but there was no evidence of hydrolysis of bonds between melamine and the primary film-former. Bauer [*27–28*] used IR to analyze acrylic-melamine coatings exposed to both UV and moisture and found evidence of hydrolysis of both residual methoxy groups and acrylic-melamine bonds, with the rate of hydrolysis being faster in the presence of UV light. The rate of hydrolysis was slowed considerably when a hindered amine light stabilizer was used.

In recent years, degradation of melamine-containing automotive coatings has been particularly severe because of etching and spotting due to "acid rain." The problem is compounded because modern high-solids automotive coatings use very high levels of melamine resins (35 to 45% of total binder weight), giving rise to correspondingly high levels of acrylic-melamine bonds and residual alkoxymethyl groups in the cured film, all of which are susceptible to hydrolysis under acid conditions. Suppliers of high-solids coatings for automobiles are presently evaluating and using alternative cross-linkers, such as isocyanates and epoxies, which are more stable under acid rain conditions and which can serve as either a partial or complete replacement for melamines. An interesting aspect of the acid etch problem is that the damage always occurs to relatively new coatings. If a newly painted automobile is protected from the acid environment for the first six to twelve weeks, damage thereafter is much less severe. An obvious conclusion is that the paint is undergoing additional cure (probably melamine self-condensation) as it ages.

Automotive paint manufacturers are also actively pursuing waterborne systems, which use higher molecular weight, less functional coreactant resins, and lower levels of melamine cross-linker and which are therefore less severely degraded by acid rain. At the present time, however, these waterborne systems are only used in the base coat, where acid attack is in any case minimized by the protective clear top coat. It is the top coat, with its high melamine content, which is the principal site for acid attack. But it is also the high level of melamine resin which provides the excellent gloss and "distinctness of image" (DOI), characteristic of basecoat/clearcoat technology. The melamine resin also minimizes the amount of solvent required because of its low viscosity at high-formulated solids, behaving in some ways as a reactive diluent and plasticizer.

End Uses of Amino Resins

Amino-based surface coatings protect and decorate the substrate to which they are applied. Their technology and use has developed over many years. As already mentioned, resins based on urea and melamine dominate the field. Urea resins are traditionally used in clear coatings for wood, e.g., furniture, kitchen cabinets, in paper, film, and foil applications, and in some appliance and general industrial coatings. They are also used to some extent in automotive primers. They cannot be used in automotive topcoats because of their sensitivity to hydrolysis.

Melamine resins are much more widely used. They give better chemical resistance, as well as resistance to weathering in exterior applications, despite some of the recent difficulties described earlier in connection with water spotting and acid etch of automobiles. Besides automobiles, they are used in appliance formulations (both coil appliance and conventional post-sprayed), general metal applications, container coatings (beer and beverage cans), etc.

In choosing an amino resin for a particular application, consideration must be given not only to interior versus exterior use, but also to possible restrictions on cure conditions and compatibility of the amino resin with its co-reactant resin, both when formulated and as the paint film is formed during solvent flash-off and cure, etc. Compatibility of the amino is especially important in water-borne coatings, which are becoming more widely used. Another factor is the stability of the amino towards advancement (molecular weight buildup) during storage of the formulated paint.

Benzoguanamine-based (Fig. 7) amino resins are used where film flexibility and hardness are required, as in some appliance applications (e.g., refrigerator doors made from coil stock, etc.). They also have good corrosion and humidity and detergent resistance. Their use is limited by cost and poor exterior durability due to the pendant phenyl group on the benzoguanamine molecule.

Glycoluril (Fig. 8) resins have been available for about a dozen years. They may require a higher cure temperature or a higher catalyst level than melamine-based resins, but show excellent corrosion and humidity resistance and release lower amounts of formaldehyde during cure [*29*].

ENVIRONMENTAL/TOXICITY

The past 20 years have seen increased emphasis on the quality of the environment both in the workplace and beyond. In the coatings industry, this has meant strict controls on exposure of workers to hazardous ingredients in the coating formulation when applied, as well as on the nature and

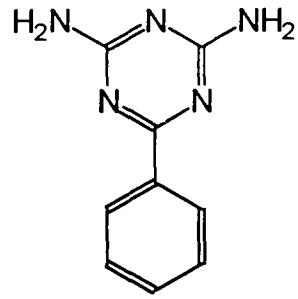

FIG. 7–Benzoguanamine.

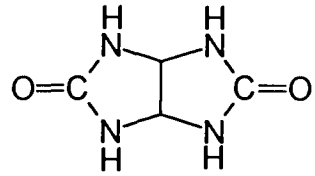

FIG. 8–Glycoluril.

amounts of volatile organics (the so-called VOCs) released to the environment when the formulation is cured.

Amino resin suppliers have responded to these environmental challenges in a number of ways. Chief among these has been a progressive shift towards higher-solids, lower-molecular-weight aminos, which are now the resins of choice of coatings formulators. Many amino resins are supplied at 100% nonvolatiles, especially for the automotive industry. Where solvents are needed, those presenting the least hazard to worker and environment are selected. For their part, paint producers have increased the functionality of the coreactant resin while lowering its molecular weight to minimize solvent use with the object of building molecular weight to the maximum possible extent during cure. This has meant using higher levels of amino resin, as much as 40 to 50% of total binder weight in some cases.

Perhaps the most intractable environmental problem with amino resins is the use of formaldehyde in their manufacture. Formaldehyde is recognized by the International Agency for Research on Cancer (IARC) as a carcinogen. The American Conference of Governmental Industrial Hygienists (ACGIH) lists formaldehyde as an "A2" substance, i.e., one suspected of carcinogenic potential for man, and the Occupational Safety and Health Administration (OSHA) has set workplace exposure limits of 0.75 ppm (8-h time weighted average) and 2 ppm (15-min short-term exposure limit).

The formaldehyde content of amino resins is predominantly "combined," i.e., chemically reacted, and represents about 30 to 50% by weight of the resin. A small amount, ranging from about 0.1 to about 3% is present free, or unreacted (see the section entitled **Analysis/Analytical Methods**). Amino resin suppliers have made considerable progress over the past several years in lowering the level of free formaldehyde in their products, which is important because of OSHA labelling requirements.

In an ideal situation, all of the combined formaldehyde would remain in the coating after cure as part of the polymer network. In practice, however, some of the combined formaldehyde and all of the free formaldehyde is released during cure and may reach the environment, depending on the mechanics of the coating and curing operation. It is the partial release of combined formaldehyde during cure which is of most concern, since the amount released can easily be several times that of the free formaldehyde. Incineration of off gases, where possible, is the best solution.

Ceramic Coatings

by Richard A. Eppler[1]

CERAMIC COATINGS ARE AN ALTERNATIVE to organic paints for surface coating applications. When painting with a suitable material will meet all service requirements, it is almost always less expensive to paint. However, organic paints have limitations in several areas where ceramic coatings are a more suitable selection.

Vitreous (glassy) ceramic coatings are chosen for application over a substrate for one or more of several reasons [*1*]. These coatings may be applied to a substrate surface in preference to an organic paint to render the surface chemically more inert, impervious to liquids and gases, more readily cleanable, and more resistant to service temperature, abrasion, and scratching.

The chemical durability of ceramic coatings in service substantially exceeds that of organic paints [*2*]. Vitreous coatings are formulated to be resistant to a variety of reagents, from acids to hot water to alkalies, as well as to essentially all organic media. The only important exception is hydrofluoric acid, which readily attacks all silicate glasses. This outstanding durability, combined with a very smooth surface, renders many ceramic coatings suitable for applications requiring the highest standards of cleanability such as ware that comes in contact with food and drink. These coatings are also suitable for applications requiring true hermeticity, usually to protect sensitive electronic equipment. No organic resins are truly hermetic.

Even the most thermally stable organic resins depolymerize at temperatures on the order of 300°C. Hence, organic paints are not suitable for applications requiring thermal stability above 300°C. For example, stove side panels are painted, but stove tops are porcelain enameled. A similar argument can be made for abrasion resistance. Organic resins are soft (Moh 2 to 3). By contrast, vitreous coatings are harder (Moh 5 to 6), and some plasma coatings are much harder. For example, alumina coatings, plasma sprayed, have Moh = 9.

Vitreous coatings are thin layers of glass fused onto the surface of the substrate. When the substrate is a ceramic, the coating is called a glaze. When the substrate is a metal, the coating is called a porcelain enamel. When the substrate is a glass, the coating is called a glass enamel.

[1]Consultant, Eppler Associates, 400 Cedar Lane, Cheshire, CT 06410.

GLAZES

A ceramic glaze is a vitreous coating applied to a ceramic substrate, usually a whiteware. Glazes are applied to their substrates by one of several powder-processing techniques: dipping, spraying, and waterfall. The raw materials are both crystalline oxides and frits. In these wet processes the raw materials are dispersed in an aqueous slip for application. After application, the coatings must be dried and fired at high temperatures (up to 1300°C, typically 1000 to 1100°C) to fuse them onto the substrate.

Applications for Glazes

Ceramic glazes find their way into a wide range of applications ranging from coffee mugs to automotive spark plugs. The major markets for ceramic coatings have different requirements, but one common theme is chemical durability and cleanability.

The major products that normally use glazes are distributed as follows:

43.9%	Sanitaryware
32.9%	Wall and floor tile
10.9%	Tableware
9.5%	Artware
2.8%	Electrical porcelain and electronics

The total market for these products in the United States was reported to be $3459 billion for 1989 [*3*], of which the glaze typically consumed 10 to 15% of the total manufacturing cost. Hence, the value of the protective, functional, and decorative properties provided by the coating usually far outweighs the cost.

Leadless Glazes

Glazes are essentially mixtures of silica with other oxides added to permit the glaze to form at a readily achievable temperature. In a leadless glaze, the alkali and alkaline earth oxides, together with magnesia (MgO), zinc oxide (ZnO), and boron oxide (B_2O_3), are used to provide the fluxing action. Table 1 gives the formulas of a few typical ceramic glazes. Glaze 1 is a feldspathic glaze suitable for use on soft paste porcelains or hard stoneware [*4*]. This glaze is typical of that used on medieval Chinese porcelains.

Glaze 2 is a sanitary-ware glaze [*5*]. It is derived from the soft paste porcelain glaze by the addition of ZnO in large quantity. Increasing the melting rate by increasing the per-

cent of fluxes yields a fast-fire, wall-tile glaze such as Glaze 3 [*6*]. To produce a glaze for dinnerware, the coefficient of thermal expansion must be reduced to match that of the ware. Glaze 4 is an example of a glaze for vitreous hotel china [*7*].

Lead-Containing Glazes

Litharge (PbO) is used in glazes for several reasons [*8*], the most important of which is the strong fluxing action of PbO, which allows the formulation of glazes that mature at temperatures lower than their leadless counterparts, leading to greater flexibility in the formulation of the glaze to obtain desired properties. Glazes for electronic substrates, artware, and some dinnerware, and tiles contain lead oxide. However, PbO is highly toxic. Therefore, use of lead-containing glazes requires special care in processing and in testing the ware produced.

Glaze 5 in Table 1 is an example of a lead-containing dinnerware glaze [*9*]. Glaze 6 is an example of a clear glaze suitable for use on artware and hobbyware bodies [*10*]. Glaze 7 is an example of a coating used on integrated circuit packages to seal them [*11*].

Satin and Matte Glazes

Satin and matte effects are due to dispersed oxide crystals of appropriate refractive index in the glaze [*5*]. Calcium aluminosilicate and zinc silicate crystals are commonly used. The crystals must be very small and evenly dispersed if the glaze is to have a smooth, velvet appearance. Glaze 8 in Table 1 is an example of a matte glaze.

Testing of Glazes

ASTM Committee C-21 on Ceramic Whitewares and Related Products has developed several test methods to evaluate the physical properties of ceramic glazes. These are listed in Table 2 [*12*]. These tests form the basis for most quality control testing programs.

There are several methods concerned with the fit of the glaze to the substrate. These include: C 554—Test Method for Crazing Resistance of Fired Glazed Ceramic Whitewares by a Thermal Shock Method; C 424—Test Method for Crazing Resistance of Fired Glazed Whitewares by Autoclave Treatment; C 539—Test Method for Linear Thermal Expansion of Porcelain Enamel and Glaze Frits and Ceramic Whiteware Materials by the Interferometric Method; and C 372—Test Method for Linear Thermal Expansion of Porcelain Enamel and Glaze Frits and Fired Ceramic Whiteware Products by the Dilatometer Method.

TABLE 2—Test methods for ceramic glazes [*12*].

Number	Title
C 1027	Test Method for Determining Visible Abrasion Resistance of Glazed Ceramic Tile
C 650	Test Method for Resistance of Ceramic Tile to Chemical Substance
C 609	Test Method for Measurement of Small Color Differences Between Ceramic Wall or Floor Tile
C 554	Test Method for Crazing Resistance of Fired Glazed Ceramic Whitewares by a Thermal Shock Method
C 424	Test Method for Crazing Resistance of Fired Glazed Whitewares by Autoclave Treatment
C 556	Test Method for Resistance of Overglaze Decorations to Attack by Detergents
C 539	Test Method for Linear Thermal Expansion of Porcelain Enamel and Glaze Frits and Ceramic Whiteware Materials by the Interferometric Method
C 372	Test Method for Linear Thermal Expansion of Porcelain Enamel and Glaze Frits and Fired Ceramic Whiteware Products by the Dilatometer Method
C 584	Test Method for 60-deg Specular Gloss of Glazed Ceramic Whitewares and Related Products
C 1034	Test Method for Lead and Cadmium Extracted from Glazed Ceramic Cookware
C 738	Test Method for Lead and Cadmium Extracted from Glazed Ceramic Surfaces
C 895	Test Method for Lead and Cadmium Extracted from Glazed Ceramic Tile

Several other ASTM methods are concerned with chemical durability. These include: C 650—Test Method for Resistance of Ceramic Tile to Chemical Substances; and C 556—Test Method for Resistance of Overglaze Decorations to Attack by Detergents. Of particular concern are ASTM methods used to control release of lead and cadmium from glazed surfaces. These include: C 1034—Test Method for Lead and Cadmium Extracted from Glazed Ceramic Cookware; C 738—Test Method for Lead and Cadmium Extracted from Glazed Ceramic Surfaces; and C 895—Test Method for Lead and Cadmium Extracted from Glazed Ceramic Tile; as well as C 1035—Specification for Lead and Cadmium Extracted from Glazed Ceramic Cookware.

PORCELAIN ENAMELS

Porcelain enamel coatings are ceramic coatings designed for application to metals. Conventional porcelain enamel coatings are prepared in an aqueous system and applied to the substrate by spray, dip, or flow coating. The coating is

dried before firing. Newer technology involves dry application of powdered porcelain enamel by electrostatic spray.

The total market for porcelain-enameled products was reported to be $5486 billion in 1989 [*13*]. About 86% of the products are appliances, such as ranges, water heaters, home laundry, and dishwashers. About 6% are cast-iron sanitary ware, and 8% are architectural, cookware, and miscellaneous items.

A porcelain enamel must be formulated such that it will bond to the metal substrate. For proper adherance of the enamel to the metal, it is necessary to develop a continuous electronic structure across the interface [*14*]. This structure is developed by saturating the enamel coating and the substrate metal with an oxide of the metal [*15*], which for iron and steel substrates is ferrous oxide (FeO).

Certain transition metal oxides, such as cobalt oxide (CoO), nickel oxide (NiO), and cupric oxide (CuO), can be added to an enamel formulation to improve the adherence between the metal and the substrate. Ground coat enamels contain adherance oxides, while cover coat enamels do not.

Ground Coat Enamels

A general-purpose ground coat enamel like Enamel 1 in Table 3 is an alkali borosilicate containing small amounts of adherance oxides to promote the bonding process. Enamel 2 is a home laundry enamel that has been formulated for outstanding alkali resistance through the addition of large quantities of zirconia (ZrO_2) [*16*]. Hot water tank coatings like Enamel 3 have very stringent thermal- and corrosion-resistance requirements.

Enamel 4 is a continuous clean coating. This is a porous coating which provides a means of volatilizing and removing food soils from the internal surfaces of ovens during normal operation [*17*].

Cover Coat Enamels

Cover coat porcelain enamels are formulated to provide specific color and appearance characteristics, abrasion resistance, surface hardness, and resistance to corrosion, heat, and thermal shock. They can be clear, semiopaque, or opaque. Opaque enamels such as Enamel 5 are used for white and pastel coatings [*18*]. They contain high concentrations of titania (TiO_2) to provide the opacification. Semiopaque enamels like Enamel 6 are used for most medium-strength colors. Clear enamels like Enamel 7 are used to produce strong, bright colors. They are similar to ground coat formulations without the adherance oxides.

Testing of Porcelain Enamels

Test methods for porcelain enamel coatings are under the jurisdiction of ASTM Committee B-8 on Metallic and Inorganic Coatings. The methods are listed in Table 4. Again, they form the basis for most quality control test programs.

Several of these test methods are concerned with the chemical durability of porcelain enamels. They include: C 282—Test Method for Acid Resistance of Porcelain Enamels (Citric Acid Spot Test); C 614—Test Method for Alkali Resistance of Porcelain Enamels; C 756—Test Method for Cleanability of Surface Finishes; C 538—Test Method for Color Retention of Red, Orange, and Yellow Porcelain Enamels; C 872—Test Method for Lead and Cadmium Release from Porcelain Enamel Surfaces; and C 283—Test Method for Resistance of Porcelain Enameled Utensils to Boiling Acid. A related issue is the possibility of defects providing a pathway from the surface to the substrate, usually called continuity of coating. Methods in this area include: C 536—Test Method for Continuity of Coatings in Glassed Steel Equipment by Electrical Testing; C 743—Test Method for Continuity of Porcelain

Enamel Coatings; and C 537—Test Method for Reliability of Glass Coatings on Glassed Steel Reaction Equipment by High Voltage.

GLASS ENAMELS

Glass enamels are vitreous coatings applied on glass. They provide a means of decoration, not an improvement in chemical durability or in cleanability. These coatings must be matured at temperatures below the deformation point of glass (1000 to 1200°F or 538 to 649°C). Hence, they require large quantities of fluxing elements so that chemical durability is difficult to achieve.

Glass enamels are produced in ready-to-use form (paste, thermoplastics, spray mediums, ultraviolet curable mediums) by a few select manufacturers. They represent a specialty product that is more akin to organic paints than to other ceramic coatings. The markets for this specialty product are categorized as tableware, glass containers, architectural, lighting, and automotive. As supplied to the user, glass enamels are mechanical mixtures of pigments, fluxes, and organic suspending media. The requirement for low maturing temperatures necessitates the use of very high lead oxide containing borosilicates for the flux. Leadless fluxes are under development, but have not yet achieved commercially acceptable properties. The organic suspending media are similar to materials used to make organic paints.

Testing of Glass Enamels

Test methods for glass enamels are under the jurisdiction of Subcommittee 14.10 on Glass Decoration of ASTM Committee C-14 on Glass and Glass Products. These methods [*12*] are listed in Table 5.

Most of these methods are concerned with the chemical durability of glass decorations. They include: C 724—Test Methods for Acid Resistance of Ceramic Decorations on Architectural-Type Glass; C 735—Test Method for Acid Resistance of Ceramic Decorations on Returnable Beer and Beverage Glass Containers; C 675—Test Methods for Alkali Resistance of Ceramic Decorations on Returnable Beverage Glass Containers; C 676—Test Method for Detergent Resistance of Ceramic Decorations on Glass Tableware; and C 927—Test Method for Lead and Cadmium Extracted from the Lip and Rim Area of Glass Tumblers Externally Decorated with Ceramic Glass Enamels.

REFRACTORY COATINGS

Flame spray techniques can be used to apply ceramic coatings in the molten state to heat-sensitive or massive substrates that cannot themselves be heated to high temperatures. Most ceramic coating materials used currently can be applied by flame spraying [*20*]. Silicates, silicides, carbides, oxides, and nitrides have all been deposited by this process.

In these processes, the coating material is melted and projected as heated particles onto the substrate, where it instantaneously solidifies as a coating. Three methods of heating and propelling the particles in a plastic condition to the substrate surface include: (1) combustion flame spraying, (2) plasma arc flame spraying, and (3) detonation gun spraying. Combustion flame spraying is used for coating materials that melt readily. Plasma arc flame spraying is used for very re-

fractory materials such as metal carbides. Detonation gun spraying is used for hard, wear-resistant materials such as tungsten carbide.

Flame spray coatings generally lack smoothness and are usually porous. They are, therefore, limited to applications such as thermal barrier coatings, where porosity is a virtue, and wear-resistant coatings, where the materials cannot be applied readily by any other technique.

Testing of Refractory Coatings

There is only one test method for flame spray coatings in the ASTM standards: C 633—Test Method for Adhesion or Cohesive Strength of Flame-Sprayed Coatings [*19*].

COATING APPLICATION

Ceramic coatings are applied to their substrates by one of several powder-processing techniques. In wet processes the raw materials are dispersed in a slip. Slip preparation involves mixing the ingredients, particle-size reduction, dispersion in water, and the addition of minor amounts of additives to modify the rheological properties of the slip [*21–22*]. These processes are carried out together in a ball mill comprising a rotating cylinder partly filled with freely moving, impact-resistant shapes.

The application process for a ceramic coating must be straightforward and foolproof, reproducible, economical, and flexible [*21*]. Selection of the application technique is one of the most important decisions the coatings engineer makes. Criteria for this selection are type of ware, shape and size of ware, throughput required, energy and labor costs, and space available. All of these factors affect the quality and the cost of a coating process, so that the best solution must be determined on an individual basis.

Dipping is a simple, efficient, rapid technique requiring no capital equipment. The ware is immersed in the coating slip, moved around in a controlled way, removed from the slip, shaken to remove excess slip, and set down to drain and dry. Any bare spots are touched up with a finger wet with coating material. Its limitations are extreme sensitivity to operator skill and difficulty in automating volume production.

Spraying is a process whereby a coating slip is broken down into a cloud of fine particles that are transferred to the substrate by either pneumatic, mechanical, or electrical forces. The method requires a gun, a container or feed mechanism, an impelling agency, and a properly designed hood or booth maintained under negative pressure [*23*]. Spraying lends itself to high-volume automated systems [*24*]. The articles are continuously fed under a battery of angled spray guns. Coating reclaim is an essential part of automated systems.

Slip can also be applied mechanically with a rotating atomizer. Slip is passed onto a set of closely spaced rotating disks which throw the coating into a fan of droplets. Costs are similar to spraying. The primary use of this technique is in producing textured coatings on tile.

If the substrate is conductive (that is, a metal), the surface quality and uniformity of a ceramic coating can be improved by using the electrostatic spray coating technique [*25,26*]. In this system, the slip is broken into droplets either by air atomization or by centrifugal force from a sharp-edged rotating surface. The drops acquire a high negative charge and are dispersed as a fine mist. They are driven forward to the grounded substrate following the lines of force. Hence, coating material can reach the underside of the ware, and full-edge coverage is achieved.

There are other techniques for specific applications. Tile require only one face to be glazed, but with a very smooth coating. This suggests the waterfall, or curtain technique [*21*], where a continuous feed of tiles is carried under a curtain of fluid slip. Painting and brushing are seldom used except for special effects and for applying glaze to inaccessible areas.

For substrates which require precisely positioned areas of coating, the silk screen process can be used [*20*]. Finely powdered dry coating material is dispersed as a smooth paste. Using a squeegee, this paste is pressed through the open areas of a fine mesh screen stretched on a frame. For coating a total piece, costs are excessive.

There are a few techniques of application that do not require the preparation of a slip. They include flame spraying, dry powder cast iron enameling, and electrostatic dry powder enameling.

Flame spraying can be used to apply ceramic coatings in the molten state to heat-sensitive or massive substrates. Flame spray coatings generally lack smoothness and are usually porous. Equipment and material costs are generally high.

In dry powder cast-iron enameling, a casting is heated in a furnace to red heat. It is then withdrawn from the furnace and, while still hot, dusted with dry powdered frit by means of a vibrating sieve placed over the surfaces to be coated. The powdered frit melts and adheres as it falls on the hot surface. This process is also extremely operator sensitive.

The most important dry application method, and the one most recently introduced, is dry powder electrostatic application of all-fritted coatings to conductive substrates. This technique involves charging individual coating particles at a high voltage and then spraying them towards the substrate surface. Charging of particles is accomplished by encapsulating the coating material with an organic silane. It is then suspended in clean compressed air in a fluidized bed container [*27*]. The fluidized powder is siphoned and propelled through powder feed tubes to special electrostatic powder guns for low-pressure application. The powder carries a potential of up to 100 kV, which causes it to seek out and attach itself to the grounded workpiece. Capital costs of this process are substantial, but operating costs are reduced through elimination of slurry preparation and drying of the ware.

Epoxy Resins in Coatings

by Ronald S. Bauer,[1] Edward J. Marx,[2] and Michael J. Watkins[2]

EPOXY RESINS HAVE BECOME technologically important materials that find extensive application in high-performance coatings, adhesives, and reinforced plastics. Almost since their commercial introduction in 1950, epoxy resin systems have been used in protective coatings. Historically, protective coatings were the largest single end use for epoxy resins. Although in recent years the noncoating applications of epoxy resin have been growing, coatings still represent about half of the annual epoxy resin usage.

Epoxy resin coatings offer a unique combination of adhesion, chemical resistance, and physical properties that provide outstanding protection against severe corrosive environments. They are used extensively in coatings for refineries, chemical plants, and marine equipment such as offshore drilling platforms and merchant ships. Other important applications where epoxy resin coatings are used almost exclusively because of the corrosion protection they afford include automotive, aircraft, and appliance primers as well as to protect both the inside and outside of pipe. Epoxy resins are the predominant thermosetting resin used for the interior linings of beer and beverage cans, cans for hard-to-contain food products such as sauerkraut, tomato juice, and meat products, and for chemical-resistant linings of pails and drums. These coatings are used not only to protect the metal of the container from corrosion, but also to protect the flavor of the contents, which can be affected by direct contact with metal.

The principal components of any epoxy resin coating system are the epoxy resin and the curing agent or hardener. Epoxy resins are reactive intermediates that can be liquid or solid, and they are converted into the final coating by reaction with curing agents (hardeners). Curing agents function by reacting with specific groups in the epoxy resin molecule to give a three-dimensional, infusible polymer network. Although the resin and curing agent are common to all epoxy coatings, other materials are incorporated to achieve the desired rheological characteristics, cure speed, and film performance.

RESIN TYPES

Generically, epoxy resins can be characterized as a group of commercially available oligomeric materials which contain one or more epoxy (oxirane) groups per molecule. The epoxy resins most widely used by far in coatings are the bisphenol A based epoxy resins, the generalized structure of which is given in Fig. 1. In commercial products, the n value ranges from 0 to about 25, although higher-molecular-weight thermoplastic resins having n values of 200 or more are available. As n increases, the epoxy equivalent weight (EEW) increases, as does the number of hydroxyl groups. Thus epoxy resins with low n values are normally cured by reaction of the epoxy group, whereas those resins with higher n values are cured by reaction of the hydroxyl functionality.

Resins having n values less than 1 are viscous liquids; they are used mainly in ambient-temperature cure coatings, electrical castings, flooring, electrical laminates, and fiber-reinforced composites. These applications require liquid resins having good flow and are cured through the epoxy ring. The higher n value resins, particularly those above 3000 molecular weight, are normally used in solution and find their greatest application in heat-cured coatings. In these resins the concentration of epoxy groups is low, and so they are cured with materials that react with the hydroxyl groups along the backbone. Table 1 displays a range of typical epoxy resins that are commercially available along with their properties and applications.

CURING AGENTS

Epoxy resins are reactive intermediates composed of mixtures of oligomeric materials containing one or more epoxy groups per molecule. To convert epoxy resins into useful products, they must be cross-linked or "cured" into a three-dimensional polymer network. Cross-linking agents, or curing agents as they are generally called, function by reaction with or cause the reaction of epoxide or hydroxyl groups in the epoxy resin. The number of curing agents that have been developed over the years for epoxy resins is overwhelming. Selection of the curing agent is as important as that of the base resin; it is dependent on the performance requirements of the film and the constraints dictated by the specific method of application.

The most important types of curing agents used in epoxy resin coatings are the amine-functional materials for ambient-cure coatings and the amino- and phenoplast resins for heat-cured systems. The principal amine-functional curing agents used in ambient-cure coatings are aliphatic amine adducts of epoxy resins, polyamides, and ketimines. Amine-functional materials cure epoxy resins by polyaddition

n is typically 0 to 1 for liquid resins with solid resins having n values as high as 15 or more

FIG. 1–Idealized structure of a bisphenol epoxy resin.

TABLE 1—Typical properties of bisphenol-based epoxy resins.

Average Molecular Wt	Average EEW[a]	Approximate Average Value of *n*	Viscosity, *P*, 25°C	Softening Point, °C[b]	Applications
350	182	...	80	...	Solventless and solvent-borne ambient cure coatings, electrical encapsulation, flooring, and filament winding

3750	3050	13	Solid	150	

[a]EEW = epoxide equivalent weight, i.e., grams of resins needed to provide 1 *M* equivalent of epoxide. Also referred to as WPE (weight per epoxide) and EMM (epoxy molar mass). All three terms are interchangeable.
[b]Softening point by Durran's mercury method [ASTM Specification for Epoxy Resins (D 1763)].

through reaction of the amine with the epoxy groups. Amino- and phenoplast cross-linking resins are generally etherified urea-formaldehyde, melamine-formaldehyde, and phenol-formaldehyde condensates. The amino- and phenoplast resins cure by condensation with the backbone hydroxyls of the epoxy resin with elimination of water or an alcohol.

Aliphatic amines such as ethylene diamine (EDA), diethylene triamine (DETA), and triethylene tetramine (TETA) have always been popular curing agents for epoxy resins because of their ability to readily cure at room temperature. However, aliphatic amines present certain handling hazards because of their high basicity and relatively high vapor pressure. Epoxy/amine adducts, amine-terminated polyamides, ketimines, and other modified polyamines are less hazardous derivatives of aliphatic amines and often provide performance and handling advantages.

EPOXY RESIN COATINGS

There are a number of possible ways to classify epoxy resin coatings. Since curing agent types have been divided into ambient-cure and heat-cure, for convenience the types of epoxy coatings can also be classified similarly. The bulk of the ambient-cure or "air-dry" coatings are cured with polyamines or modified polyamines and generally find application as maintenance and marine or architectural coatings. Ambient-cure coatings are based on low-molecular-weight epoxy resins having high epoxy group content and are generally cured through reaction of the epoxy group. In addition to the "two-package" type ambient cure epoxy coatings, air dry epoxy esters, prepared by esterifying epoxy resins with unsaturated fatty acids, dry by the same mechanism as alkyd resins. Historically ambient-cure coatings have been applied out of solvent, typically at about 40% weight solids. However, with the regulation of emissions of volatile organics, the trend has been toward coatings with lower volatile organic content, 100% solids, and waterborne systems.

Heat-cure coatings are used in industrial finishes, automotive primers, appliance primers, pipe coatings, and coatings for beer and beverage cans, as well as cured coatings for pails and drums. Conventional solvent-borne and waterborne heat-cured coatings are based on the higher-molecular-weight epoxy resins, and they are generally cured through reaction of the hydroxyl groups. Powder coatings, however, are generally manufactured from intermediate molecular weight solid resins and are cured through the epoxy group. The usual curing agents for heat-cured epoxy resin coatings are amino- and phenoplast resins, as well as dicyandiamide and polycarboxlic acids, which are used in powder coatings.

TWO-PACKAGE, AMBIENT-CURE COATINGS

By far the largest volume of ambient-cure epoxy resin coatings are the "two-package" type, which are typically manufactured from liquid or low-molecular-weight solid epoxy resins cured with a polyamine, amine adduct, or polyamide. A two-package coating, as the name implies, is a two-part system:

the epoxy component and the curing agent, which are packaged separately and often in volume ratios of 2 to 1 or 4 to 1 of epoxy component to curing agent. Two-package epoxy coatings are mixed just prior to application and are characterized by a limited working life or pot life after the resin and curing agent components are mixed. Commercial systems will have pot lives of a few hours to a couple of days, with typical working times of about 8 to 12 h.

Two-package epoxy resin coatings include a broad range of products and properties. Specific film properties depend on selection among many epoxy resins, curing agents, pigments, and modifiers, as well as the ratios of these materials. Resins differ primarily in molecular weight. As the molecular weight of the resin increases, the flexibility, flexibility retention, film-leveling properties, and pot life of the coating increase. However, cross-link density decreases with increasing molecular weight, resulting in reduced solvent and chemical resistance as well as nonvolatile content of the paint at application viscosity.

Although aliphatic polyamines are less expensive and have been used extensively as curing agents, polyamine adducts, amine-terminated polyamides, and ketimines are generally preferred. Among the advantages provided by aliphatic amine adducts are:

- Milder odor.
- Lower volatility.
- Less tendency to produce blush when coatings are applied under conditions of high humidity.
- Greater suitability for application at low temperature.
- Less tendency to corrode metal containers.

Two general types of polyamine adducts are available, i.e., those based on a low-molecular-weight liquid epoxy resin and those based on a high-molecular-weight solid epoxy resin. The performance properties of amine-cured coatings are not significantly different from those of aliphatic polyamine cured systems. Like polyamines, amine adducts offer maximum resistance to solvents, acids, and other highly corrosive chemicals. Initial flexibility and impact resistance are excellent, and retention of these properties is adequate for most uses over rigid or semi-rigid substrates.

More pounds of polyamide curing agents are consumed annually in the United States than any other type of epoxy resin curing agent. Polyamides are obtained from the condensation of dimerized and/or trimerized fatty acids with aliphatic polyamines such as diethylene triamine and triethylene tetramine to give an amine-terminated polyamide. Polyamide cured epoxy coatings develop superior adhesion to moist and poorly prepared surfaces, and they provide a high degree of corrosion resistance. Like epoxy resins, polyamides are also mixtures of oligomers. Thus, a range of polyamides which vary in viscosity, amine equivalent weight, and reactivity is available. Polyamide cured coatings exhibit somewhat better retention of flexibility and impact resistance on aging than polyamine adducts. Although resistance to solvents and acids is not quite as good as with other types of amine curing agents, polyamides are adequate for most applications where amine cure epoxy coatings are used.

Ketones add reversibly to primary amines with the loss of water to give ketimines. The ketimines obtained from the typical polyamine curing agents have rather low volatility compared to the precursor polyamine. Ketimine curing agents can be considered blocked polyamines, which in the presence of water hydrolyze to produce a ketone and a polyamine. These ketimines react at a practical rate of cure under ambient conditions. Atmospheric moisture, which is absorbed during and following application of the coating, serves as the source of water required to activate the curing agent. Ketimine curing agents are similar in behavior to the aliphatic amine polyamines and amine adducts in rate of cure and performance of cured films, but they provide much longer pot lives.

Typical applications of two-package coatings of the above type are in heavy-duty maintenance and marine coatings, tank linings, aircraft primers, internal pipe coatings, for gas transmission lines, coatings for plastic products, and high-performance architectural coatings.

EPOXY RESIN ESTER, AMBIENT CURE COATINGS

Epoxy resin esters are prepared by esterifying the resin with vegetable oil fatty acids. Epoxy esters are usually prepared from solid epoxy resins having EEWs in the range of 900. As in conventional alkyd technology, these coatings are made by esterifying the resin with fatty acid at temperatures of 400 to 450°F (204 to 232°C). Initially, the fatty acid reacts with the epoxy ring at lower temperatures, forming hydroxyl esters. Subsequently, these hydroxyl groups and those already present in the resin are esterified at higher temperatures with the aid of esterification catalysts and with azeotropic removal of water. Typically, between 30 and 90% esterification is chosen, depending on the oil length desired.

Like alkyd resins, epoxy resin esters may be made in long, medium, and short oil lengths. The oil length refers to the degree of esterification of the epoxy resin with the fatty acid: long indicates 70 to 90% esterification, medium indicates 50 to 70% esterification, and short indicates 30 to 50% esterification. By proper selection of acids and adjustment of reaction ratios, long, medium, or short oil esters may be prepared with drying, semidrying, or nondrying characteristics. The terms "drying" or "air dry"are used instead of ambient-cure since cross-linking of epoxy resin esters does not involve a curing agent. Air-dry epoxy resin ester coatings are "one-package" or one-component systems, since they cross-link or cure only on exposure to air.

Air-dry epoxy ester coatings are used in maintenance and marine coatings, especially where mildly corrosive conditions are encountered. They do not, however, possess the outstanding chemical resistance of amine-cured epoxy coatings, but they are superior to alkyd paints. In addition, their toughness and durability make them well suited for long-wearing floor finishes.

HEAT-CURED SOLVENT-BORNE EPOXY RESIN COATINGS

Conventional solvent-borne heat-cured or "baked" epoxy resin coatings are based on high-molecular-weight epoxy resins, that is, resins with EEWs around 1750 or greater. The concentration of epoxy groups is low in these resins, and

cross-linking occurs principally through the hydroxyl functionality. Thermosetting resins such as urea-formaldehyde, melamine-formaldehyde, and phenol-formaldehyde resins are used as cross-linkers for the coatings of this type. This cross-linking requires heat, and usually a strong acid catalyst is used to accelerate the cure. Thus, these systems are supplied as "one-component" systems, i.e., the resin, curing agent, and accelerator are packaged together.

Aminoplast (urea-formaldehyde or melamine-formaldehyde) cross-linking resins are used because of their good color and relatively low cure temperature. They are typically used in linings for beer and beverage containers and as clear coatings for brass and jewelry. Pigmented aminoplast cured coatings are used as coatings for industrial equipment, appliances, and hospital and laboratory furniture. Phenoplast (phenol-formaldehyde) cured coatings are more chemically resistant, and they find application in beer and beverage containers (particularly in Europe), drum and pail linings, internal coatings for pipe, wire coatings, and appliance primers. Phenoplast resins, generally giving coatings of poorer color than aminoplast resins, are used only when maximum resistance to solvents and other chemicals is required.

HEAT-CURED WATERBORNE EPOXY COATINGS

The earliest epoxy resin coatings for beer and beverage containers were solvent-borne amino- or phenoplast cured systems, the particular systems used being dependent on the application. Although application technology has changed over the years and is now dominated by waterborne systems, the coatings are still basically amino- or phenoplast cured systems. These coating systems are based on high-molecular-weight epoxy resins onto which are grafted terpolymers of, for example, styrene/methacrylic acid/ethyl acrylate. These epoxy/acrylic graft polymers are neutralized with base, such as dimethylethanolamine, to give a resin easily dispersible in water. The dispersed resin can then be cured with an aminoplast resin to give coatings with properties that make them suitable for beer and beverage containers.

ELECTRODEPOSITION COATINGS

Epoxy resin electrodeposition coatings are also waterborne coatings formulated from either anionic or cationic epoxy resin polymers. The part to be coated is dipped into the electrodeposition bath, and an appropriate electrical charge is applied, causing the coating to deposit onto the part. The part is then removed from the bath, rinsed, and baked to cure the coating. In the United States, epoxy-based electrodeposition coatings account for over 92% of all electrodeposition coatings. Epoxy-based cathodic electrodeposition (CED) automotive primers dominate this application, accounting for over 82% of all electrodeposition coatings. Over 40 million pounds of epoxy resin are used in the United States in CED automotive primers, making this one of the largest single end uses for epoxy resins in coatings. Virtually every automobile made in the United States, Europe, and Japan is primed with a CED primer. CED primers are used because they afford exceptional corrosion protection and because they are deposited uniformly to all areas of the automobile, even in areas which would be inaccessible to other coating application methods such as spray. Because of their major importance, the remainder of this discussion will deal with CED automotive primers.

The preparation of CED coatings generally begins by reacting a bisphenol A based liquid epoxy with bisphenol A to give an epoxy resin with an epoxy equivalent weight in the range of 500 to 1000. This epoxy resin is then reacted with a flexibilizing diol. This diol can be an aliphatic diol or a polyether diol. The principal requirement is that the diol contain primary hydroxyl functionality. These primary hydroxyls are reacted with the epoxy groups in the presence of a suitable catalyst (e.g., a tertiary amine) to form ether linkages between the epoxy and the flexibilizing diol. At this point, the resin will have an epoxy equivalent weight in the range of 1000 to 1500. The remaining epoxy functionality is then reacted with amines. Generally, secondary amines are chosen to minimize further chain extension. One favored method to accomplish this is to use a diketimine of diethylene triamine. During coating preparation, the ketimine groups decompose to give primary amines. These primary amines are fairly basic, resulting in stable dispersions at a relatively high bath pH (pH > 6). At this point, the CED resin preparation is complete. In practice, specialized CED resins are used to make the pigment grind pastes. These are developed to efficiently make stable pigment dispersions, which retain good stability in the CED coating bath.

Curing agents used are generally blocked isocyanates. These are chosen to be stable and unreactive in the coatings bath, but to unblock and cure the coating at baking temperature. An example of such a curing agent would be the reaction product of 3 mol of toluene diisocyanate with 1 mol of trimethylolpropane. This is then reacted with 3 mol of a suitable blocking agent, such as 2-ethyl-1-hexanol. Catalysts such as tin or lead salts are generally used to facilitate unblocking and coating cure. The coating is prepared by blending the resin with pigment paste, curing agent, catalysts, additives, and solvents. A low-molecular-weight organic acid, such as lactic or acetic acid, is then added to the mixture to make ammonium salts with the amine groups in the resin. This mixture is then dispersed in water to make the CED coating. Solvents may be required in the preparation of the CED resin or other components. In order to reduce the volatile organic compound content of the finished coating, it is usually subjected to a vacuum stripping step which can reduce VOC to less than 0.7 lb/gal. When the automobile is dipped into the CED bath, a negative charge is applied to it (making it the cathode) relative to counter electrodes in the bath. Electrolysis of water occurs, forming hydroxide ions in the immediate vicinity of the automobile surface. These hydroxide ions react with the ammonium ion groups in the resin near the surface, regenerating the neutral amine groups and causing the coating to be deposited onto the surface. In this way, a uniform film is applied to the entire conductive surface of the automobile. The automobile is then removed from the bath, rinsed, and baked.

EPOXY RESIN POWDER COATINGS

Powder coatings are produced by melt blending homogenous dispersions of nonvolatile solid resins, curing agents, pigments, fillers, and various additives. The dispersion is solidified by cooling, ground into a finely divided powder form, and classified for subsequent use. The resultant powder is normally electrostatically deposited onto grounded substrates and, through the application of heat, converted into very high performance thermoset films. The process of applying coating powders allows nearly 100% powder utilization and evolves almost no volatile organic compounds.

The 1970's volatiles regulations and energy concerns raised interest in powder coating technology. The real sustaining driving forces for growth, however, have been improvements in powder coating raw materials, formulations, manufacturing technology, and application equipment. The advantages for the use of powder coatings can best be summed up in the "Four E's," used by The Powder Coating Institute: (1) excellence of finish, (2) economy in use, (3) energy efficiency, and (4) environmental acceptability. The Clean Air Act, as amended in 1990, has contributed to even greater interest in the use of powder coatings to meet more stringent volatile organic requirements. Powder coatings is the fastest growing area of coatings technology. Growth rate for powder coatings in the 1990 to 1995 time frame is projected to be at 10 to 12% versus a conventional "wet" coatings rate of about 2%.

The unique characteristics of solid epoxy resins account for their choice by formulators for use in powder coatings applications. Bisphenol-A based epoxides with equivalent weights greater than about 650 are nonsintering and extremely friable. They have relatively low melt viscosity and high reactivity via the terminal oxirane functionality. The addition reaction with amines, phenolics, or carboxylic acid functional curatives allows a wide range of formulations. The primary limitations for bisphenol-A based epoxy resins in powder coatings are yellowing and loss of gloss that occur when these coatings are exposed to exterior weathering conditions.

Powder coatings are broadly divided into either "functional" or "decorative" uses. Functional coatings are normally applied at film thicknesses greater than about 3 mil and are expected to withstand some rather severe service. Examples of functional uses are coatings for exterior and interior pipe, rebar, and various electrical devices. Although decorative powder coatings are functional, these are normally used at a film thickness of 3 mil or less and are not expected to perform significantly better than baked films derived from "wet" coatings. Some examples of decorative uses are coatings for appliances, furniture, and underhood automotive parts.

Phenolics

by John S. Fry[1]

DEFINITION: *a polymeric, resinous reaction product of a phenol with an aldehyde. Said products may be used alone or in formulations with other polymers to produce useful coatings.*

HISTORY

Phenolic resins, initially commercialized in 1909, were the first completely synthetic materials for the burgeoning plastics business. The expansion of several new technologies of the time, namely the electrical, communications, and automotive industries, all required and depended on new materials that had better electrical insulating properties, higher heat resistance, and improved resistance to chemicals, acids, oils, and moisture. The heat-reactive resins, developed by Dr. Leo H. Baekeland [*1*], were formulated into blends that were convenient for mass production compression moldings and satisfied the above-mentioned requirements. Improved and new items such as coil supports, commutators, distributor heads, telephone sets, vacuum tube bases, radio parts, and electrical switches all blossomed onto the market within a few years.

FIRST PHENOLIC COATINGS

Concurrent with the above developments, the nonheat-reactive phenolics or "novolak" resins were prepared as a hoped-for substitute for shellac. These resins were not as resilient as shellac and, when used alone, were not successful in coatings. However, combined with the formaldehyde donor, hexamethylene tetramine, the novolaks could be compounded into another set of thermosetting molding materials which found early use in phonograph records.

While the above-mentioned novolaks had to wait for success in coatings, the alcohol solutions of the heat-reactive resins were found, by 1911, to form excellent films when baked and cross-linked. These coatings, still in wide use today, are hard and glass-like and have excellent resistance to chemicals, acids, water, and solvents. Early applications included protective coatings for brass beds as well as other hardware items. These solution resins also initiated the manufacture of laminates, which engendered radio circuit boards and, later, printed circuit boards.

CHEMISTRY

The reaction of phenol with aldehydes to produce resinous products was difficult to understand in the early years because many of said products were insoluble or infusible. After studying the variables, Baekeland at least defined the conditions to produce three stages of products: "A" stage—soluble and fusible; "B" stage—insoluble, but swellable and softenable; and "C" stage—cured to an insoluble and heat-resistant material. With the advent of modern analytical tools, the chemistry of the reactions has been more fully defined by various workers [*2,3*]. A brief description follows.

RAW MATERIALS

The commercially important phenols used in coatings resins are shown in Fig. 1. While phenol is the most common, the substituted phenols are also used to vary the solubility and reactivity properties of resins. The cresols, butyl phenol and bisphenol-A, are widely employed while the others have limited or specialty uses.

Phenol has three aldehyde reactive ring positions; the 2 and 6 carbon atoms (ortho) and the 4 position (para). Phenols with substituents in the above positions have lower functionalities and are frequently used to modify resin properties.

The aldehyde co-reactant of choice for the phenols is formaldehyde, the most reactive of those commercially available. Formaldehyde, a gas, is conveniently handled as an aqueous solution (formalin) or as a solid polymeric form known as paraform. Formaldehyde in aqueous solutions exists as hydrated glycols or low-molecular-weight glycol ethers.

$$CH_2O + H_2O \longrightarrow HOCH_2OH \cdot HOCH_2O[CH_2O]H$$

Both of the above forms of formaldehyde depolymerize on heating to supply reactive formaldehyde for the phenolic reactions. The type of reaction products and resins formed depends on the catalysts and conditions used.

BASE CATALYST

Strong base catalysts (pH above 8) produce initial reaction products such as the methylol phenols shown in Fig. 2*a*. Phenol can produce five different methylol-related species, while the substituted phenols, with lower functionality, produce fewer methylol derivatives. Further reaction causes the methylol groups to condense with other ring positions (meth-

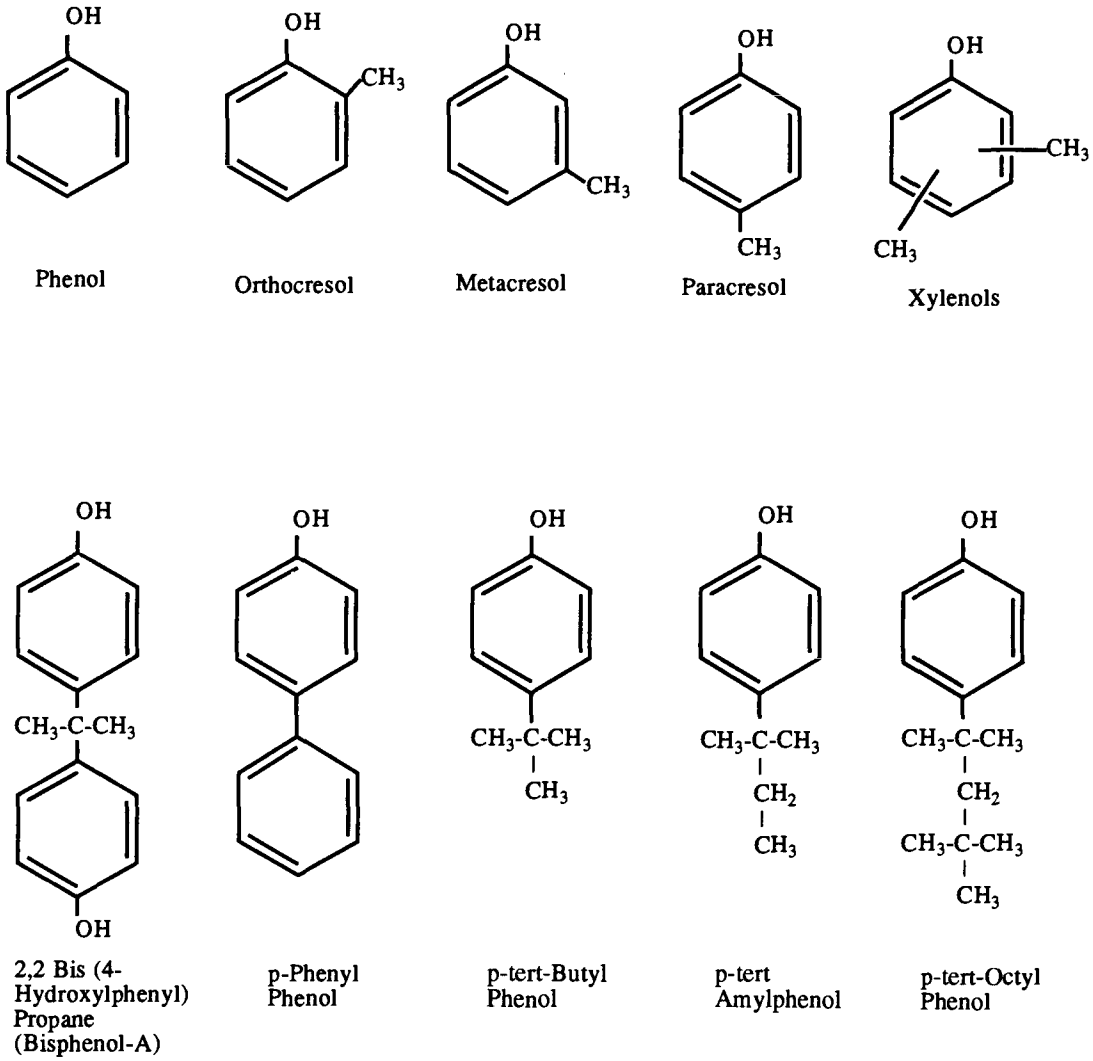

FIG. 1–Phenols used to make phenolic resins.

ylene link) or to etherify with other alcohol groups (methylene ether links) (Fig. 2*b*). Additional reaction raises the molecular weight to branched, heat-reactive resin products which are dehydrated, dissolved in solvents, or isolated as grindable solids for later formulation.

ACID CATALYST

At a pH of 0.5 to 1.5, the acid-catalyzed phenol-formaldehyde reaction proceeds through an unstable addition intermediate to condensed, methylene-linked phenolic rings (Fig. 3). When phenol is used, highly branched "novolaks" are obtained. However, when substituted phenols are used, the functionality of the system is reduced to two and mostly linear resins are formed.

INTERMEDIATE pH CATALYSIS

When salts of zinc, magnesium, or aluminum are used as catalysts, the pH of the phenol-formaldehyde reaction falls in the 4 to 7 range. Under such conditions, the formaldehyde addition to the phenolic ring is highly directed to ortho substitution. With excess formaldehyde, hemi-formals and ortho methylol groups are formed. Using lower formaldehyde levels leads to the formation of nonheat-reactive ortho-ortho novolaks. With the highly reactive para ring position still open, these resins have been employed in relatively rapid crosslinking formulations.

TESTING OF PHENOLIC RESIN PRODUCTS

Typical quality control tests for phenolic resin products may include the following.

1. Gel time [ASTM Test Method for Determining Stroke Cure Time of Thermosetting Phenol-Formaldehyde Resins (D 4640-86)] (heat-reactive resins).
2. Volatile content [ASTM Test Method for Volatile Content in Phenolic Resins (D 4639-86)].
3. Viscosity (solution).

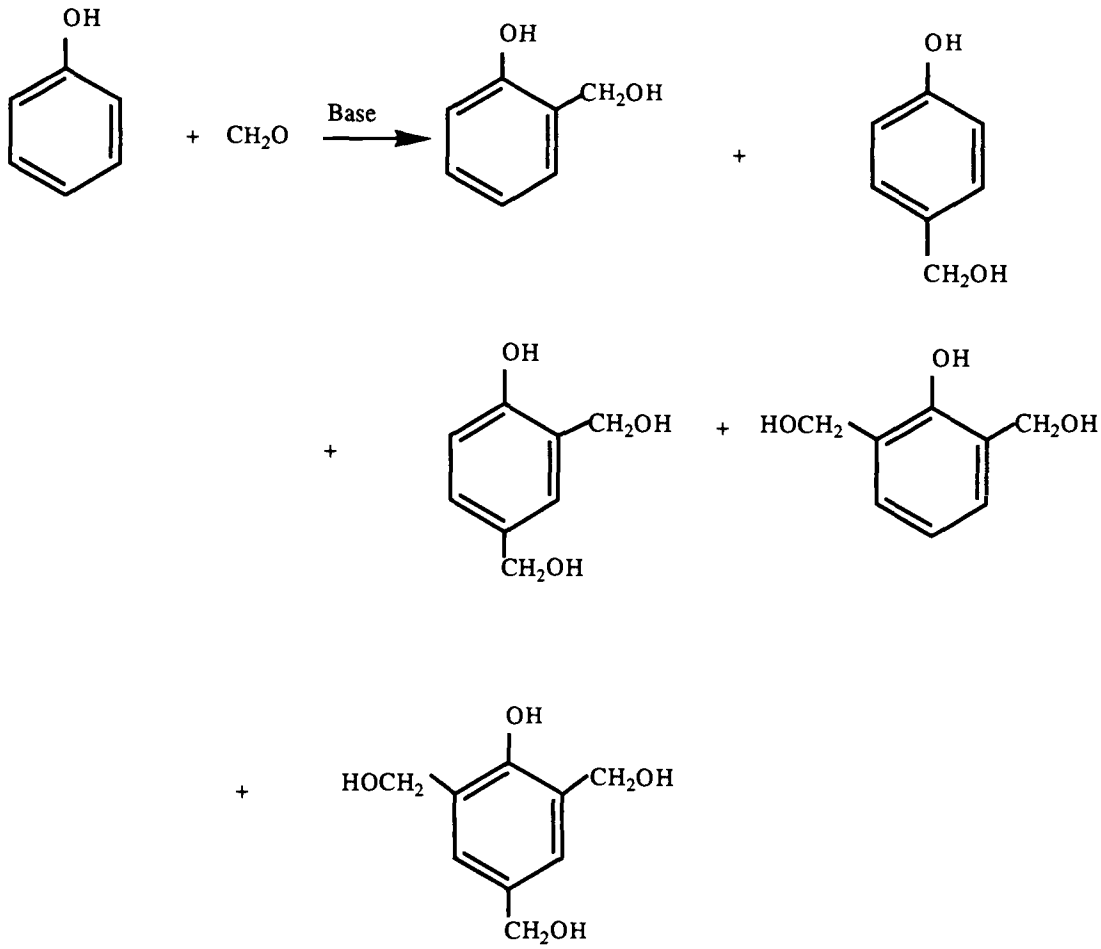

FIG. 2*a*–Base-catalyzed initial reaction products.

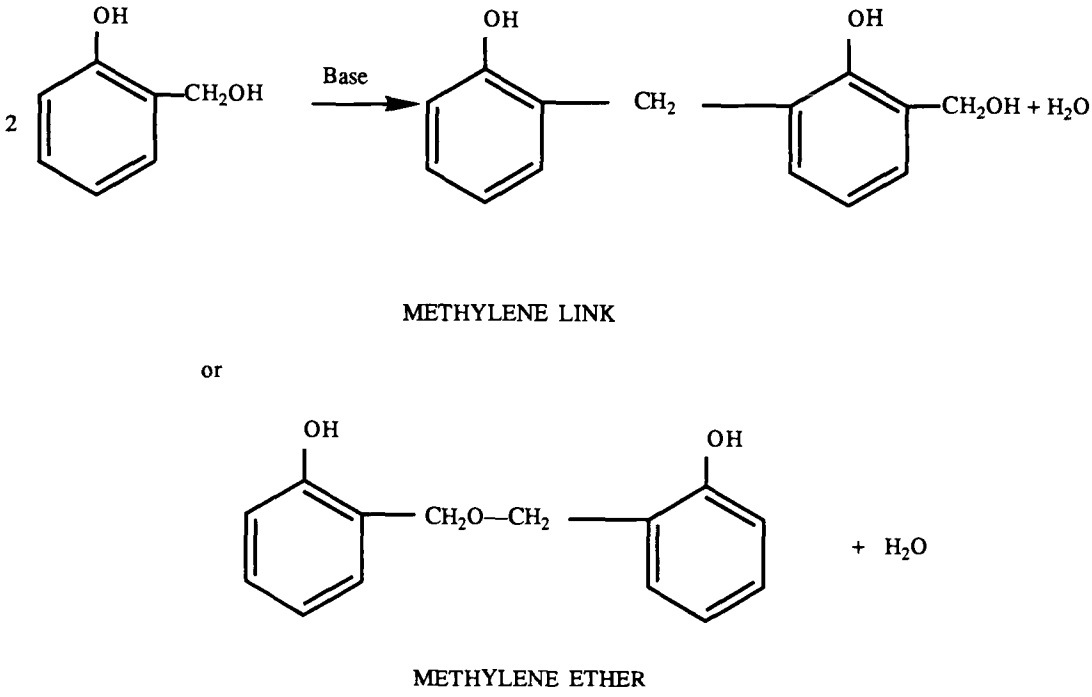

FIG. 2*b*–Methylol phenol reaction products.

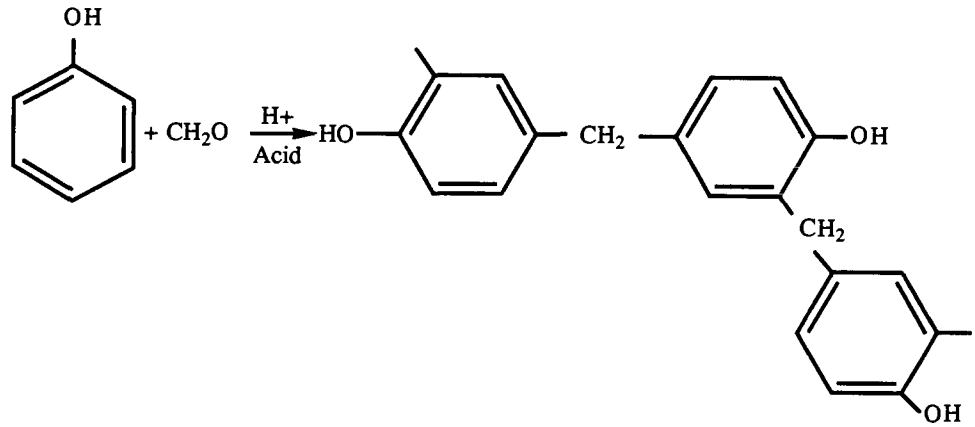

FIG. 3—Acid-catalyzed reaction products.

4. pH [ASTM Test Method for Measuring Apparent pH or Water Insoluble Phenol-Formaldehyde Resins (D 4613-86)].
5. Color (Gardner).
6. Specific gravity.

Other tests to characterize resins may be used:

1. Molecular weight distribution and free phenols—gel permeation chromatography.
2. Structure analysis—NMR, I.R.
3. Thermal analysis (curing curves).
4. Free formaldehyde–hydroxyl amine method.

HEAT REACTIVE RESINS IN COATINGS

Alcohol-Soluble Resins

The thermosetting, alcohol-soluble resins are based on multifunctional monomers such as phenol, cresols, xylenols, and bisphenol-A. These resins are also soluble in ketones, esters, and glycol ethers, but insoluble in aromatic and aliphatic hydrocarbons. They are compatible with amino resins, epoxies, polyamides, and poly(vinyl butyral) and are, in many cases, formulated with said resins as crosslinking agents. The resins are commercially available as solvent solutions, solids, or waterborne systems. Low-molecular-weight resins with a high methylol content form water solutions, while higher molecular weight resins may be used in dispersion form [*4,5*].

Once formulated into vehicles, the resins may be applied by spray, dip, brush, or roller coating methods. The films are then baked at typical temperatures of 135 to 250°C for times varying from several minutes to several hours. When used alone, phenolic resins crosslink with the release of water to form 0.2 to 1.0-mil films. Since volatiles are released during cure, bubbles may develop in thicker films. Multiple coats may be applied as long as the intermediate coats are given a short bake.

Baked phenolic coatings are hard and glass-like with excellent resistance to organic solvents, boiling water, acids, and acidic or neutral inorganic salts. They are not resistant to alkalies unless combined with epoxides as will be discussed later. These phenolic coatings have excellent electrical resistance and also resist dry heat to 370°C for short periods. As a result, these products find applications in oil industry drill pipe, production pipe, as drum and pail linings, tank linings, printing plate backing, printed circuit masks, and as corrosion-resistant hardware coatings. Tests performed on such coatings may include:

1. Electrical properties.
2. Physical and mechanical.
3. Environmental resistance.
4. Applications.

Phenolics as Crosslinking Agents for Other Polymers

Coatings based on heat-reactive phenolics alone are not very flexible. To obtain better toughness and flexibility for applications such as can coatings or coil coatings, the phenolic resins are combined with a linear resin, such as an epoxy resin, in ratios of about 15/85 to 50/50 phenolic/epoxy. Upon baking, the phenolic resin's methylol groups react with the secondary hydroxyls of the epoxy resin backbone to crosslink the system (Fig. 4). Depending on the ratio used, some of the phenolic resin may self condense, but to a lesser extent than the pictured cross-linking reaction. In the case of can coatings, thin films (0.2 mil) are applied to tin plate or tin-free steel and typically baked for 10 to 12 min at 200°C. The coated metal is then formed into can bodies and lids, and foods are then packaged. The linings have to withstand a steam sterilization cycle of about 90 min at 250°F (121°C) while protecting the metal and the food. For beer and beverage cans, phenolics based on bisphenol-A may be used to minimize critical taste effects. Similar formulations have been used for wire coatings or coil coating primers. Phenolic/epoxy systems are also more resistant to alkalies than phenolics alone and are used for linings when basic substances are packaged.

Heat-Reactive Aromatic Soluble Resins

Heat-reactive resins or copolymers based mainly on substituted phenols such as *p*-tertiary butyl phenol or those with higher alkyl groups form resins which are soluble in aromatic solvents and even tolerate some aliphatic diluents. These resins are blended with blown oils or alkyd resins to form electrical coil and armature impregnation varnishes. Such var-

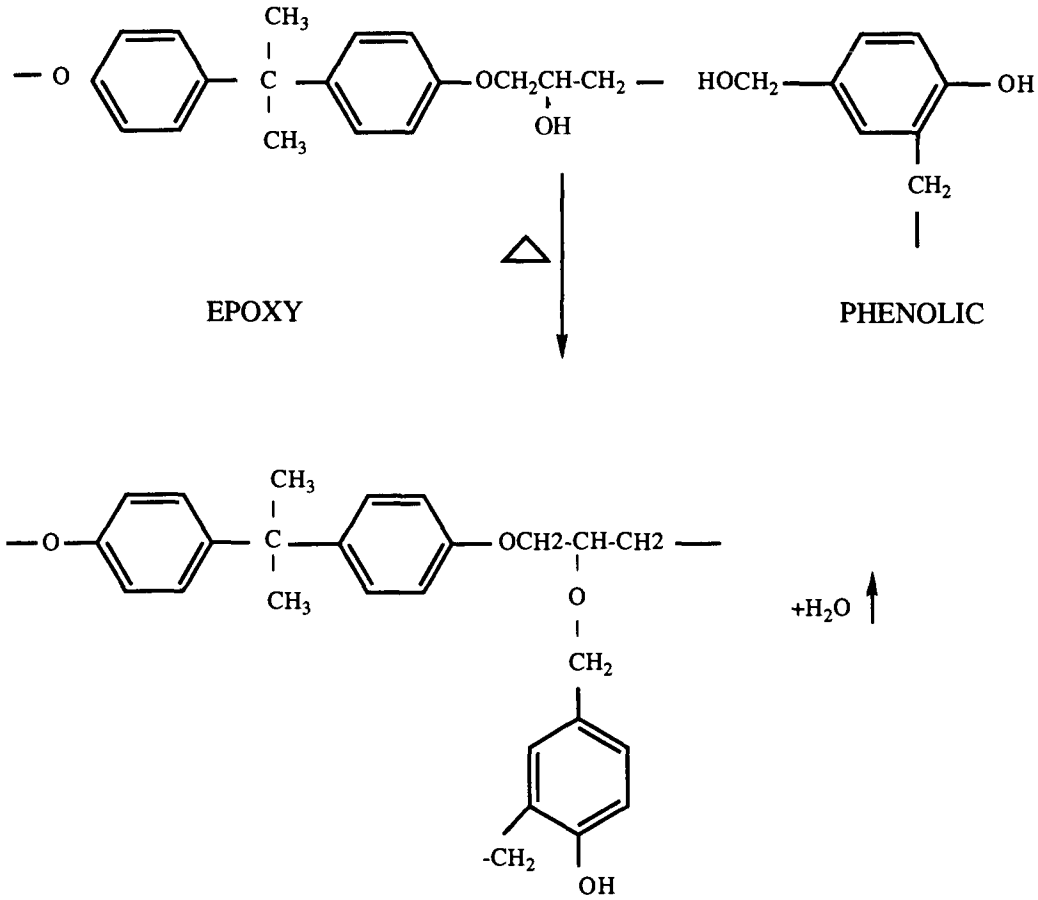

FIG. 4–Crosslink formation.

nishes may be used in both new and reconditioned electrical equipment.

Nonheat-Reactive Resins—Unsubstituted

The acid-catalyzed reaction of formaldehyde with an excess of phenol and/or cresols produces the nonheat-reactive, novolak-type resins. These resins do not form useful films by themselves, but when formulated with polyfunctional epoxy resins they act as co-reactants (hardeners) to produce thermoset systems. In this case, the chemistry involves the base-catalyzed reaction of an epoxy group with the phenolic hydroxyl group to form ether-type crosslinks which are resistant to chemicals, moisture, and heat (Fig. 5). Since this reaction does not produce by-products, thick films may be obtained via powder coatings or high solids solution coatings. Such coatings find application as pipe coatings, reinforcement bar, and electronic encapsulation coatings.

Varnish Resins

Substituted phenols containing the *tert*-butyl group or higher alkyl groups are reacted with formaldehyde under acidic conditions to produce "oil soluble" novolak resins.

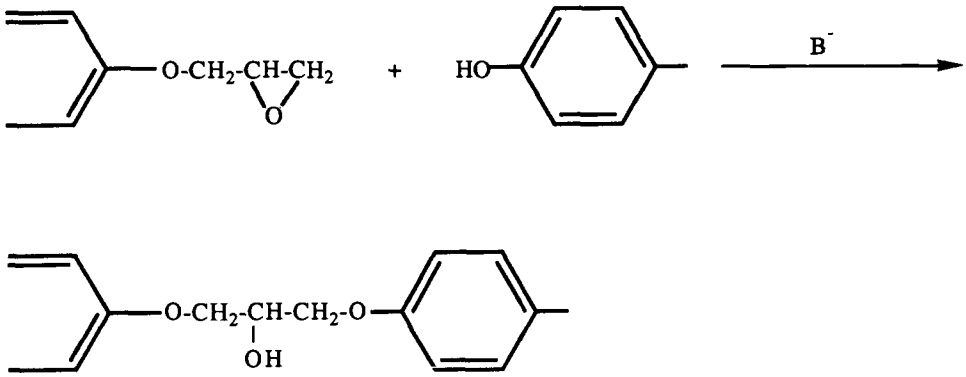

FIG. 5–Epoxy phenolic reaction.

Additionally, substituted phenols may be co-reacted with tall oil resin and formaldehyde to form modified resins, which are also "oil soluble." While they are again nonfilm formers, combined with drying oils or alkyds, the above resins produce useful air-dry or baking formulations. Varnishes based on natural oil-soluble resins and drying oils were known long before phenolic resins, but the advent of the synthetic phenolic resins led to more consistent production quality. Varnishes were originally prepared via a "cook" method where the phenolic resin was dissolved in the oils at 230 to 310°C while the oil then polymerized to a specified viscosity. After adding solvents, the varnish was cooled and then finished with additives such as driers, UV absorbers, and anti-skinning agents. In the 1950s, novel phenolic resins of higher molecular weight allowed the cold blend preparation of varnish vehicles [*6*]. In this process, the resin is dissolved in the solvents and the oils and additives are added at mild temperatures. Such vehicles are still used as baked can coatings, air drying clear wood coatings, porch and deck enamels, maintenance paints, and as alkyd reinforcements.

In the 1980s, high solids coatings were mandated by various federal and state regulations. Newer phenolic varnish resins were introduced that allowed vehicle solids of 70 to 80% to be achieved. Applied with airless spray, air drying primers and aluminum-pigmented topcoats have been successfully used for maintenance painting of major steel structures such as bridges and airport light towers [*7*].

While phenolic resin technology represents a mature field, the product class is hardly passé. Newer resins, formulations for waterborne, high solids and powder coatings, and the continued high performance in container and pipe coatings all indicate a promising future for this class of materials.

Polyamides

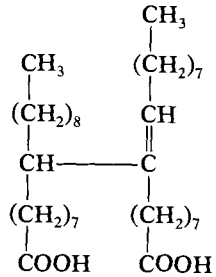
by Robert W. Kight[1]

POLYAMIDES ARE POLYCONDENSATION products of dimerized fatty acids and polyamines. Reactive polyamides are oligomers designed primarily for use in the manufacture of two-component polyamide/epoxy coatings and adhesives. The two-component coatings are generally labeled Part A and Part B, with the polyamide usually (though not always) contained in Part B. The polyamide may function as the curing agent, coreactant, or hardener for epoxy resin. Polyamides should not be considered as catalysts although they may initiate the reaction; the polyamide reacts with the epoxy resin and becomes part of the polymer. The majority of polyamides used in coatings are viscous liquids that are usually supplied by the coatings manufacturer as a solution in organic solvents. The solution may be a clear amber liquid or may contain pigments in colored systems.

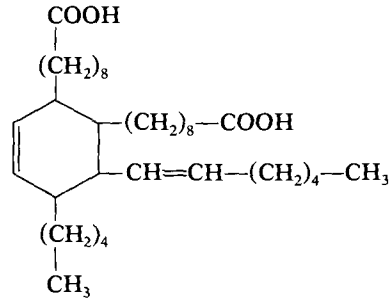
ACIDS

The dibasic fatty acids of commercial importance used to manufacture polyamide curing agents are prepared by dimerizing unsaturated C_{18} fatty acids from linseed, soya, or tall oils. Linseed and soya fatty acids are extracted from flax and soybeans, respectively. Crude tall oil (CTO) is a by-product from the Kraft process for papermaking and is a mixture of fatty acids and rosin acids, from which the fatty acids are separated by distillation. The tall oil fatty acids are a mixture of C_{18} isomers with a variable number of double bonds. Some of the isomers combine via Diels-Alder addition and other mechanisms to form C_{36} dibasic acids or dimer acids. The dimer acids produced may be acyclic, monocyclic, or polycyclic in structure, depending on the location and number of double bonds in the feedstock. Many isomers are present in commercial dimer acids, most of which are difunctional carboxylic acids [*1*]. Examples of three possible isomer types follow.

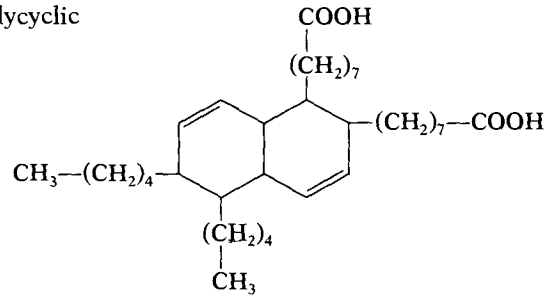
Acyclic



Monocyclic



Polycyclic

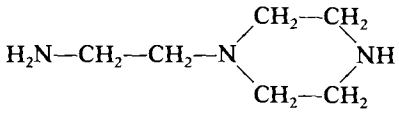


AMINES

The dimer acids are reacted with various polyamines to form polyamides and a variety of other useful products. The polyamines commonly used in industry are polyethylene polyamines of various chain lengths that are linear, branched, or cyclic. The linear polyethylene polyamines are characterized as secondary amine groups separated by ethylene chains, terminated on either end by primary amine groups. Diethylenetriamine is an example of a simple linear polyethylene polyamine.

$$H_2N—CH_2—CH_2—NH—CH_2—CH_2—NH_2$$

The cyclic and branched polyamine isomers contain tertiary amine groups in addition to the primary and secondary amine groups. Aminoethylpiperazine is an example of a cyclic polyamine.



The reaction between dimerized fatty acids and polyamines yield amide oligomers with amine group termination. These amide oligomers are used as coreactants with epoxy resins in high-performance coatings, as well as components of a variety of other useful commercial compositions including two-component adhesives.

EARLY HISTORY

Polyamides were commercialized in the late 1950s for use with epoxy resins in the manufacture of two-component adhesives and high-performance coatings. The early commercial epoxy/amine coatings contained aliphatic amines, primarily diethylenetriamine, which had several negative features, such as requiring critical mix ratios and toxicity. The introduction of polyamides allowed the coatings manufacturer to produce high-performance coatings characterized by convenient mix ratios, such as 1:1 or 2:1, with very low toxicity.

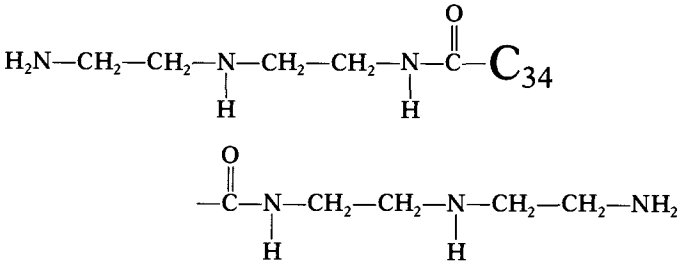
Epoxy/polyamide coatings find utility in a wide variety of applications, such as industrial maintenance coatings, machinery and equipment enamels, and marine applications. The presence of the long fatty chains gives coatings with much better flexibility as well as better wetting and adhesion than was obtained with the earlier aliphatic amine cured systems.

The epoxy/polyamide coatings are not, however, without some disadvantages. The advantage of having a long usable pot life comes with a much slower cure rate; thus epoxy/polyamide coatings generally take 8 to 10 h to reach an early cure and three to four days for a full cure. Another disadvantage is that epoxy/polyamide coatings are prone to severe chalking during exterior weathering.

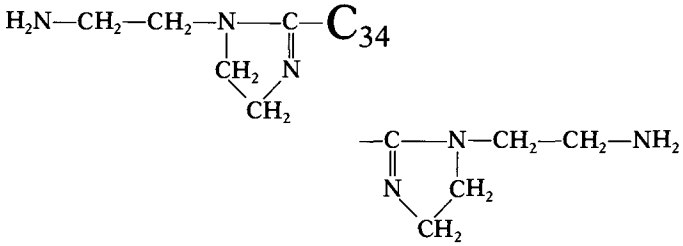
SYNTHESIS OF POLYAMIDES

Polyamides are polycondensation products of difunctional fatty acids and polyfunctional amines. In a typical commercial example, 1 mol of dimer acid is reacted with 2 mol of diethylenetriamine. During this condensation reaction, 2 mol of water are evolved. As the reaction proceeds, an interesting side reaction occurs: an additional mol or so of water evolves from a secondary reaction. One of the primary amine groups reacts with the dimer acid to form an amide linkage, which is a nitrogen bonded carbonyl. In addition, the ethylene chain next to the amide function and the secondary amine nitrogen are incorporated into a five-membered ring, known as an imidazoline ring. This condensation reaction, which also evolves water, eliminates an active hydrogen to yield a tertiary amine group. The degree of cyclization obtained is controlled to yield a product with specific useful properties, such as improved solubility and compatibility and longer pot life. Similar reactions occur at the other carboxylic acid group of the dimer [*2*]. If 50% of the diethylenetriamine present in the polyamide is cyclized to imidazoline, a total of 3 mol of water of reaction is evolved. These products are shown in the following structures:

For the polyamide



and for the imidazoline



Commercial products range from about 35% to more than 80% imidazoline to allow the coatings formulators latitude in customizing the properties of their products.

Other properties of the polyamide that are important to the coatings formulator are the amine value, which is related to active hydrogen equivalent weight, and the viscosity level of the polyamide in solvents. Amine values range from about 100 to about 400, with active hydrogen equivalent weights of about 550 to 140, respectively. The active hydrogen equivalent weight is used to calculate the amount of polyamide required to react with a given amount of an epoxy resin of known epoxide equivalent weight. The ratio of these values, known as the stoichiometric mix ratio, is most often only a starting point for the formulator. By varying the mix ratio of the polyamide to the epoxy resin, certain properties of the cured coating are enhanced (and others are sacrificed) to obtain specific application properties.

CHEMICAL PROPERTIES

The total amine value of the polyamide is determined by potentiometric titration using ASTM Test Method D 2073: Test Methods for Total, Primary, Secondary, and Tertiary Amine Values of Fatty Amines, Amidoamines, and Diamines by Referee Potentiometric Method. Note, however, that the methods specified therein for primary, secondary, and tertiary amine values are not applicable to polyamides. The total amine value is commonly listed in the specification properties of commercial polyamides and is defined as the number of milligrams of potassium hydroxide equivalent to the basicity in 1 g of sample.

The acid value, generally less than 5, that is also specified in commercial polyamides is defined as the number of milligrams of potassium hydroxide required to neutralize 1 g of sample. The acid value may be determined using ASTM Test Method D 2076: Test Methods for Acid Value and Amine Value of Fatty Quaternary Ammonium Chlorides. The procedure specified for determining the amine value in Method D 2076 is not applicable to polyamides.

The imidazoline content is not specified in commercial polyamides except in special cases where the level is deemed critical. The level of imidazoline is usually controlled by the polyamide manufacturer to provide products with specific compatibility and/or solubility. Imidazoline level can best be measured by scanning the polyamide with an infrared spectrophotometer and comparing the absorption at 6.25 μm to the absorption at 6.05 μm. The imidazoline ring absorbs at 6.25 μm, and the nitrogen-bonded carbonyl, or amide, absorbs at 6.05 μm. The result is reported as either a ratio of imidazoline:amide (I/A) or as a percentage. In the example

reaction described previously, the imidazoline ratio would be 1.0 and the percentage would be 50%.

PHYSICAL PROPERTIES

Polyamides are supplied commercially in solution or as 100% reactive liquids depending on the handling and storage requirements of the coatings manufacturer. For ease of handling, they may be supplied in various solvents. Most polyamides suitable for coatings applications are quite viscous, and these polyamides are soluble in a variety of organic solvents including alcohols, glycol ethers, ketones, and aromatic hydrocarbons. Thus the coatings manufacturer has considerable latitude in selecting specific solvents for optimum applications properties.

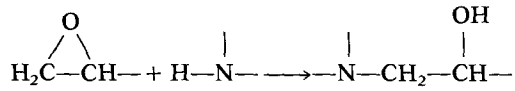
The percent nonvolatile content of polyamide solutions may be determined in accordance with ASTM Test Method D 1259: Test Method for Nonvolatile Content of Resin Solutions. Commercial polyamides are generally supplied in a single organic solvent at between 60 and 80% solids, which provides a handleable viscosity. The coatings formulator further dilutes the polyamide solution with more of the same solvent, or with a solvent blend, to form one component of the two-component system.

The polyamide component may be clear or may contain pigments in colored coatings formulations. The color of the polyamide or polyamide solution is determined in accordance with ASTM Test Method D 1544: Test Method for Color of Transparent Liquids (Gardner Color Scale).

The viscosity of the polyamide may be measured at elevated temperature in accordance with ASTM Test Method D 2196: Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer. The viscosity of commercial polyamides is typically specified at 75 or 150°C. The viscosity of polyamide solutions that may also be measured by this method is generally specified at 25 or 40°C. The viscosity of polyamide solutions may also be measured in accordance with ASTM Test Method D 1545: Test Method for Viscosity of Transparent Liquids by Bubble Time Method. A modification of this Method is usually used in which the polyamide solution is placed in a sample tube, the viscosity is compared to Gardner-Holdt Letter standard tubes, and the observation is reported as the alphabetic letter of the tube most closely matching the sample. A plus (+) or a minus (−) is then used to indicate that the viscosity is greater or less than the designated letter.

REACTION OF POLYAMIDES IN COATINGS

Polyamides react with epoxy resins in several stages to form a complex insoluble cross-linked matrix. The initial reaction is between the terminal primary amine groups of the polyamide and the oxirane ring of the epoxy resin. The active hydrogen opens the ring and the oligomers join end to end. This initial reaction can be represented by the following simplified structure.



The reaction of the oxirane ring and active hydrogen, which also occurs at the secondary amine sites in the polyamide, is one mechanism for the cross-linking that occurs. A secondary reaction occurs between pendant hydroxyl groups in the epoxy resin molecule and other oxirane rings present, which is another mechanism for the cross-linking reaction [3]. Because of this latter reaction it is desirable to mix the polyamide and epoxy in less than a stoichiometric ratio to provide coatings with maximum cross-link density. Such coatings will be characterized by excellent impact and chemical resistance but will tend to be less flexible. To provide more flexible coatings with greater elongation, the use of close to or greater than the stoichiometric ratio is recommended.

Polyamide/epoxy coatings contain organic solvents, which when applied appear to dry because of solvent evaporation. This early dry time is not, however, an indication of cure. Cure results from a chemcial reaction between the polyamide and epoxy resins that generally requires about 8 to 10 h before the film will resist mechanical deformation. Chemical resistance of the coating is not achieved before three to four days, and ultimate cure is achieved after about three weeks.

Polyamide/epoxy coatings may be applied by any conventional commercial applicator, including spray, brush, or roller. The coatings formulator may design the solvent system for a particular type of applicator. Polyamide/epoxy coatings may be applied to wood, concrete, or steel. For optimum adhesion to the substrate, the surface to be coated should be thoroughly cleaned and degreased. Polyamide/epoxy coatings are not normally applied to wood: when so used, the wood surfaces should be first cleaned thoroughly and any old loosely adhering paint removed. Concrete surfaces may be chemically acid etched or mechanically brushed. Steel surfaces should be sandblasted, if possible, or at a minimum should be wire brushed and chemically cleaned [4,5].

ENVIRONMENTAL/TOXICITY CONSIDERATIONS

In response to environmental concerns over the emission of organic compounds into the atmosphere, many coatings manufacturers have begun to produce high solids coatings that contain much lower levels of volatile organic compounds (VOCs). These products do not contain polyamides; instead, amidoamines are used, products formulated from monomer fatty acid rather than dimer acid [6]. A significant volume of polyamide/epoxy coatings continues to be used.

Though polyamides are less toxic than aliphatic amines and amine adducts, direct contact exposure with the skin, eyes, and the respiratory system must be avoided. Polyamide solutions must also be handled with care to avoid exposure to ignition sources as they contain flammable or combustible solvents and the vapor level from polyamide solutions must be monitored in the workplace to avoid overexposure to the organic solvents present.

Polyamide manufacturers supply material safety data sheets (MSDS), which should be consulted for hazard information and guidance on the safe use of the products. The MSDS also contains information regarding procedures to follow if a spill occurs, as well as guidelines for hazardous waste disposal. Those polyamide solutions that are classified as hazardous waste due to the presence of organic solvents must

be incinerated. Liquid (100%) polyamides are not generally classified as hazardous waste though their disposal may be regulated as an oil because of their liquid nature; these products must be either incinerated or absorbed by a suitable solid absorbent medium, such as a ground clay absorbent product, and placed in a sanitary landfill.

Though polyamides are reactive in the presence of epoxy resin, they are quite stable compounds when kept in a cool, dry environment, and they may remain unchanged for a year or more. Polyamides may be stored in drums or tanks constructed of stainless steel or aluminum. Carbon steel tanks should be avoided because of darkening of the product from iron contamination.

Polyurethane Coatings

by Joseph V. Koleske[1]

INTRODUCTION

THERMOPLASTIC POLYURETHANES WERE FIRST developed by Otto Bayer [*1,2*] in the Leverkusen laboratories of I. G. Farbenindustrie AG in 1937 [*3,4*] as they searched for a product that would be competitive with the polyamides, now known as nylons, that had been introduced by duPont. Shortly thereafter, Schollenberger and coworkers [*5*] used formula modification to prepare elastomeric polyurethane products from Bayer's products that were like nylon or other engineering plastics in physical characteristics.

Polyurethanes are widely used in coatings, flexible and rigid foams, elastomers, and composites. In an overall sense, the polyurethane business is huge and is concerned with rigid foams, flexible foams prepared in both slab and molded forms, elastomers, including reaction-injection-molded products, and coatings. Excluding coatings, the 1988 U.S. consumption of polyurethanes was about 2750 million lb (1.25 million metric tons) with the forecast for 1993 about 3150 million lb (1.43 million metric tons) [*6*]. In 1991, the national market for polyurethane coatings was about 209 million lb (95 000 metric tons) [*7*]. Although the market for polyurethane coatings is large and growing, it is readily apparent that it represents only about 5 to 10% of the total domestic polyurethane market. In 1991 consumption of polyurethanes for coatings in Western Europe and Japan was 301 and 100 million lb (137 000 and 46 000 metric tons), respectively [*7*]. Reasons for the use of polyurethane coatings include: high-performance characteristics such as flexibility, toughness, strength, and abrasion resistance; chemical resistance such as water, detergent, many industrial chemicals, and stain resistance; good light stability when aliphatic isocyanates are used; and low temperature-cure characteristics. The latter factor is a major reason for use of polyurethanes on plastic substrates.

DEFINITIONS

ASTM [*8*] defines *polyurethane coatings* as vehicles containing a minimum of 10% by weight on a nonvolatile vehicle basis of a multifunctional isocyanate monomer reacted in such a manner as to yield polymeric systems with urethane linkages, active isocyanate groups, or multifunctional isocyanate monomers in any ratio, proportion, or combination. Excess isocyanate groups capable of reacting at the time of application may be contained in the reaction products. ASTM has classified such polyurethanes into six general types [ASTM Terminology Relating to Paint, Varnish, Lacquer, and Related Products (D 16)] [*8*]:

Type I. "One-package prereacted" polyurethane coatings are characterized by the absence of any significant quantity of free isocyanate groups. They are usually the reaction product of a multifunctional isocyanate and a polyhydric ester of vegetable oil acids and are hardened with the aid of metallic dryers such as cobalt napthenate, manganese neodecanoate, and similar compounds. For example, linseed oil and glycerol may be first reacted and then modified with a diisocyanate that reacts with a part or all of the available hydroxyl groups. If any residual isocyanate is present, it is removed by addition of a monofunctional alcohol. Catalysts such as dibutyltin oxide and dibutyltin dilaurate are used to promote urethane-linkage formation. The coatings are also called uralkyds, urethane-modified alkyds, urethane alkyds, and oil-modified urethanes. Cure is achieved by the oxidative crosslinking of unsaturated fatty acid molecules. They are often used as automobile refinish coatings and wood and floor finishes because they provide improved scuff, water, and stain resistance over those of conventional alkyds.

Type II. "One-package, moisture cured" polyurethane coatings are isocyanate-terminated, polyester or polyether prepolymers that are capable of reacting with adventitious moisture to form mainly urea linkages between the molecules and the final coating is a polyurethane/polyurea coating. For the most part, these polyurethanes are used as clear coatings. They are often used as sealers for concrete and wood, floor finishes, and deck finishes.

Type III. "One-package, heat cured" polyurethanes cure or crosslink by thermal release of blocking agents which results in regeneration of active isocyanate groups that will subsequently react with active hydrogen groups contained in the formulation. The coatings are often used in coil coatings and electrical wire coatings.

Type IV. "Two-package catalyzed" polyurethanes are made up of one package that contains a prepolymer having free isocyanate groups and a second package that is a catalyst, initiator, accelerator, and/or crosslinking agent. Catalysts are compounds such as metal napthenates or tertiary amines. Initiators or crosslinking agents are glycols or other monomeric, multihydroxyl- or amine-functional compounds. Pot life is limited after the two packages are combined. These coatings are not widely used.

Copyright© 1995 by ASTM International

Type V. "Two-package polyol" polyurethanes coatings have one package that contains an isocyanate-terminated prepolymer or a multifunctional isocyanate and a second package that is made up of a polymer that contains active hydrogen groups. These relatively low molecular weight polymers are usually polyesters, polyethers, or acrylics. The second package may or may not contain a catalyst. After mixing the two packages, the systems have limited pot life. These coatings, which are high-solids in nature, are used in high performance areas such as automobile refinishes, original automotive equipment clear coats over pigmented decorative coatings, aircraft coatings, truck and bus coatings, and industrial-structure maintenance coatings.

Type VI. "One-package nonreactive lacquer" is a system that basically is a solution of a high molecular weight polyurethane (weight-average molecular weight from about 40,000 to 100,000). They are characterized by the absence of any significant quantity of free isocyanate groups, and they are converted into a solid film by solvent evaporation. The lacquers are low solids, about 10–15% by weight, in nature because of the high molecular weight involved and concomitant high viscosity of such molecules in solution. These films have very high gloss and are used in the textile industry to achieve the "wet look" that was popular in the late 1970s. They are used today for the popular cast or transfer-process fabric coatings as well as other fabric coatings.

Three other types of polyurethanes not included in the ASTM classifications are polyurethane and polyester- and polyacrylic-urethane powder coatings, ultraviolet light-curable urethanes, and waterborne urethanes [7]. The first two types have been considered as energy-activated materials and thus related to the ASTM Type III coatings.

CHEMISTRY

As with many phases of chemistry, one can consider the chemistry of urethane coatings in a simple or a complex manner. Simplistically, urethane coatings contain urethane linkages, —NHCO—, that are formed through a rearrangement reaction when an hydroxyl group reacts with an isocyanate group and that can be represented with monofunctional materials as follows

$$\mathrm{ROH} + \mathrm{R'NCO} \longrightarrow \mathrm{RO{-}\underset{\underset{\mathrm{O}}{\|}}{C}{-}\underset{\underset{\mathrm{H}}{|}}{N}R'}$$

In actual practice, functionalities of two or greater are usually involved. In addition, there are many ramifications of this reaction that will lead to the polyurethane products currently in use. It is interesting to note that urethane formation takes place through a rearrangement reaction and that no by-products are formed. The following information is meant to give the reader a brief excursion into the raw materials and some of the reactions that are important to polyurethane chemistry. Other linking groups that may be found in polyurethane coatings are allophanate, urea, biuret, and isocyanurate groups. These linkages will be discussed later.

Raw Materials

Isocyanates

Two types of isocyanates are used in coatings—aliphatic and aromatic. Polyurethanes prepared from either type isocyanate have excellent chemical and physical properties. Aromatic isocyanates are used in products where weathering resistance, particularly sunlight or ultraviolet light resistance, is not important because of discoloration, which almost always manifests itself as yellowing. Yellowing in itself is a loss of an aesthetic property, but its cause and result do not deleteriously affect mechanical properties. Ultraviolet light attacks the labile hydrogen atoms on the aromatic ring structure. Aliphatic isocyanates are less reactive and more costly than aromatic isocyanates and, while these factors can be cost considerations, aliphatic isocyanates are widely used for both interior and exterior applications.

The two main aliphatic isocyanates currently used are 4,4'-diphenylmethane diisocyanate (MDI) and toluene diisocyanate (TDI), which is a mixture of the 2,4- and 2,6-isomers. Moisture-cure urethanes and urethane alkyds usually employ TDI, though MDI has some use due to its low vapor pressure. Xylylene diisocyanate (XDI) is used to some extent, but mainly in Japan. Recently tetramethylxylylene diisocyanate (TMXDI) and isopropenyl dimethyltoluene diisocyanate (TMI) have been introduced by American Cyanamid. Naphthalene diisocyanate has also been used.

Aliphatic isocyanates are more costly, and they are used for urethane coatings that require excellent sunlight resistance and no discoloration. These coatings are used on plastics, automobiles, signs, and similar outdoor end-use products. The main aliphatic isocyanates are hydrogenated MDI (4,4'dicyclohexylmethane diisocyanate, HMDI, or H_{12}MDI), hexamethylene diisocyanate (HDI), particularly in a biuret or trimer form for improved vapor pressure, mixtures of 2,2,4- and 2,4-4-trimethyl hexamethylene diisocyanate (TMHDI), 1,4-cyclohexane diisocyanate (CHDI), and isophorone diisocyanate (3-isocyanatomethyl-3,5,5-trimethylcyclohexyl isocyanate or IPDI) [9]. IPDI and H_{12}MDI are the isocyanates most widely used in coating preparation.

Type III polyurethane coatings, including powder coatings, employ blocked isocyanates that provide room-temperature stable, one-package systems that are activated at elevated temperatures. At elevated temperatures, the molecules dissociate and the blocking group leaves, freeing the isocyanate functionality that then readily reacts due to its nature and the kinetic effect of elevated temperature with available active hydrogen groups. Blocking groups are proton donors such as ϵ-caprolactam, malonic, and acetoacetic esters as well as other enolizable esters, ketoximes, phenol, etc. For example, trimethylolpropane (TMP) can be reacted with TDI and then blocked by reacting the free isocyanate groups with phenol:

$$\underset{\text{TMP}}{\mathrm{C_2H_5C(CH_2OH)_3}} + \underset{\text{TDI}}{\mathrm{C_6H_3(CH_3)(NCO)_2}} \longrightarrow \underset{\text{ISOCYANATE-TERMINATED ADDUCT}}{\mathrm{C_2H_5C(CH_2OCONH{-}C_6H_3(CH_3){-}NCO)_3}}$$

$$\underset{\text{ISOCYANATE-TERMINATED ADDUCT}}{\mathrm{C_2H_5C(CH_2OCONH{-}C_6H_3(CH_3){-}NCO)_3}} + \underset{\text{PHENOL}}{\mathrm{3\ C_6H_5{-}OH}} \longrightarrow \underset{\text{PHENOL-BLOCKED TRIISOCYANATE}}{\mathrm{C_2H_5C(CH_2OCONH{-}C_6H_3(CH_3){-}NHOCOC_6H_5)_3}}$$

Technology such as this is used in polyurethane powder coatings.

Active Hydrogen Sources

Isocyanates readily react with active hydrogen sources such as hydroxyl groups and amines. Hydroxyl groups are usually supplied by polyfunctional compounds such as glycols, triols, tetraols, polyester polyols, polyether polyols, acrylic polyols, and polylactone polyols. Polyether polyols are usually poly(propylene oxide) polyols that may or may not be copolymerized with ethylene oxide in a random manner or in an end-capping manner to provide primary hydroxyl end groups. These polyols, which are described in detail elsewhere in the manual, are usually di- or trihydroxyl functional compounds, though higher functionalities are used in special cases, that have number-average molecular weights of from about 200 to 3000. Polyols function as soft segments and impart flexibility to polyurethanes [*10*]. As would be expected, primary hydroxyl groups react much more rapidly than secondary hydroxyl groups, and tertiary hydroxyl groups react slower than either other type. For example, primary hydroxyl groups reacted about 3.5 faster with phenyl isocyanate than secondary hydroxyl groups and about 200 times faster than tertiary hydroxyl groups [*11*]. It was also found that *n*-butanol reacted five times faster with the isocyanate group in the para- or 4-position group than with the isocyanate next to the methyl group in 2,4-toluene diisocyanate. This demonstrated that neighboring groups can significantly affect isocyanate reactivity.

Low-molecular-weight or monomeric compounds are used as chain extenders when preparing polyurethanes [*12*], and these chain extenders in combination with the isocyanates are termed "hard segments" that function as pseudocrosslinks [*13*]. In high-molecular-weight polyurethanes, such as those used for Type VI products, these chain extenders represent only a few percent of the total polymer molecular weight yet play a significant role in final physical properties. Glycols and low-molecular-weight triols require relatively large amounts of isocyanates, usually the most costly ingredient, and impart hardness and rigidity to the final coating. These compounds are also used as initiators for preparation of the various polyols with glycerol often used for poly(propylene oxide) polyols and with glycols and triols such as 1,4-butanediol, diethylene glycol, trimethylolpropane, and the like, often used for polylactone polyols. Polyesters other than polylactones are prepared from difunctional carboxylic acids, particularly adipic acid, and glycols, particularly ethylene glycol, diethylene glycol, butanediols, and 1,6-hexanediol. An excess of glycol is used to ensure that most end groups in the polyester are hydroxyl groups. Acrylic polyols are prepared from hydroxy functional compounds, particularly 2-hydroxyl ethyl and 2-hydroxypropyl acrylate and methacrylate, other acrylates and methacrylates, and other ethylenically unsaturated, copolymerizable monomers. Examples of such monomers are ethyl acrylate, butyl acrylate, styrene, vinyl esters, etc. Epoxide, silicone, vinyl, phenolic, and oligomers that contain hydroxyl groups are also reacted with isocyanates to form urethane linkages and accompany property enhancement in specialty finishes. The epoxide, vinyl, and phenolic-based materials have good chemical resistance, and the silicone-based materials have good thermal resistance.

Polyfunctional amines, which form urea linkages with isocyanates, are also used as chain extenders. Low-molecular-weight compounds such as ethylenediamine are used as chain extenders to make polymers for Type VI lacquers. Amine-terminated oligomers based on the alkylene oxides are available [*14–16*].

Catalysts

Catalysts are often used to promote the reaction between isocyanates and hydroxyl-containing compounds. Only small amounts, on the order of 10 to 100 parts per million, of catalyst are needed to cause marked increases in reaction rate. Popular catalysts include dibutyltin dilaurate, stannous octoate, and zinc octoate. Diaza(2.2.2)bicyclooctane (DABCO), dibutyltin diacetate, bismuth stearate, and zirconium octoate have been used.

Reactions

As indicated above, hydroxyl groups react with isocyanates to form polyurethanes. Multifunctional reactants are used to link molecules as in Type I urethane alkyd [*17*] to cause molecular chain length increase in either a prereaction to form the final polyurethane that could be used in a Type VI lacquer coating or to form prepolymers that are later reacted in two-package coatings as would be used in Type IV and Type V coatings. In other instances, multifunctional (usually difunctional) isocyanates are used to end cap diols, triols, and tetraols with isocyanate functionality as is needed for Type II, IV, and V coatings. Both hydroxyl-functional and isocyanate functional prepolymers are used. For example:

$$\underset{\text{DIOL}}{\text{HO—R—OH}} + \underset{\text{DIISOCYANATE}}{2\,\text{OCN—R'—NCO}} \longrightarrow \underset{\text{ISOCYANATE-TERMINATED PREPOLYMER}}{\text{OCN—R'NHCOO—R—OOCNHR'—NCO}}$$

$$\underset{\text{DIOL}}{2\,\text{HO—R—OH}} + \underset{\text{DIISOCYANATE}}{\text{OCN—R'—NCO}} \longrightarrow \underset{\text{HYDROXYL-TERMINATED PREPOLYMER}}{\text{HO—R—OOCNH—R'NHCOO—R—OH}}$$

Other prepolymers can be prepared by reacting, for example, an hydroxyl-terminated prepolymer with two molecules of diisocyanate to produce an isocyanate-terminated prepolymer that contains urethane linkages in the central portion of the prepolymer. It should be apparent that this method of chain extension cannot be carried too far since viscosity will increase very rapidly as chain extension takes place, which is not a desirable result if materials for high-solids or other energy-conserving formulations are produced.

Moisture-cure polyurethanes are molecules with free isocyanate end groups. Sufficient quantities of isocyanate are reacted with polyols such that there are more equivalents of isocyanate groups compared to hydroxyl groups. For example, a trifunctional oligomer or polyol can be reacted with an isocyanate under moisture-free conditions and then packaged under moisture-free conditions.

$$\text{OLIGOMER(OH)}_3 + 3\,\text{R'(NCO)}_2 \longrightarrow \text{OLIGOMER(O—CONHR'NCO)}_3$$

Exact ratios of hydroxyl to isocyanate are seldom used, and final free isocyanate content usually ranges between about 3 and 16% [7]. Moisture-free conditions are achieved by blanketing the system during preparation and storage with dry nitrogen. Since these products are almost always prepared in solution, the solvent used for the reaction and for any dilution to final product must be carefully dried to exclude moisture. Solvent drying can be done with molecular sieves. When applied to a substrate and contacted with ambient moisture, these products cure by reaction with water to form an unstable carbamic acid intermediate that dissociates into an amine and carbon dioxide. The amine in turn rapidly reacts with isocyanate to form a urea linking group. This can be described by the following reaction scheme:

$$-R'NCO + H_2O \longrightarrow \underset{\text{CARBAMIC ACID, AN UNSTABLE INTERMEDIATE}}{[-R'NHCOOH]} \longrightarrow -R'NH_2 + CO_2 \uparrow$$

$$-R'NCO + -R'NH_2 \longrightarrow \underset{\text{UREA LINKAGE}}{-R'NHCONHR'-}$$

$$-R'NCO + -R'NHCONHR'- \longrightarrow \underset{\text{BIURET LINKAGE}}{-R'NHCON(CONHR-)R'-}$$

The first reactions leading to urea linkages predominate. These systems cure relatively slowly, which allows time for the evolved carbon dioxide to leave before it is undesirably entrapped in the solidifying film. Biuret linkages are formed in thermally accelerated systems, particularly at 100°C or higher, and they contribute to cross-linking (note that biurets can be equivalent to trifunctional isocyanates). Even though these cured films, strictly speaking, are urethane/urea polymers, they are usually referred to as polyurethanes.

Isocyanates will also react with urethanes to produce allophanate linkages.

$$-R'NCO + -R'NHCOOR'- \longrightarrow \underset{\text{AN ALLOPHANATE LINKAGE}}{-R'N(CONHR'-)COOR'-}$$

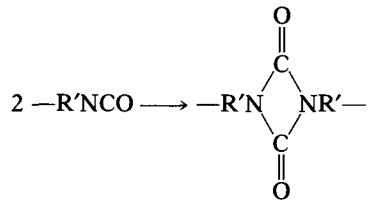
Isocyanates are less reactive with urethanes than with ureas, and temperatures of about 120 to 140°C are required to give a significant reaction rate for the formation of allophanate linkages. Allophanate formation results in branching in the polymeric network.

Carboxylic acids will react with isocyanates to form unstable mixed anhydrides that decompose into an amide and carbon dioxide.

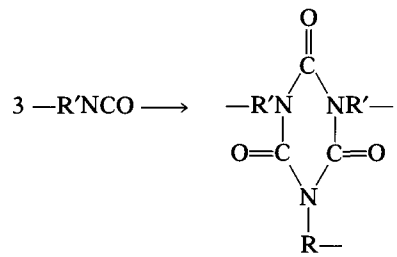
$$R'NCO + RCOOH \longrightarrow \underset{\text{MIXED ANHYDRIDE}}{R'NHCOOCOR} \; 2 \longrightarrow \underset{\text{AMIDE}}{R'NHCOR} + CO_2 \uparrow$$

This reaction is important to keep in mind when polyesters prepared from glycols and dicarboxylic acids are used or when acid numbers are unexpectedly high in polyether, polylactone, or other polyols. The end product of this reaction results in stoppage of chain growth and a lower than expected molecular weight. In most cases this is undesirable. Amides will react with isocyanates to form acyl ureas.

Isocyanates will dimerize (aromatic) to form uretidine diones and trimerize (aromatic and aliphatic) to form isocyanurates. These reactions decrease the expected equivalent weight of isocyanates, a cost factor, and will lead to branching, cross-linking, and unexpected molecular weight increases which often are undesirable in various polyurethane formulations.



URETIDINE DIONE



ISOCYANURATE

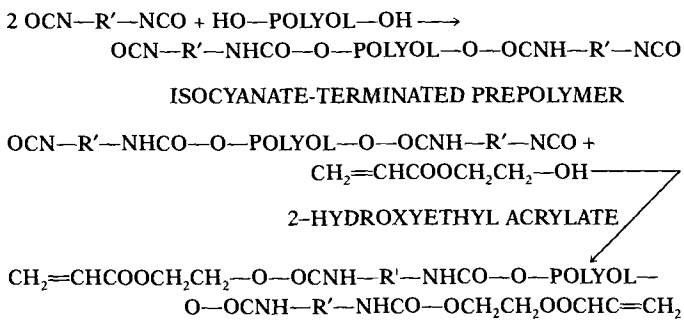
Thermoplastic Polyurethanes

Thermoplastic polyurethanes are used in Type VI lacquers and in many industrial end uses that require solid products. Their chemistry is similar to that of prepolymers except short-chain extenders are used to connect the prepolymer molecules and build them into long polymeric materials. In a structural sense, they may be described as linear block copolymers of the AB_n type. One of the blocks is a relatively long, number-average molecular weight of about 300 to 3000, polyether or polyester that forms the soft or flexible segment. The other block is formed by the reaction of a diisocyanate and a low-molecular-weight diol chain extender. The polar nature of the urethane linkages in the hard segment results in hard segment aggregation and domain segregation from the soft segment. The hard segments act as pseudo cross-links, and as a result tough, strong, elastomeric macromolecules are formed.

In a mole sense, these polymers can be viewed as polyol/diisocyanate/short-chain extender polymers that are formed in an equivalents ratio of $1/X/(X - 1)$. The number X can vary from 1 or less to as much as 20 or more, though more typically in coatings X has a value of one or less to about 3 or 4 [*10,13*]. Because of solubility characteristics, a ratio of about 1/2/1 is often used. A small excess of hydroxyl groups is used to keep final free isocyanate content and storage reactivity at a nil level. When the wide range of values of X, the types of isocyanates, the types and functionalities of polyols, and the range of polyol molecular weight available is considered, it is readily apparent that a myriad of polyurethanes can be prepared and that a broad range of mechanical and chemical properties can be achieved. The chemistry is basically isocyanates reacting with hydroxyl groups to form urethane linkages.

Radiation-Curable Urethanes [18–20]

Acrylate-terminated polyurethanes are used in a number of ultraviolet light and electron beam curable formulations. The products are termed "urethane acrylates" or "acrylated urethanes." They are prepared by first forming an isocyanate-terminated prepolymer from a polyol and then end capping the prepolymer with an hydroxy acrylate such as 2-hydroxyethyl acrylate. The reactions leading to urethane acrylates are almost always carried out in an inert solvent.

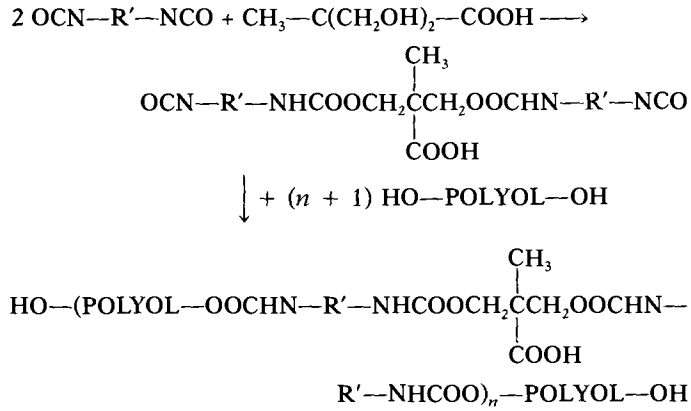


The reactions as depicted above have been idealized. In all commercial and most laboratory preparations there is a significant amount of reaction between the ingredients so that chain extension occurs and molecular weight increases. This causes the final product to have a markedly higher-than-expected viscosity. Oligomeric compounds such as these are formulated with triacrylates such as trimethylolpropane triacrylate to provide cross-linking, monomeric acrylates, N-vinyl pyrrolidone, or other compounds for viscosity reduction to provide low-viscosity, essentially 100% solids systems that will cure when exposed to actinic radiation. In formulations, the urethane acrylate is considered as the main ingredient contributing to mechanical properties of the cured film. When the actinic radiation source is ultraviolet light, a photoinitiator (for example, 2,2-diethoxyacetophenone or benzophenone in combination with an amine synergist, etc.) is added as a free radical source. Electron beam curable formulations do not require a photoinitiator.

Radiation-cured polyurethanes are often used on plastic substrates that require only low or moderate curing temperatures such as clear overprint lacquers on vinyl decals, electronic circuit boards, "no wax" vinyl flooring, and tile. Although radiation-cured colored and pigmented inks and coatings are used in the marketplace, the skill needed in preparing such products, because of difficulty with light penetration or absorption, is readily apparent.

Water-Borne Polyurethanes

Water-borne polyurethanes are prepared in bulk or in a solvent by first preparing an ionomer prepolymer that is neutralized and then chain extended to a desired molecular weight. The polymer then is dispersed into water. Both cationic [21,22] and anionic [23,24] systems are known. Cationic systems employ an amine-containing diol such as diethanolamine, methyl diethanolamine, *N,N*-bis(hydroxyethyl)-α-aminopyridine, lysine, *N*-hydroxyethylpiperidine, and similar compounds. Anionic systems use a carboxylic acid-containing diol such as dimethylolpropionic acid (2,2-bis(hydroxymethyl) propionic acid), dihydroxybenzoic acid, sulfonic acids as 2-hydroxymethyl-3-hydroxypropanesulfonic acid, and similar compounds. For example:



Water-borne polyurethane laminating adhesives that are completely free of volatile organic compounds are expected to be the next developments in this area [25]. These adhesives are expected to be for the low-to-medium demand product area such as for snack food and similar packaged products.

Powder Coatings

Polyurethane powder coatings are usually urethane-modified polyesters and polyacrylics that cure at high temperatures. High temperatures are needed for the powdered polymer to flow and level to the extent needed for a particular end use. The key to successful powder coatings is related to a balance between molecular weight and related viscosity and a cross-linking mechanism that is stable under storage conditions and not effected to any significant degree until flow and leveling takes place at the cure temperature. Another requirement is that the glass transition temperature should be sufficiently high that the powder does not block during storage. The main end use for powdered polyurethanes is in the major appliance market—refrigerators, dryer drums, range cabinets, etc.—coatings.

MARKETS

Polyurethanes of the various types are used in a number of market areas and end uses. Many of these were mentioned above. Two features of polyurethane coatings that have been often looked on as disadvantages are high cost and special handing of the potentially hazardous isocyanates that are used in manufacture or as curing agents. However, the various industry segments have been able to develop safe handling and use methods that overcome one of the objections. The very high performance characteristics of polyurethanes, their ability to cure at lower baking temperatures, and the

improved total coating solids, i.e., decreased volatile organic compound content, that can be obtained are factors that offset their high cost. For example, polyurethanes are replacing poly(vinyl chloride) plastisols as undercoatings and sealants in the automotive and other transportation coating market. Lower coating thickness and equivalent or improved performance make the applied cost of the polyurethane competitive with the plastisol. The textile area is a moderate growth area for thermoplastic polyurethane lacquers with the excellent combination of properties as the main driving force for use. These include good elasticity at low temperatures, abrasion resistance, solvent and water resistance, dry cleanability, machine washability, and an ability to be prepared in a broad variety of tensile/elongation properties. In addition, the high performance can be achieved with very thin coatings that do not markedly increase fabric weight or change styling factors such as drape. To decrease volatile organic content, new low-viscosity, aliphatic isocyanates [*26*] and polyurethane polyols [*27*] are being developed. Although it is not a complete listing, Table 1 is a summary of many end uses for polyurethane coatings.

In the five-year period between 1991 and 1996, it is estimated that the U.S. polyurethane coating market will grow at a compounded annual rate of 5% or from 209 million lb to 265 million lb (95 000 to 123 400 metric tons) [*7*]. It is expected that the two-package (ASTM Type IV and V) systems will have almost double the compounded annual growth rate of the overall urethane coating market, i.e., about 10%, with consumption rising from 84 million lb in 1991 to 133 million lb in 1996 (38 200 to 60 500 metric tons). Waterborne and powdered polyurethanes are also important growth areas.

Silicone Coatings

by D. J. Petraitis[1]

UNIQUE PROPERTIES OF SILICONES THAT MAKE THEM USEFUL AS COATINGS

Silicone based coatings are among the most useful materials for a wide variety of applications. Because the basic bond energies of Si—C and Si—O bonds are so high, the chemical processes usually associated with aging of coated surfaces are often much slower and in many situations virtually eliminated for silicone coatings. Also, because the Si—O and Si—C bonds are not present in the natural organic world, biocompatibility and resistance to degradation via biochemical and biophysical processes are also significantly reduced. In a similar manner, some silicone resinous coatings and fluorosilicone based coatings, in particular, have excellent solvent resistance.

Silicone coatings based on trifluoropropyl methyl polysiloxanes have resistance to swelling from such agents as gasoline, jet fuel, solvents, and various other reagents. Highly branched resinous silicone coatings chemically begin to approach the properties of silica surfaces as the organic pendant content is reduced. As the organic pendant groups are reduced, the $SiO_{4/2}$ content increases and the chemical resistance increases. Such resinous coatings can provide physical scratch resistance as well as chemical resistance. Silicone elastomeric coatings, however, do not provide good resistance to strong acids and/or bases. Strong acids or bases, in particular at elevated temperatures, can cause depolymerization of the siloxane backbone, resulting in failure, or in the case of silicone elastomeric coatings, dissolution of the coating itself.

In a similar manner, silicone coatings are resistant to virtually all frequencies of the electromagnetic spectrum. For complaint coatings, silicones are unsurpassed in resistance to hard radiation, such as that from a cobalt-60 source for doses in excess of 20 Mrd, as well as the ultraviolet and infrared frequencies. When combined with their hydrophobicity and oxygen and ozone resistant properties, silicones provide excellent weatherability characteristics, and when these properties are combined with the resistance to atomic oxygen in low earth orbit, silicone coatings provide protection for organic substrates in varied spacecraft applications.

Another family of applications which combine the chemical and biochemical characteristics of silicones are those which are used to provide coatings for medical devices. Silicone coatings are used to encapsulate and seal permanent implants such as heart pacemakers. They have also been used to coat temporary implants such as catheters and surgical drains. Also, thin silicone elastomer coatings are used to provide soft tissue replacements by forming an envelope to encapsulate gels and/or normal saline solutions. Recent applications for biocompatible silicone coatings include drug delivery devices for both transdermal and long-term implantable, controlled-release drug delivery.

A final characteristic which makes silicone coatings useful is their inherently low or nonflammability. Typically, silicone elastomer coatings have been rated SE-1 when tested via Underwriters' Laboratories Flame Test (UL-94). This property makes silicone coatings ideal for conformal coating of various electrical circuits and devices. In the event of catastrophic thermal degradation, the silicone coatings can and do provide an SiO_2 ash coating which may permit the emergency operation of the electrical device on a short-term temporary basis.

FORMS OF SILICONE COATINGS

Silicone coatings are available in various forms ranging from a hard, rigid resin to a compliant elastomer to a soft, almost gel-like character. The rigid resins are typically supplied in a solvent solution and are mixed with curing agents prior to application. Among the most common curing agents are lead and zinc octoate, which require approximately 1 h at 250°C to attain complete cure. The cross-linking mechanism involves the condensation of silanol groups

$$\equiv SiOH + HOSi\equiv \longrightarrow \equiv SiOSi\equiv + H_2O$$

Specific coating applications include jet engine components, furnace parts, incinerators, high-temperature appliances, and missile coatings. In addition, specific silicone resins have been designed to mix with organic coatings and paints, providing higher performance under moderate heat environments.

By varying the R group:Si ratio, the hardness of the final coatings can be varied. As the R:Si ratio is decreased, the cross-link density of the resin effectively increases. Similarly, variation of the R group itself can result in somewhat different flexibility and other properties. Properly designed and condensed resins can be formulated to provide hard silica-like abrasion-resistant coatings. Such coatings often involve the condensation of alkoxy groups with silanol groups as well as condensation between silanol groups alone. Technology to minimize shrink and maximize adhesion during the cure

[1]Vice president, Operations, NuSil Technology, 1040 Cindy Lane, Carpinteria, CA 93013.

Copyright© 1995 by ASTM International

needs to be incorporated to prevent cracking and subsequent flaking of the coating from the substrate. Aminofunctional alkoxy silanes are often incorporated into the formulation to simultaneously optimize cure rate and adhesion.

Silicone elastomeric coatings incorporate the use of polymeric siloxanes with appropriate cross-linkers to provide compliant, flexible coatings. Among the cure mechanisms which result in elastomers are the following

1. $\equiv SiOH + HSi\equiv \xrightarrow{Sn} \equiv SiOSi\equiv + H_2$
2. $\equiv SiOH + CH_3COOSi\equiv \xrightarrow[H_2O]{Sn} \equiv SiOSi\equiv + CH_3COOH$
3. $\equiv SiOH + ROSi\equiv \xrightarrow{Sn} \equiv SiOSi\equiv + ROH$
4. $\equiv SiCH{=}CH_2 + HSi\equiv \xrightarrow{Pt} \equiv SiCH_2CH_2Si\equiv$
5. $\equiv SiOH + R_2NOSi\equiv \xrightarrow[H_2O]{Sn} \equiv SiOSi\equiv + R_2NOH$

These elastomeric coatings can range from extremely tough, high-strength elastomers to soft gel-like coatings. Typically, the elastomer could have properties within the following ranges:

Durometer:	Type 00 = 10
	Type A = 70
Tensile Strength:	0.34 to 13.8 MPa
Elongation:	50 to 1500%
Tear Strength:	0.88 to 43.8 kN/m

The properties and the cure systems which are chosen for these elastomeric coatings depend, to a large extent, on the end use and the method of application. For instance, the SiOH + HSi (No. 1) mechanism is often used to provide release coatings for backing paper for pressure sensitive adhesives. The actual coating itself has poor strength but attains its properties by simply impregnating the substrate.

The acetoxy cure system (No. 2) is used where one-part convenience is desired, where relatively slow cure is acceptable, and where acetic acid given off during the cure is not a problem.

The oxime (No. 5) cure system provides many of the properties of the acetoxy cure system, but results in an oxime leaving group instead of an acetic acid leaving group. Among the applications for the oxime cure systems are coatings for electronic components and protection for organic composites to prevent atomic oxygen degradation, and coating of quartz blankets to provide adequate emissivity and reflectivity characteristics for certain thermal protection surfaces on the space shuttle. The alkoxy 2-part (No. 3) cure system, when combined with certain thermal enhancing fillers such as iron oxide, glass microballoons, and various fibers, is often used to provide ablative and thermally insulating coatings. Various products incorporating the alkoxy two-part cure system are used to protect surfaces and components exposed to plume radiation from various rocket motors and jet engines.

The addition cure system (No. 4) has characteristics which permit rapid heat-accelerated cure, tough physical properties, virtually nil shrinkage, and, due to the platinum catalyst, the best overall flame resistance. Applications include solar cell protection, particularly for satellites, and burn-through protection for the liners of solid rocket motors. The only negative characteristic of the addition cure system is its susceptibility to inhibition. Because the system contains parts-per-million levels of platinum catalyst, it can be readily "poisoned." Among the most common inhibitors are sulfur-containing organic rubbers and organo-tin compounds which are often used as plasticizers in plastics and also as catalysts for other silicone coatings.

There are other silicone elastomeric cure systems, and one of the most significant applications is to coat fiberglass blankets for fire resistance. Spark protection welding blankets are a common application for peroxide-cured silicone coatings. Since peroxide-cured silicones require higher temperature cures, their usefulness is constrained by the substrate upper temperature limits. Also, selectivity of the specific peroxide is critical to prevent poor cures due to the oxygen inhibition; characteristic of many peroxides.

Another novel silicone elastomer coating which has been developed is a combination cure involving the ultraviolet photoinitiation via free radical formation to provide cross-linking. This ultraviolet mechanism is often combined with a standard cure mechanism to provide a combination cure. This system provides quick surface cure followed by the slower room temperature cure of unexposed, shadowed areas to ultimately provide a fully cured conformal coating. Processes using the combination cure can be used to minimize the time and space required to hold the coated parts until cure is completed before downstream assemblies can take place.

Other cure systems have been developed for silicone elastomers, but they find limited use as coating materials and were generally developed for specific applications such as building sealants or glazing compounds.

The most common form for silicone coatings is a dispersion of the silicone in solvent. If the coating is based on a tough elastomeric silicone, the uncured elastomer base is most commonly described as a dispersion because it contains insoluble components such as high surface area fumed silica for reinforcement and often other solid components such as titanium dioxide pigments for coloration or reflectivity properties. The carrier solvent for these dispersions may include chlorinated hydrocarbons, fluorochlorohydrocarbons, and both aromatic and aliphatic hydrocarbons. The dispersions also often include blends of solvents to provide the proper combinations of flow, evaporation, and application ease. Among the most common solvents for silicone dispersions are 1,1,1-trichloroethane, VM&P naphthas, and xylene. Low-molecular-weight alcohols such as ethanol and isopropanol and ketones such as acetone are not suitable because silicones are generally incompatible with these lower-molecular-weight oxygen-containing solvents. Fluorosilicones require the use of such solvents as methyl ethyl ketone and methyl isobutyl ketone for adequate dispersing. Fluorosilicone-dimethyl copolymer-based silicones can be dispersed adequately in 1,1,1-trichloroethane for thin layer application.

True solutions can also be made if the silicone contains no insoluble components. For example, true solutions can be made for unfilled silicones or for silicones that are resin reinforced. These coatings have limited use, however, because the final cured elastomeric coating lacks the overall toughness of the filled materials.

Recent developments have resulted in silicone coatings which have not involved the use of solvents. Because of environmental concerns, the use of solvent carriers for dispersions and solutions has become less desirable. In particular, fluorochlorocarbons and chlorinated hydrocarbons, despite

their low toxicity and nonflammability, are being phased out because of Montreal Protocol Agreements. Similarly, hydrocarbon solvents are undesirable because of their flammability, toxicity, and environmental effects. Silicone-based conformal coatings have been developed without solvent carriers. However, thin layer applications are difficult unless the viscosity is low enough to permit proper coating. Unfortunately, the technology for high-strength, low-viscosity, 100% solids, silicone coating does not exist. The current products, therefore, when cured, are very low strength and do not provide coatings that are resistant to handling. Research is ongoing to develop water-based dispersions, but to date, the demonstrated physical properties, although higher than the 100% solids coatings, are significantly less than the current solvent-based silicone coatings.

Methods of Applications

The methods of applications for silicone coatings depend on the device being coated and the specific type of silicone being used. Dipping, spraying, and painting are the most common types of application. The thinnest coatings result from spraying of two solvent dispersion utilizing standard aerosol spray guns. Needless to say, experience involving aerosol spraying is critical for acceptable coatings. Among the variables to consider are the following: viscosity, solvent, percent solids, pot life, and cure system choices.

The most securely sealed surface layer is accomplished by dip coating. Again, variables including solvent, bath life, and cure systems must be optimized. Additionally, the evaporation of solvent during the dip processing needs to be compensated for by periodically or continuously adding make-up solvent to maintain optimal bath viscosity. If a one-part humidity-actuated cure system is used, consideration must be given to provide a dry blanket over the bath to prevent a partially cross-linked elastomeric skin from forming. Dry argon is often utilized to prevent moisture in the air from reacting with the silicone base coating. Another consideration for the dip coatings is the possibility of air bubble inclusion. Again, several variables need to be considered. Low viscosity, controlled immersion and withdrawal rates, and vibration of the bath and/or object to be coated can be used to minimize bubble entrapment. Similarly, the use of two distinct solvents with different rates of evaporation are often used to ensure uniform coating with minimal drip regions and minimal bubble formation.

Painting or brush coating substrates is yet another method to apply a uniform silicone coating. Painting, however, is usually not applicable for either large areas or mass production coatings. For painting application, virtually all of the variables discussed in the above dipping and spraying also apply.

Regardless of the methods of application, the cure parameters demand significant considerations. Vacuum exposure may be used to remove air bubbles and to ensure flow under surface irregularities or impregnation of porous substrates. Vacuum treatment may also be used to enhance removal of the solvents, but care should be taken to prevent evaporation of the reactive volatile components which would prevent cure even after removal from the vacuum. Of course, most commonly, the vacuum removal of solvent is unwarranted and therefore solvent is merely evaporated at ambient pressures. The solvent evaporation can also be enhanced by air circulation and by acceleration with heat. However, the application of heat should be limited or applied in a stepwise manner to prevent solvent entrapment below the surface resulting in solvent bubble formation. Also, for one-part silicone coatings which are cured via moisture activation, it is ineffective to use heat acceleration because humidity is obviously reduced in a normal air circulating oven. If accelerated cure is required for one-part coatings, a steam autoclave may be used, *but only after all of the carrier solvent is removed.*

TESTING CONDITIONS

The test requirements for silicone coatings include MIL-I-46058C for qualifying silicone coatings as insulating compounds for electrical coating applications of printed circuit board assemblies. MIL-I-46058C includes the following tests:

Curing Time and Temperature
Appearance
Coating Thickness
Fungus Resistance
Insulation Resistance
Dielectric Withstanding Voltage
Leakage Current Testing
Q Resonance
Q Resonance after Immersion
Thermal Shock
Flexibility
Thermal Humidity Aging
Flammability

Materials which are used in applications for spacecraft are tested via ASTM Test Method for Total Mass Loss and Collected Volatile Condensable Materials from Outgassing in a Vacuum Environment (E 595). This test is used to determine the amount of collected volatile condensable material and total mass loss that eludes from a material when exposed to 125°C for 24 h at vacuum less than 5×10^{-5} torr. Basically, the maximum CVCM value for coatings intended for space applications is 0.1% and the maximum TML is 1.0%. The coatings intended for satellite applications require these high levels of purity to prevent the contamination of solar cells, optical surfaces, and other sensitive instrumentation. For most silicone materials, extended devolatilization is required for the polymeric components prior to compounding into the finished product.

For silicone elastomeric coatings, the physical properties of the cured elastomer are critical parameters. The tensile strength, elongation, and modulus are defined in ASTM Test Methods for Rubber Properties in Tension (D 412). Durometer and tear strength measurements are defined in ASTM Test Method for Rubber Property—Durometer Hardness (D 2240) and ASTM Test Method for Tear Strength of a Convential Vulcanized Rubber and Thermoplastic Elastomer (D 624) respectively. The viscosity, nonvolatile content, and specific gravity tests are defined in ASTM Test Method for Viscosity of Adhesives (D 1084), ASTM Test Method for Weight Loss of Plasticizers on Heating (D 2288), and ASTM Test Method for Specific Gravity (Relative Density) and Density of Plastics by Displacement (D 792), respectively.

Other tests have been developed for silicone coatings to meet the requirements of specific applications. Included among these are the "blocking" test to determine the propensity of silicone coatings to cause "sticking" to contacted surfaces after application and cure. This test involves contact between the silicone-coated surface and the surface to be tested by subjecting the interface to an applied pressure for a fixed time followed by measurement of the force needed to reseparate the surfaces. A variety of tests have been developed to measure the adhesive force of the coating on the substrate. Again, a number of tests which are oriented toward the specific application have been developed and revised.

SPECIFIC APPLICATIONS FOR SILICONE COATINGS

Among the varied applications for silicone coatings is the conformal coating of electronic circuit boards. Because of their previously described stability properties, silicones make ideal conformal coatings. Silicone coatings typically have stiffening points of −65°C, and can be formulated with stiffening points as low as −115°C. This makes them ideal for extreme environment electronic device protection.

Silicone coatings are used almost exclusively to provide protection from atomic oxygen degradation in low earth orbit (approximately 100 to 500 miles high). Atomic oxygen degradation is significant enough to rapidly erode and degrade organic substrates including epoxies, urethanes, and polyester-based thermosets. Coating protection permits the use of composite materials in space applications where the advantages of high strength and low weight associated with composite materials would be unusable due to their atomic oxygen degradation.

The high-temperature stability and excellent dielectric properties of silicone resins make them ideal impregnant coatings for high-energy capacitors used in jet engine ignitions. The inherent stability of silicone coatings when combined with specific fillers including zinc oxide, titanium dioxide, and zinc orthotitanate are often used to provide specific emissivity and reflectance required for thermal control coatings. Similarly, silicone elastomeric coatings are produced by the addition of iron oxide, glass or ceramic microballoons, and graphite fibers, which provide ablation protection. Launch vehicles, launch equipment, and thrust reversers are often coated with specially formulated silicone ablative coatings. The incorporation of phenyl siloxanes into the basic silicone polymeric species provides increased ablative properties, and various copolymers—including silicone-boranes and silphenylenes—have and are being evaluated to provide protection from impingement of high-energy lasers.

As discussed previously, the biocompatibility of silicones makes them ideal for medical applications. Coating permanent implants as well as temporary implants with silicones provides improved safety and efficacy. Foley catheters coated with silicone elastomers result in less patient discomfort and reduced infection rates. For similar reasons, temporary pressure-sensitive silicone adhesive coatings are used to provide adhesion directly to the skin. Combinations of silicone coatings are being investigated for use in various drug delivery devices. Specifically layered coatings of silicones impregnated with drugs can be used for transdermal drug delivery. When combined with a silicone pressure sensitive adhesive, a complete system of controlled drug delivery devices can be fabricated.

NEW REQUIREMENTS FOR SILICONE COATINGS

Research and development efforts continue to provide silicone coatings with even more stringent requirements and specifications. Electrical coatings with semiconducting properties for electronic applications and elastomeric coatings with volume resistivities in the 10^{-4} to 10^{-5} ohm-centimetre range are being investigated. Silicone coatings with variable electric properties are also being researched.

Similarly, silicone coatings which provide specific biological properties are also being developed. Specifically, hydrophilic silicone coatings are being developed for reduced thrombogenicity, and microporous coatings are under development for controlled tissue in-growth response.

Vinyl Resins for Coatings

by Richard J. Burns[1]

VINYL RESINS FOR COATINGS

Definition

THE VINYL RESINS USED IN solvent-based coatings, inks, and adhesives are low-to-medium molecular weight co- and tercopolymers of vinyl chloride, vinyl acetate, or other monomers to improve solubility. Functional monomers contribute specific properties; thus, carboxylic acid-containing monomers provide adhesion, while hydroxyl-containing monomers contribute to reactivity, compatibility with other resins and polymers, or adhesion to specific surfaces. These modified vinyl resins are most often used as thermoplastic, solvent-soluble lacquers, though by formulating with appropriate modifiers, air-dry or baking finishes can be produced having thermoset-like properties.

Special techniques have been developed that enable the use of high-molecular-weight vinyl chloride homopolymers as dispersions in organic media called plastisols or organosols that require a heat fusion step to form films or coatings. Vinyl chloride homopolymers and copolymers are also compounded for use as powder coatings for application by either electrostatic spray or fluidized bed techniques. Water-based vinyl chloride polymers and copolymers include high-molecular-weight polymer latexes that require heat to fuse, and also aqueous dispersions of low-molecular-weight polymers that utilize coalescents to form films at room temperature.

General

Important characteristic features of vinyl resins/coatings are: (1) relatively high glass transition temperature; (2) excellent resistance to water, alcohols, aliphatic hydrocarbons, vegetable oils, dilute acids, and alkali; and (3) inertness in contact with foods (FDA-listed resins only).

Vinyl resin films can be degraded by exposure to high temperatures or by long-term exposure to ultraviolet light, with a resultant change in color from clear to amber, red, and eventually black. Suitable heat stabilizers are employed that allow the processing of vinyl coatings at high temperature, while proper pigmentation helps to protect vinyl coatings from attack by UV light. Some stabilizer systems can provide limited protection to clear vinyl films.

[1]Union Carbide Corporation, Bound Brook, NJ 08805.

History

About 1912 Ostromislenski pioneered the industrial investigation of vinyl polymers and made and fractionated poly(vinyl chloride). E. W. Reid invented the copolymers of vinyl chloride and vinyl acetate in 1928. In 1933, Davidson and McClure described applications of vinyl resins including their use as swimming pool coatings [*1*].

Commercial production of poly(vinyl chloride-vinyl acetate) resins was begun in 1936. Carboxyl-modified copolymers were introduced in 1939 and hydroxyl-modified resins in 1945. The first commercial use of these vinyl resins was in 1936 as a coating for the inside of beer cans.

Organosol and plastisol coatings technology that permitted the use of very-high-molecular-weight resins were developed about 1943 [*2,3*].

Polymerization

Vinyl chloride monomer is a gas at standard conditions with a boiling point of −13.9°C. Polymerization is carried out in autoclaves under moderate to high pressure. The reaction is typically initiated by free radical generating compounds such as peroxides. The polymerization is exothermic, and reaction temperature regulation is necessary to control the growth (molecular weight) of the polymer. The use of high pressure and low temperature generally favors the formation of high-molecular-weight resins, and chain transfer agents are commonly used to control molecular growth. The number average molecular weight (M_n) of commercially available solvent-soluble vinyl chloride homopolymers and copolymers ranges from a low of a few thousand to about 45 000. The M_n of vinyl resins used for plastisol and organosol coatings ranges between about 60 to 110 000 [*4*].

Manufacture

Vinyl resins for coatings are made by several processes. Polymerization by solution and suspension processes is used to make the solvent-soluble resins, while emulsion or dispersion polymerization is used to make the much higher molecular weight polymers for plastisols and organosols. Some solvent-soluble grades are also made by the emulsion process. Post-polymerization processes are applied to some resins to achieve special properties.

Copyright© 1995 by ASTM International

Solution Process

Polymerization is carried out in a solvent in a batch or continuous process. The viscosity of the reaction medium increases as monomer is converted to polymer, and the extent of polymerization can be monitored and controlled via viscometry. When the appropriate viscosity is attained, the autoclave varnish is stripped of unreacted vinyl chloride monomer, and the polymer is precipitated by the addition of water or water/alcohol mixtures; the slurry is centrifuged to remove most of the liquid, then the resin is dried in fluid-bed dryers. The particle size of the dried resins produced by this process ranges from about 75 to about 200 μm, and the particle shape is irregular.

Suspension Polymerization

Suspension polymerization is generally carried out in a water medium. High-molecular-weight water-soluble colloidal polymers are used in small amounts to stabilize the droplets of suspended monomer(s) to control particle size. The stabilizer used remains with the resin during and after polymerization and resin recovery. Normally the preparation of solutions of suspension resins requires that mild heating be employed to achieve maximum clarity of solutions at minimum viscosity. Particles of suspension vinyl resins are characterized as spherical with a size between 100 to 300 μm.

Emulsion Polymerization

Like the suspension process, emulsion polymerization is also carried out in water, but in place of water-soluble polymers, surfactants are normally used to stabilize the smaller monomer droplets during polymerization. A special form of emulsion polymerization called dispersion polymerization uses an oil-soluble rather than water-soluble initiator and produces resin of particles size ranging from about 0.2 to 2 μm. These high-molecular-weight powdered products are used in plastisol and organosol coatings.

Post-Polymerization Process

Some vinyl-alcohol modified resins are prepared in a two-step process. The first step consists of the preparation of a poly(vinyl chloride-acetate) copolymer by either a solution or suspension process. Next, the copolymer resin is dissolved in a suitable solvent and a catalyst is added to partially hydrolyze the pendant acetoxy groups to yield a vinyl alcohol moiety. The modified resin is then precipitated from solution and dried as described for the solution process. The resin thus formed has only secondary hydroxyl groups, which accounts for its unique solubility/compatibility properties.

These vinyl-alcohol-containing resins differ from those prepared directly using other hydroxy-containing monomers in their compatibility with alkyds and in the rate of reactivity with coreactants such as isocyanate or amino-formaldehyde cross-linkers.

Vinyl Chloride Copolymer Coating Resins

Four types of solvent-soluble coating resins offered by Union Carbide are shown in Table 1. These polymers are produced by the solution polymerization process.

1. Vinyl chloride-vinyl acetate copolymers.
2. Carboxyl-modified vinyl chloride-vinyl acetate copolymers.
3. Hydroxyl-modified copolymers of two types:
   a. Hydroxyalkyl acrylate modified directly polymerized.
   b. Vinyl-alcohol-modified polymer derived from poly(vinyl chloride-vinyl acetate) in a post-polymerization process.
4. Epoxy-modified vinyl chloride copolymers.

Other suppliers of solvent-soluble vinyl resins and their product lines are listed in Tables 2 through 5 for Denka Kagaku, BASF, Wacker Chemie, and Nissan.

FDA Status

Vinyl copolymer resins are listed by chemical identity in several U.S. Food and Drug Administration regulations such as 21CFR 175.300, 176.170, 176.180, and 177.1210 as components of coatings on metal and paper substrates for use as food contact surfaces of articles used in processing, manufacturing packing, producing, heating, packaging, holding, or transporting food, or as components of closures with sealing gaskets for food containers. Vinyl chloride-acetate copolymers, hydroxyl-modified vinyl chloride-acetate copolymer, and several other vinyl chloride copolymers made with monomers having acid or ester functionality are described.

Vinyl Resins—Analysis

There are many references to chemical methods for identifying and characterizing vinyl resins [*5,6*]. However, the infrared spectra of vinyl resins are very useful for qualitative and quantitative purposes. Spectra of neat vinyl resins can be found in sources such as atlases, encyclopedia of plastics, or specific papers dealing with the subject [*7–9*].

Also, several ASTM documents deal with the identification and characterization of vinyl resins used in coatings materials. ASTM Guide for Testing Poly(Vinyl Chloride) Resins (D 4368-89) describes methods for homo- and copolymer vinyl resins to determine important characteristics such as total chlorine content for composition, dilute solution viscometry to assess polymer molecular weight, high and low shear viscosity measurements to characterize vinyl dispersion resins for plastisols and organosols [*10*].

ASTM Test Method for Infrared Identification of Vehicle Solids from Solvent-Reducible Paints (D 2621-87) covers the qualitative characterization of separated paint vehicle solids by infrared spectroscopy. A spectrum for an ortho-phthalic alkyd, vinyl chloride-acetate modified vehicle is presented [*11*].

ASTM D 2124-70 (Reapproved 1988), Test Method for Analysis of Components in Poly(Vinyl Chloride) Compounds Using an Infrared Spectrophotometric Technique, presents methods whereby vinyl compounds can be separated into components including resins, plasticizers, stabilizers, and fillers. Each component can then be analyzed by infrared technique [*12*].

Formulation of Solution Coatings

A typical vinyl coating usually consists of resin, solvent(s), plasticizer, pigments (required for exterior exposure), and optional ingredients such as stabilizers, modifying resin(s), and cross-linker(s).

The resin is normally selected on the basis of its ability to provide adhesion to the substrate. While, in most cases, strong adhesion is desired, there are special coatings such as strippable or peelable coatings where adhesion is not wanted. Table 6 lists the relative adhesion of several vinyl resins to various polymers and substrates.

The resin selection may be made on the need for reactive functionality to produce cross-linked coatings that change the nature of the coating from thermoplastic to thermoset-like properties that are characterized by improved solvent or stain resistance.

Solubility

Variation in the ratio of vinyl chloride to vinyl ester and the degree of polymerization produce a wide range of vinyl polymers with different solubility characteristics. Highest solubility is favored by low vinyl chloride content and low molecular weight. This relationship in terms of viscosity of resin solutions is compared in Table 1.

Vinyl solution resins are dissolved by ketones, esters, certain chlorinated solvents, and some nitroparaffins. As a class, ketones are the best solvents in terms of the ability to dissolve higher solids at lower solution viscosity. Hydrocarbons are chiefly used as diluents primarily to lower cost. Aromatic and aliphatic hydrocarbons can be usd as diluents. Aromatic hydrocarbons, chiefly toluene and xylene and higher boiling fractions such as Aromatic 100 or 150, are preferred as they can be used at high levels, in the range of 50 to 65% of the solvent blend depending on the resin composition, molecular weight, and desired solids. The Aromatic 100 and 150 are usually used only in baking finishes.

Aliphatic hydrocarbons can be used in limited amounts, up to about 30% of the solvent blend. Higher levels can lead to viscosity instability, and only low boiling aliphatic hydrocarbons, those with boiling points up to 117°C, are suitable. The use of higher boiling aliphatic hydrocarbons can cause precipitation of the resin during drying.

Alcohols are strong precipitants for vinyls and are not generally used in unmodified vinyl lacquers. However, in some cases vinyls, usually hydroxyl-modified vinyls, are readily formulated with other resins that are carried in alcohol. With these, up to 15 to 20% alcohol may be used in the solvent blend. Careful attention must be paid in vinyl coating formulations that contain alcohols to be sure that problems do not develop during application and drying of the coatings. Glycol ethers and glycol ether esters are sometimes used in vinyl coatings to improve flowout of baked coatings.

In response to regulations restricting the type and amount of solvents used in coatings, such as Los Angeles Rule 66 and later versions, vinyl coatings were reformulated as compliant systems by reducing the amount of branched ketones and aromatic hydrocarbons and making up the difference with esters and aliphatic hydrocarbons [*13*]. Though it was necessary to use more oxygenated solvents, the performance of compliant coatings stayed the same. Typical solvent blends used for spray application and the reformulated compliant systems are shown in Table 7.

Solution Characteristics

From the time a vinyl resin is dissolved, the viscosity of solutions increases with time until an equilibrium is reached after which the viscosity remains constant. This behavior is believed due to the formation of regions of microcrystallinity between polymer molecules in solution. The extent of the viscosity increase is dependent on: (a) resin molecular weight; (b) solids content of the solution; (c) and the strength of the solvent blend. The viscosity increase may be small or so large that the solution sets to a gel. Properly formulated vinyl resin solutions usually reach an equilibrium viscosity in about 3 to 5 weeks. Guidelines for the preparation of viscosity stable solutions for resins of varying molecular weight are shown in Table 8.

Vinyl chloride copolymer solutions also exhibit what is known as the memory effect. When a vinyl resin solution is heated to about 60°C, the effect of microcrystallinity is eliminated. If the solution is then cooled to its original temperature, the viscosity will not immediately return to its original value because of the time lag needed for the effect of the microcrystallinity to redevelop. With time, the viscosity of the solution will return to the same value as that of a solution that was not heated. The converse relationship hold when vinyl solutions are cooled. A graphical presentation of the memory effect is presented in Fig. 1.

Plasticizers

Plasticizers are often used with vinyl resin coatings to improve flexibility, formability, and impact resistance of the coating. Monomeric as well as polymeric plasticizers or compatible polymers with low glass transition temperature (T_g) may be used to plasticize a vinyl coating.

Phthalate, phosphate, and glycol ester plasticizers are typically used. Plasticizers are selected to meet the requirements of the coating that may include low-temperature flexibility, resistance to extraction by solvents, resistance to migration, to humidity, etc. Blends of plasticizers may be required to meet specific requirements. Table 9 presents a listing of plasticizers that are commonly used with vinyl resins. Care must be exercised in choosing the level of plasticizer as excessive amounts tend to make the film soft and prone to dirt retention. Ordinarily, a level of 25 phr (parts per hundred parts resin) of plasticizer is considered about maximum for use with coating resins.

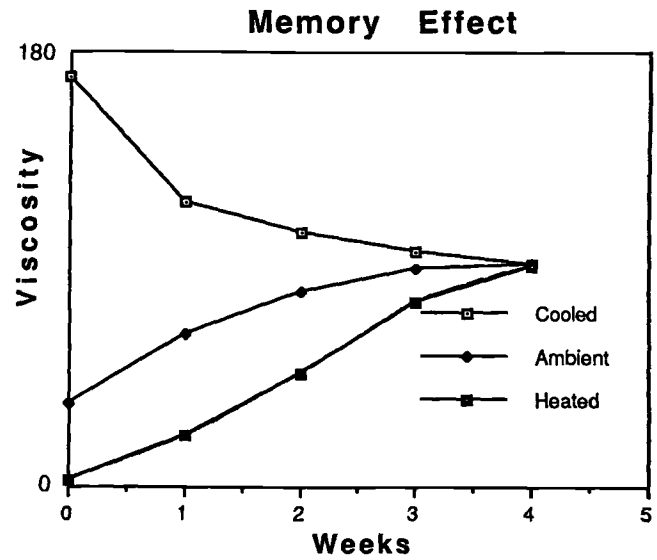

FIG. 1–Memory effect.

Pigmentation

Vinyl coatings are pigmented (1) to achieve the desired color, and (2) to prevent degradation of the vinyl resin from the effect of ultraviolet light for coatings that are intended for use outdoors [*14*]. Most organic and inorganic pigments can be used. However, basic pigments must be avoided with carboxyl-modified resins, as these pigments can react to form irreversible gel.

Prime or color pigments which absorb UV radiation must be used at a level sufficient to protect the vinyl resin. Extender pigments or fillers do not absorb UV radiation and can only be used in combination with a UV absorbing pigment. For titanium dioxide (T_iO_2) pigments, a minimum level of about 75 phr is needed to provide resistance to UV light. Other inorganic pigments can be used to replace T_iO_2 by substituting on an equal volume basis. Organic pigments that are

manufactured to smaller particle size are used at a lower concentration, and blends of inorganic and organic pigments are often used to achieve the desired color. Excessive high loading of pigments can lead to early chalking.

Organosols and Plastisols

A plastisol is a dispersion of discreet particles of high-molecular-weight vinyl homopolymer resin in plasticizer, with a low level of heat stabilizers sufficient to prevent degradation during baking (fusing). Plastisols normally require a minimum amount of about 55 to 60 parts plasticizer per hundred parts of resin to form a fluid mix. The viscosity of the dispersion is dependent on packing effects, the volume of dispersed resin relative to the volume of liquid plasticizer, the size and shape of the suspended particles, solvating or swelling effect of the plasticizer on the resin particles, and the viscosity of the liquid plasticizer. The relatively high levels of plasticizer needed to produce a flowable liquid mix results in the formation of fused films too soft for use as coatings. Plastisol coatings are usually formulated with the addition of coarser particle-size PVC resins called extenders from suspension or bulk (mass) polymerization that allow the use of less plasticizer and thus harder films. Additionally, small amounts of thinner, usually aliphatic hydrocarbon, are used (up to about 10 wt%) to reduce viscosity and provide better flow and leveling of the plastisol coating. Plastisol coatings do not adhere well to most substrates and most often require the use of a suitable primer.

An organosol differs from a plastisol in that much lower levels of plasticizer are used. A combination of weak solvents called dispersants in combination with hydrocarbon solvents called diluents are used to provide sufficient fluid to make a fluid dispersion. Because lower levels of plasticizer are used, films with much greater hardness can be obtained.

Commercial organosols are usually modified with a solvent-soluble resin to prevent mud cracking or film splitting during the bake to fuse the film. The modifier resin may contain carboxyl groups to make self-adherent coatings, or it may be a hydroxyl containing resin to provide functionality to react with cross-linkers such as amino or phenol/formaldehyde resins to achieve a degree of thermoset properties. Though vinyl copolymers are usually the modifier of choice for organosols, other polymers such as acrylic polymers may be used.

Careful consideration must be given to the selection of the solvent/diluent mix for organosols to attain the highest solids coupled with good viscosity stability. Commercial organosols of 50 to 55% nonvolatile by weight are typical.

Plastisols and organosols require a high baking temperature of about 350°F (177°C) to fuse the films. At elevated temperature, the plasticizer or plasticizer diluent mix exerts a strong solvating or swelling effect on the dispersed PVC resin particles. At fusion, the resin no longer exists as discreet particles, but rather as a continuous, homogeneous film. Films of plastisols or organosols need only to reach fusion temperature and do not have to be held at the fusion temperature for a long time period. Undercuring or baking at temperatures lower than that required for fusion will yield films deficient in tensile strength, elongation, abrasion resistance, and all other properties.

Plastisols and organosols also require the use of heat stabilizers to protect the vinyl resin against degradation during the fusion bake. Heat stabilizers are usually combinations of metal salts of organic acids in combination with epoxidized oils or liquid epoxy resins. Special attention must be given to the selection of heat stabilizers for organosols modified with solvent-soluble resin, especially when carboxyl-modified polymers are used. In such cases, the metallic salts must be avoided as these will usually cause gellation; typically, mercapto tin or tin ester compounds are used in combination with an epoxy stabilizer.

The type of pigment and level of pigment used in pigmented organosols follow the guidelines given for solution vinyl resins.

It is, however, more difficult to prepare pigmented plastisols because there is generally little solvent used to control viscosity. Low oil absorption pigments must be used to avoid excessively high viscosity.

Primers for Plastisols and Organosols

Plastisol coatings need a primer to develop good adhesion to metal substrates. An organosol coating may also require a primer if it is not modified with an adhesion-promoting modifier. Suitable primers can be formulated from carboxyl-modified vinyl resins and may require the use of thermoset resins such as amino-formaldehyde or phenolic resins to provide

resistance to excessive softening from highly plasticized plastisol or organosol coatings.

MAJOR MARKET AREAS FOR VINYL COATINGS

Rigid Packaging

Liners for Interior Surface Coatings, Cans, Can Ends, Closure/Caps and Crowns

The first commercial use for vinyl coatings was as the topcoat lacquer for the inside of beer cans. As beverage cans evolved from three- to two-piece construction, the vinyl coating also changed from lacquer to hydroxy vinyl/amino-formaldehyde thermosets to meet the need for higher corrosion resistance. Thermoset coatings of epoxy-modified vinyl resin with carboxyl-modified vinyl resin are used to coat on coil stock. The coated coil stock is then formed into the stay-on tab can ends, an application that requires excellent mechanical properties to withstand the forming steps without cracking.

Organosol coatings containing a solution resin component, usually carboxyl-type for adhesion, have also been used on precoated stock for can ends. Vinyl organosols are further modified with amino-formaldehyde or phenolic resins to upgrade chemical resistance and permit the use of such coatings for packaging food that will be autoclaved to sterilize the contents [*15*].

Vinyl lacquer and vinyl thermoset coatings are used as size coats for metals that are formed in caps and closures for jars or as crowns for beverage bottles. These systems serve as the primer coat for gasketing compounds made with plastisol or vinyl resin dry blends.

Flexible Packaging

Solvent-soluble carboxyl-modified vinyl chloride copolymers have good adhesion to most materials used in flexible or semi-rigid packaging including aluminum foil, paper and plastic films such as polyethylene terephthalate, polycarbonate, PVC, and cellophane. This type of resin is used for its adhesion characteristic, ease of heat sealing, and resistance to attack by the packaged product. The vinyl resin may be used alone or modified with plasticizers or other resins and polymers to formulate heat-sealable coatings for applications requiring varying degrees of force needed to open the container. This could range from applications such as blister packaging where the bond needs to be strong enough to cause substrate failure when the package is opened, to items such as jellies or cream containers found in restaurants where a tight but readily peelable bond is required.

Vinyl coatings are also used to coat collapsible metal tubes for packaging materials such as pharmaceutical preparations, toothpastes, and the like where the need is for a very flexible coating that will not crack nor be attacked by the contents of the package even though high stresses from collapsing and rolling up the tube are encountered.

Other applications include decorative coatings for the aluminum foil paper laminates for cigarette packaging, food wrappers for fast food restaurant items, for butter, margarine, soups, and so on. Decorative foil for floral wrappings, decorative labels, and coatings for aluminum foil for the vapor barrier insulation for construction applications are also coated with vinyl resin coatings.

Inks

The major markets for vinyl inks are on vinyl surface products such as floor and wall coverings, swimming pool liners, vinyl upholstery, and garment fabrics. Ink formulation is quite similar to that used with coatings except solvent choices are somewhat narrowed and higher pigment loadings are needed to achieve hiding in the thin films typical of inks.

Vinyl inks are often reverse printed on a clear vinyl film, and the printed film is then laminated to substrates such as wood or metal to make articles having simulated wood finish.

Vinyl inks are printed by gravure or screen process because these presses are compatible with the strong solvents needed for vinyls; flexographic printing is not suitable for vinyls because the plates are susceptible to solvent attack. Inks for highly plasticized vinyl surfaces are usually formulated with ester solvents to avoid excessive softening of calendered films and puckering of the films.

Dry Film Printing (Hot Stamp Transfer)

In this application, vinyl inks are printed on a carrier sheet such as polyethylene terephthalate, polyethylene, polypropylene, or other suitable surfaces to which the ink will not adhere strongly. The inks are applied and dried usually in web form. When ready for use, the printed carrier film is placed with the inked side on the surface to be decorated. A heated die presses the composite to make intimate contact with the surface, so that when the die is removed, the ink is firmly bonded to the substrate and the carrier is peeled away cleanly.

Maintenance and Marine Finishes

Heavy duty marine finishes were developed in the mid-1940s. These systems consisted of a poly(vinyl butyral) wash primer, vinyl-red lead anticorrosive intermediate coatings [based on poly(vinyl alcohol)-modified resin needed for adhesion to wash primer], and vinyl copolymer/wood rosin/cuprous oxide anti-foul top coats. This system has become the subject of numerous specifications; many U.S. Government agencies and agencies of other governments have written specifications with this coating system specified for use below the waterline of ships.

Because of their good water resistance, good weathering qualities, flexibility, fast dry and ease of application, and repair, vinyls quickly became established as maintenance finishes. This area includes coatings for locks, dams, appurtenant structures for waterways, interior linings for potable water tanks, steel structures such as bridges, electrical towers, equipment in chemical plants, and the like. Many specifications have been written that require the use of vinyls as maintenance paints [*16,17*].

The early vinyl maintenance and marine finishes were applied by air atomizing spray guns at low solids. Several coats were needed to attain coverage sufficient for good corrosion

protection. High-build airless spray-applied vinyl coatings were developed in the 1970s to fill the need for coatings systems that could be applied in fewer coats at less expense [*18*].

Wood Finishes

Reactive heavy duty vinyl finishes for wood have been developed consisting of a hydroxyl-modified vinyl resin cross-linked with amino/formaldehyde resins. Alkyd resins were often added to improve film build. Such finishes became established as the standard for kitchen cabinets because of their retention of excellent adhesion and water resistance, particularly when the coated wood becomes wet from high humidity or water splashing. These finishes also have excellent resistance to a variety of household chemicals, solvents, and stains and have been used as fine furniture finishes [*19*].

Magnetic Recording Media

Vinyls, especially hydroxy-modified vinyls, have been used as binders for magnetic iron oxide tapes since the beginning of the development of tape recording. The vinyl resins are used because of their good adhesion, abrasion resistance, and good pigment wetting properties. The early binder formulations used alkyd resin as plasticizers, then polyesters; currently, polyurethane resins are used as the plasticizer as the technology of tapes advanced and placed more stringent requirements on the performance of magnetic tape for audio and video [*20*].

Powder Coatings

Vinyl powder coatings are formulated with vinyl chloride homopolymers and copolymers for application by fluidized bed, powder spray, or electrostatic powder spray. Powder coatings are prepared by dry compounding resins, plasticizer, pigments, and additives in ribbon blenders followed by attrition or dispersion to powder in mixers such as the Henschel mixer. Some powder coatings are prepared by a melt mix technique followed by cryogenic grinding. This latter technique produces powders of smaller particle size [*21*].

Powder coatings prepared by dry compounding are usually applied by fluidized bed or by spray techniques. The metal parts are heated for fluid bed application so that the powder will adhere to the part and begin to flow to form a film. A bake after the powder application is needed to complete the film-forming process by fusion or melting.

Cryogenically ground powder coatings are applied by electrostatic powder spray. With the electrostatic method, it is not necessary to preheat the parts, but a bake is necessary after application to fuse the powder to a film. The finer particle size allows the deposition of smoother and thinner films than is attainable from fluidized bed or powder spray process. However, the high costs of cryogenic grinding made these materials substantially more expensive than dry grinding and as a consequence, the cryogenic ground powders account for only a small share of the PVC powder-coating market.

PVC powder coatings are used to coat products such as pipe, fencing, and metal furniture.

PVC Latex

Emulsion polymerized vinyl chloride homopolymers and copolymers are used in the latex form not so much to make finished coatings but rather as material coated on a base or support to provide the substrate for items such as wall coverings, backing for carpeting, and the like. In a sense, such use could be considered analogous to a waterborne version of an organosol coating. The vinyl chloride homopolymers need to be modified with a substantial loading of plasticizer, and some grades are sold as preplasticized latexes. These water-based materials require a high temperature bake to fuse the resin plasticizer mix into a continuous film.

By varying the type and amount of comonomer used to make emulsion polymerized copolymer latexes, lower T_g products are available that can use lower temperature bakes to form films.

Waterborne Vinyl Dispersions

Waterborne vinyl dispersions made from solution-polymerized vinyl copolymers became available in the 1980s. These waterborne vinyl dispersions are of medium molecular weight and have high T_g, about 80°C. Coalescents are needed with these products to form a film. Some dispersions are available with a glycol ether coalescent already present in the product, and a co-solvent free variety is also available. With the latter, the formulator can choose whichever coalescent, glycol-ether, glycol-ether ester, plasticizer, or blend of coalescents that best meets performance requirements. A line of waterborne vinyl dispersions is shown in Table 10.

Waterborne vinyl dispersions are used in many ink, coating, and heat-sealable coating applications where solvent-based vinyl coatings had been used.

Trends in Vinyl Coatings

To meet the VOC requirements that are either in place or proposed for the future, developments in vinyl coatings have centered on high solids and waterborne systems.

For high solids vinyl coatings, substantially increased resin solubility was achieved by reduction in the polymer molecular weight, so that viscosity stable solutions could be prepared at two to three times the level of solids content that was possible with earlier vinyl resins. However, at the low molecular weights needed for high solubility, the performance of coatings made from such resins was greatly reduced in terms of chemical resistance and physical properties. As a result, high solids vinyl resins are modified to contain hydroxyl functionality to allow for reaction with added coreactant materials to build molecular weight. Though the high solids resins may be used alone for less demanding applications, they are

TABLE 10—A line of waterborne vinyl resins dispersions.

best used either as a reactive system, with amino-formaldehyde or isocyanate cross-linker, or as modifiers for alkyds, polyester-isocyanate, or epoxy-amine coatings to improve initial drying or set-to-touch rate, or to improve recoatability [*21*].

The waterborne vinyl dispersions previously described represent an alternative to high solids vinyls as a way to formulate low VOC coatings. The waterborne vinyls are compatible with a wide variety of other waterborne resins with low VOC content such as acrylics, alkyds, urethanes, and amino-formaldehyde cross-linkers.

Miscellaneous Materials and Coatings

by Joseph V. Koleske[1]

THIS CHAPTER IS CONCERNED WITH A VARIETY of products that are not discussed elsewhere in the manual. Some topics are mentioned only briefly to indicate that the area has not been forgotten and that the topic is not within the scope of the manual.

POLYOLS

Polyols, or polyalcohols as they are sometimes known, are compounds containing one or more, but usually two or more, free hydroxyl groups. Most definitions, and particularly those over ten years old, list typical polyols as compounds such as ethylene glycol, propylene glycol, neopentyl glycol, glycerol or glycerin, trimethylolpropane, pentaerythritol, and sorbitol that were used in the preparation of alkyds and polyesters. Today the word "polyols" is far more encompassing and more often than not refers to alkylene oxide [*1*] and ϵ-caprolactone [*2*] adducts of the above-mentioned and other monohydric or polyhydric alcohols, low-molecular-weight polyesters prepared from the above mentioned as well as other polyhydroxyl compounds and dicarboxylic acids (particularly adipic acid) [*3–5*], polytetrahydrofurans prepared by a cationic ring-opening polymerization of tetrahydrofuran [*6,7*], and low-molecular-weight polycarbonates [*8–10*]. There are other compounds that meet the above definition, but they are not usually termed polyols. Compounds such as these are certain vinyl chloride copolymers, hydroxyl-containing glycidyl ether compounds, vinyl alcohol copolymers, and so on. This chapter will not be concerned with these latter compounds since they are dealt with elsewhere in the manual.

Polyols are important compounds used in the manufacture of alkyds and polyurethane coatings, of intermediates used in radiation curable formulations, as copolymerizable ingredients in high solids and cationic photocure systems, as well as in a number of other end uses including elastomeric fibers, dentistry, artifact preservation, and pharmaceutical preparations. The two main classes of polyols used in coatings are the polyether polyols, which are typified by the poly(propylene oxide) polyols (PPO), and the polyester polyols, which include both poly(glycol adipates) (PEA) and poly-ϵ-caprolactone polyols (PCP). Both classes of polyols are available as difunctional and

$$HO—[CH(CH_3)—CH_2]_a—O—R—O—[CH_2—CH(CH_3)]_b—OH$$

Poly(propylene oxide) Polyol

$$H—[O(CH_2)_4O—CO(CH_2)_4CO]_u—O(CH_2)_4O—[CO(CH_2)_4CO—O(CH_2)_4O]_v—H$$

Poly(1,4-butanediol adipate) Polyester Polyol

$$H—[O(CH_2)_5CO]_s—O—R'—O—[CO(CH_2)_5O]_t—H$$

Poly-ϵ-caprolactone Polyol

trifunctional hydroxyl compounds though the adipates are almost always difunctional in nature. Higher functional polyols are known and available, but their usage is less common than that of the di- and trifunctional products. In the above structural formulas, R and R′ may be the same or different and —O—R—O— and —O—R′—O— are the residues of the polyhydric alcohol initiators.

Difunctional and trifunctional PPOs are usually initiated with 1,2-propylene glycol and glycerol, respectively. The adipate polyols are usually prepared with an excess of diol, so most end groups are hydroxylic rather than carboxylic in nature. Since these polyols are prepared by a condensation reaction, there is no need for an initiator. Caprolactone polyols are initiated with a variety of diols and triols such as diethylene glycol, ethylene glycol, 1,4-butanediol, trimethylol propane, glycerol, etc. The above structure for PPO indicates that the hydroxyl groups are both secondary, which is the usual case. However, from time to time a primary hydroxyl group will be found due to an unexpected opening of the propagating 1,2-epoxide. The subscripts *a*, *b*, *u*, *v*, *s*, and *t* in the above structural formulas can be the same or different, and they can take on a wide variety of values with the number average molecular weight ranging from about 150 to 3000 for polyols usually used in coatings. Details about preparation of urethane coatings based on polycaprolactone polyols for rigid substrates [*11*] and flexible substrates [*12*] are available.

A variety of other specialty polyols also exist such as poly(butylene oxide) and polybutadiene polyols, which are useful when very high levels of barrier hydrophobicity are needed [*13*]. Poly(tetramethylene oxide) polyols also have good hydrophobic character. New polyols are also being developed, including polyols based on lactose that have flame-retardant characteristics as well as polyols with different end capping, etc. [*14*]. Although new polyols such as these are often designed for use in the manufacture of polyurethane foams and elastomers, they can be and are used in coating formulations.

[1]Senior consultant, Consolidated Research, Inc., 1513 Brentwood Road, Charleston, WV 25314-2307.

Copyright© 1995 by ASTM International

End capping polyols can provide adducts with different properties. For example, poly(propylene oxide) polyols which contain terminal secondary hydroxyl groups can be end capped with ethylene oxide to provide polyols with more reactive primary hydroxyl groups [*1,7*]. Ways to apply nuclear magnetic resonance to measure the ethylene oxide content of these and other propylene oxide/ethylene oxide copolymers is detailed in ASTM Test Methods of Polyurethane Raw Materials: Determination of the Polymerized Ethylene Oxide Content of Polyether Polyols (D 4875). Also described in the literature [*1,7*] are polyols modified to have amine, allyl, carboxyl, cyano, and vinyl ether end groups. Glycols that are solid and/or that have subliming characteristics, as 2,2'-dimethyl-3-hydroxypropyl 2,2'dimethyl-3-hydroxypropionate, can be modified with a few ethylene or propylene oxide groups to yield new polyols that are liquid, have low viscosity, and do not sublime with even a few molecules of ethylene oxide having nil or very little effect on moisture resistance [*15*]. Polyols can be end capped with an anhydride to form adducts that have free carboxylic acid functionality or a mixture of it and hydroxyl functionality as has been done with the poly-ε-caprolactone polyols [*16*] or the alkylene oxide capped glycols [*17*]. In other instances, poly(propylene oxide) polyols have had carboxyl groups grafted to their backbone with acrylic or methacrylic acid. These grafted polyols retain their original hydroxyl end groups and are used in coating formulations [*18*].

Polyols can be incorporated into alkyds, made into moisture-curing urethanes, can be cross linked with aminoplasts, and can be cross linked with cycloaliphatic epoxides when terminated with carboxylic acid end groups. In using the polyols, the hydroxyl number [*19*] is their most important physical characteristic to be measured and used. Five wet chemical methods and two nuclear magnetic resonance methods for determining the hydroxyl number are given in ASTM Method for Testing Polyurethane Polyol Raw Materials: Determination of Hydroxyl Numbers of Polyols (D 4274) and in ASTM Method for Testing Polyurethane Raw Materials: Determination of Primary Hydroxyl Contents of Polyether Polyols (D 4273), respectively. The equivalent weight or combining weight of a polyol is determined from the hydroxyl number by the following relationship

$$\text{Equivalent Weight} = 56\ 100/\text{Hydroxyl Number}$$

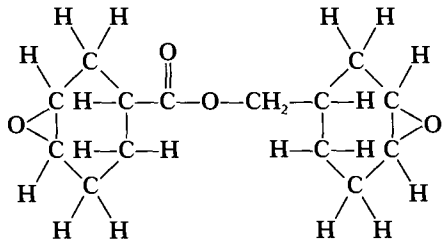
when potassium hydroxide is used as the titrating agent. Of course, if functionality is known, polyol molecular weight can be calculated by multiplying the equivalent weight by the functionality. Manufacturers provide information about hydroxyl number and usually about methods for analytically determining it.

Another important reactivity parameter is the acid number described in ASTM Test Method for Polyurethane Raw Materials: Determination of Acid and Alkalinity Numbers of Polyols (D 4662). Acidity and alkalinity in polyols can affect reactivity, shelf life, color, and hydrolytic stability of coatings prepared from polyols. Polyethers and poly-ε-caprolactone polyols usually have very low acid numbers. However, due to the nature of the condensation reaction coupled with transesterification used to produce polyester polyols, these polyols have relatively high acid numbers. Color, which has obvious implications, can be determined with ASTM Test Method for Polyurethane Raw Materials: Determination of Gardner and APHA Color of Polyols (D 4890).

CYCLOALIPHATIC EPOXIDES

Although the topic of epoxides in coatings is the subject of a separate chapter in this manual, that chapter deals with glycidyl or 1,2-epoxides that are not attached to a ring structure. Such epoxides are the largest volume products of all epoxides used, and the main products in this class are the diglycidyl ethers of bisphenol A. However, there is a special class of epoxides, termed "cycloaliphatic epoxides," that are used in specialty coatings and in cationic radiation-cure coatings. These epoxides are characterized by a saturated ring structure that imparts a high degree of weatherability and excellent electrical properties such as dielectric constant, dissipation factor, dielectric breakdown voltage, etc., to coatings and other products made from them. The good weatherability of the cycloaliphatic epoxides is apparent from the fact that they have been used for decades to make the large electrical insulators used in substations [*20*]. These compounds react well with carboxylic acids, as evidenced by their time-honored use as acid scavengers, and this reactivity often forms the basis for their use in coating formulations.

The main commercial cycloaliphatic epoxide is 3,4-epoxycyclohexylmethyl 3,4-epoxycyclohexane carboxylate that has the structure



This epoxide is well known by the familiar name designation ERL-4221. Table 1 contains the properties of this epoxide and other cycloaliphatic epoxides that are commonly known in the industry. Epoxide equivalent weight can be determined with ASTM Test Methods for Epoxy Content of Epoxy Resins (D 1652). Manufacturers can also be helpful in supplying information about methods of analysis for specific products. Usually these epoxides are reacted with polyols that function as flexibilizing agents for the highly cross-linked polymeric network that results. These epoxides polymerize by nucleophilic attack on the epoxide ring to form an ether linkage and a hydroxyl group on the ring. The hydroxyl group that is formed on the ring is quite acidic in character and will readily open other cycloaliphatic epoxide groups.

In the coatings industry, cycloaliphatic epoxides are used as a major formulating ingredient in cationic, photocurable formulations [*22*]. Usually they are formulated with polyols, onium-salt photoinitiators, and other ingredients. The onium salts photolyze in the presence of ultraviolet light to form strong protic acids that cause rapid polymerization of the epoxides as well as their copolymerization with active hydrogen compounds such as polyols. The presence of alkalinity including even very weak bases can result in neutralization of the protic acids formed by photolysis. Since the protic acids

TABLE 1—Commercial cycloaliphatic epoxides and their physical properties [*20,21*].

Chemical Name	Viscosity, cP at 25°C	Specific Gravity, 25/25°C	Color, 1933 Gardner (max)	Epoxide Equivalent Weight	Boiling Point, °C (mm Hg)	Vapor Pressure at 20°C, mm Hg	Solidification or Glass Point, °C
3,4-Epoxycyclohexylmethyl 3,4-epoxycyclohexane carboxylate	350–450	1.175	1	131–143	354 (760)	<0.1	−20
Bis(3,4-epoxycyclohexylmethyl) adipate	550–750	1.15	1	190–210	258 (10)	<0.1	9
2-(3,4-Epoxycyclohexyl-5,5-spiro-3,4-epoxy)cyclohexane-m-dioxane	7000–17 000 at 38°C	1.18	2	133–154	>250 (760)	<0.01	<0
1-Vinyl-epoxy-3,4-epoxycyclohexane	<15	1.18–1.10	1	70–74	227 (760)	0.1	−55

function as initiators, their neutralization will cause a marked decrease in polymerization rate. It may even result in nil reactivity. Coatings such as these are used as conformal coatings [*23–25*] in the electronics industry because of their excellent electrical (MIL-I-46058C approved, QPL Type ER) flammability (UL QMJU2 at a 2-mil thickness) and water permeability properties, as exterior can and other packaging coatings, overprint varnishes, printing inks for paper and metal, etc.

Cycloaliphatic epoxides have been reacted with the free carboxylic acid groups on anhydride adducts of polyols [*26*]. Such coatings are characterized by pot lives of less than 8 h, high solids, and low-temperature curing capabilities with very high gloss and depth of image, high hardness, excellent solvent resistance, adhesion, and toughness. In other instances, the epoxides have been reacted with polyols in the presence of triflic acid salts (as diethylammonium triflate, 3M Co.). In this case, shelf lives of more than eight months have been obtained and the formulated systems have high solids coupled with low viscosity and low temperature-cure characteristics. Cured coatings have an excellent balance of properties similar to those described above.

TABLE 2—A partial listing of polymeric films available for coating or other uses [*27*].

Type Polymer	Available as	
	Conventional Film	Shrink Film
Cellophane	Yes	No
Cellulose acetate	Yes	No
Cellulose acetate-butyrate	Yes	No
Cellulose triacetate	Yes	No
Ethylene/vinyl acetate copolymer	Yes	
Fluorocarbon	Yes	No
Ionomer	Yes	No
Nylon	Yes	Yes
Polycarbonate	Yes	No
Polyester	Yes	Yes
Polyethylene	Yes	Yes
Polyethylene linear low density	Yes	No
Polypropylene, nonoriented	Yes	No
Polypropylene, oriented	Yes	Yes
Polyurethane	Yes	No
Poly(vinyl alcohol)	Yes	No
Poly(vinyl chloride)	Yes	Yes
Polyvinylidine chloride	Yes	Yes

COATING FILMS

Films of many different polymers are available in different forms for use as functional and decorative coatings, adhesive backings, and other uses. Some of these materials [*27,28*] are listed in Table 2. A directory of film manufacturers that lists the manufacturer product name or number and a short description of the product is available [*29*]. Full description of these films and their uses is beyond the intent and scope of this manual.

METALLIC COATINGS [*28,30,31*]

Metallic films are used in a variety of ways. Some metallic coatings are described elsewhere in this manual. The previously described coatings are formulations wherein powdered or flaked metals are combined with a binder. However, solid metallic films are used as coatings in other ways familiar to us. Such films are both functional and decorative in nature. Metals can be applied to plastics and glass by a variety of processes including the physical vapor deposition processes known as vacuum metallizing by thermal evaporation, cathode sputtering, and ion plating of aluminum, copper, chromium, gold, silver, and silicon monoxide [*32*]. Many special effects can be produced including multilayers for cost and protection, iridescent effects by using compounds with high (CeO_2, ZnS) and low (MgF_2, SiO) refractive index, dyeing—particularly of aluminum to achieve a gold color and other colors, and glass coatings on plastic optical parts. Coatings formed by such vacuum deposition processes are most often applied to plastic substrates with end uses for the coated parts including automotive parts, plastic and paper webs for decorative and functional packaging of cosmetics, drugs, clothing, foods, etc., household fixtures, data storage systems, optical components, semiconductor devices, and glass for automotive and architectural applications. As indicated above, the packaging industry has a very large use for thin metallic films on paper and plastic substrates.

A new plasma technique [*33*] known as unbalanced magnetron sputtering (UBM) has advantages over conventional balanced magnetron sputtering (CBM), which is usually used to metalize silicon wafers and architectural glass. In such techniques, an argon plasma is used to remove atoms from a negatively charged target, and magnets are then placed at the outer edges of the target, which is made the cathode. Each of the magnets produces a field of the same strength, and because of this the system is termed "balanced." This conven-

tional system works well when the substrate is silicon and the coating is thin. However, in certain end uses, thick, dense coatings with excellent adhesion are required, and it is herein that UBM has significant advantages for applying coatings of hard, wear-resistant alloys such as TiN, NbN, TiC, CrN, TiNbN, and the like to metal-cutting saw blades and other tools, cams, and gears.

Metallic and ceramic coatings are also applied to metals by a thermal spray technique in which a metallic or ceramic wire, rod, or powder is melted and driven through air or a vacuum at high velocities [*34,35*]. The molten material, which can range from soft, abradable nickel-graphite to hard ceramic zirconia, is deposited on a surface of base metal to which it bonds through chemical and mechanical processes. Thermally sprayed coatings are used as abrasion, corrosion, and heat barriers for expensive machined components, castings, and other parts used in hostile chemical, mechanical, and thermal environments encountered in automotive, spacecraft including aerospace and aircraft, and industrial applications. The special protection provided by these coatings is needed to improve reliability and durability.

Other metal deposition processes for protective, cost savings and/or decorative coating metal, glass, and plastics include electrodeposition by electroplating (Cu, Ni, Cr) and electroless plating (Cu) and galvanizing (Zn). Other than this brief introduction, the metallic coatings mentioned in this short chapter are beyond the scope and intent of the manual and will not be treated further.

SPECIALTY ORGANIC COATINGS

Polysulfides

Liquid polysulfide coatings [*36*] have excellent barrier properties due to low permeability, good chemical and weather resistance, adhesion, low shrinkage, and low-temperature flexibility coupled with good stress relaxation characteristics. These coatings are based on polysulfide polymers prepared

$$HS—(C_2H_4O—CH_2OC_2H_3—S—S)_xC_2H_4OCH_2OC_2H_4SH$$

from bis(2-chloroethyl)formal, 1,2,3-trichloropropane and sodium polysulfide. The polymers are available in a molecular weight range of 1000 to 8000. The thiol or mercaptan end groups of this polymer provide sites for curing in an oxidative manner with manganese dioxide, dicumene hydroperoxide and organic peroxides in general, *p*-quinonedioxime, by reaction with glycidyl epoxides in the presence of tertiary amines, or by reaction with multifunctional isocyanates. The polymers are used as rubbery coatings and sealants in buildings and civil engineering projects requiring excellent ultraviolet light resistance and other general weatherability properties. Polysulfide coatings have been commercially used for over 50 years. The most recent use of the polymers is to provide chemically resistant barrier coatings on chemical-containment storage-tank dikes that protect the environment from chemicals that could cause serious pollution problems.

Phenoxy

Polyhydroxyethers which are commonly known as phenoxy polymers or merely phenoxy, are high-molecular-weight, high-performance thermoplastic materials that are similar in character to the diglycidyl ethers of bisphenol A that are described in Fig. 1 of the manual chapter entitled "Epoxy Resins in Coatings." However, there are significant differences that make the phenoxy polymers separate and unique polymers [*37–39*]. These polymers have the structure

$$—[O—C_6H_4—C(CH_3)_2—C_6H_4—O—CH(OH)—CH_2]_n—$$

where n is about 100, indicating a molecular weight of about 30 000 compared with a molecular weight of about 300 to 10 000 for the diglycidyl ethers of bisphenol A. In addition, phenoxy polymers do not have active epoxide end groups and are thermally stable materials with no limit on shelf life, are tough and ductile, and can form useful, resistant films by solvent evaporation without cross-linking. The hydroxyl functionality associated with phenoxy polymers provides a site for cross-linking with isocyanates, epoxides, or aminoplasts. Films from these polymers are considered to have excellent physical and chemical resistance properties when the polymer is in a thermoplastic form, but if improved resistance to certain solvents is needed, the polymers may be cross-linked. The high molecular weight of these polymers results in relatively low solids (~20%) coating systems, and this might be a restriction to their use in today's climate for high solids. The excellent properties of these polymers has led researchers into investigations of ways for advancing molecular weight of the diglycidyl ethers of bisphenol A during the curing stages [*40*].

Parylene Coatings [*41,42*]

Parylene coatings are applied by exposing a substrate to a gaseous atmosphere of *p*-xylylene. The gaseous monomer is stable, but when it is condensed on a substrate it spontaneously polymerizes to form high-molecular-weight, linear, poly(*p*-xylylene), which is commonly known as parylene [*43*]. The resultant coating of crystalline polymer provides a pinhole-free coating with an outstandingly uniform thickness and conformality even over pointed objects such as a needle. The polymer has excellent electrical properties, including high dielectric breakdown voltage, low dielectric constant and dissipation factor, and high-volume resistivity due to low moisture absorption and freedom from ionic impurities. Parylene is used for coating printed wiring assemblies, semiconductors, capacitors, electrets, contamination and corrosion control, medical and surgical devices, as well as similar end uses that require an inert coating that can be uniformly applied in a very thin film.

Part 4: Plasticizers

17

Plasticizers

by Peter Tan[1] *and Leonard G. Krauskopf*[2]

PAINT AND COATING FORMULATIONS often incorporate high boiling fluids as plasticizers where rigid or brittle resins fail to meet toughness and flexibility requirements. The primary function of the plasticizer is to impart flexibility to the resin, thus minimizing film cracking. Depending on resin and other ingredients used in the system, plasticizer choice may affect compatibility, toughness, flammability, smoke generation, heat and light stability, and other aging or permanence-related performances. Plasticizers are primarily employed in heavy gage coatings and/or when improved toughness is required for industrial, automotive, and appliance applications.

Plasticizers function by reducing the glass transition temperature of the resin to a point below its application temperature. The chemical mechanism of plasticization involves a strong polar association of polymer-plasticizer molecules, but not a chemical reaction between them. Plasticizers fundamentally reduce Van Der Waals forces between polymer-polymer molecules in the amorphous regions and do not penetrate crystallites [*1–3*]. The plasticized morphological phase is then of a different nature than that of the neat polymer and has unique mechanical properties.

The absence of a chemical bond between the plasticizer and the polymer impairs permanence; plasticizer molecules are free to leave the polymeric coating by means of extraction and volatility. Plasticizer loss, however, is minimal in most applications except for very low molecular weight plasticizers and/or exposure to very severe thermal conditions. Thus, plasticized coatings products have high durability and long service life in most applications. Plasticizers are liquids of molecular weight greater than that of solvents—to limit volatility—but are not solids, such as alloying polymers, etc. It should be noted that cross-linked resinous coatings significantly reduce plasticizer loss due to diffusibility and volatility. Several thousand high boiling fluids are potential plasticizers for coatings applications. The choice of plasticizer is dependent on compatibility with the resin in use, cost, and other desired attributes.

Plasticizers may be classified by both chemical structure and performance characteristics, as shown in Table 1 [*4*]. Typical plasticizers are liquid esters of molecular weight between about 200 to 800, with specific gravities between 0.75 and 1.35 at 20/20°C, viscosities between 50 to 450 cSt, vapor pressure of less than 3.0 mm of mercury at 200°C, and flash points greater than 120°C (248°F). They are generally stable and innocuous and should not be considered a significant threat to humans or the environment [*5–6*].

Plasticizer extenders are commonly used in extruded or molded flexible plastic shapes. Extenders are low-cost organic oils that may be subdivided as groups of aliphatic, aromatic, or chlorinated hydrocarbons. They are seldom used in coatings due to their relatively high volatility and limited compatibility in polar resins.

This chapter lists the basic properties of plasticizers and methods for their determination. Methods for the isolation, identification, and quantitative determinations of these plasticizers are also included.

PHYSICAL AND CHEMICAL PROPERTIES

Acidity

Plasticizer acidity may be due to improper processing, degradation during storage, contamination, presence of by-products, or residual catalyst. ASTM Test Method for Acidity in Volatile Solvents and Chemical Intermediates Used in Paint, Varnish, Lacquer, and Related Products (D 1613) may be used for determination of acidity. Either ethyl or isopropyl alcohol may be used as diluent for the plasticizer, which is titrated with aqueous sodium hydroxide or potassium hydroxide to the phenolphthalein end point. Results may be expressed in weight percent, as weight equivalents of acetic acid, acid number (milligrams potassium hydroxide consumed per gram of sample), or if the plasticizer is an ester, as weight percent of the parent acid of the ester (see section entitled "Ester Value").

Color

The majority of plasticizers are colorless. As a class, esters are very stable chemical reagents. However, exposure to abnormal conditions such as high thermal or ultra-violet energy, moisture, or chemically active surfaces may induce development of color bodies and/or chemical decomposition of the plasticizers. Higher molecular weight phthalates, polymeric plasticizers, and chlorinated paraffins may range in color from light to bright yellow. ASTM Test Method for Color of Clear Liquids (Platinum-Cobalt Scale) (D 1209) is the standard color measurement method for plasticizers.

APHA is a scale that is likewise used for liquids of low color. The standards are based on platinum solutions without cobalt and are described in ASTM Standard Method of Testing Urethane Foam Polyol Raw Materials (D 2849).

ASTM Test Method for Color of Transparent Liquids (D 1544) employs the Gardner Color Scale for amber and dark-colored plasticizers which cannot be read on the platinum-cobalt (Pt-Co) or APHA scales. Gardner standards are colored disks held in a "Hellige" gage. Gardner values of "1" and "2" are approximately equivalent to 250 and 400, respectively, on the APHA scale. The Gardner scale goes up to "18" for use with increasingly darker amber and brownish color liquids.

The platinum-cobalt scale is also known as the Hazen scale, but readers should be aware of potential confusion with The American Public Health Association (APHA); APHA adopted a version of this scale in which a Hazen color of one is the same as APHA 100. To avoid confusion, it is recommended that only the Pt-Co scale be used when referring to Procedure D 1209.

The APHA color scale in ASTM D 2849 reflects a slightly greenish hue for APHA versus the Pt-Co scale, which is slightly yellowish. The scale readings are similar in the 25 to 50 range, but in the vicinity of 100 Pt-Co, the APHA scale (Pt only) reads 10 to 20 units lighter (lower). Both the Pt-Co and APHA scales cover a range from "3" up to "500," but are recommended for use for liquids having colors ≤250 units.

An instrumental method (Hunter Colorimeter) that is five to seven times more precise may also be used for color measurement, replacing the subjective comparisons of the above methods using Nessler tubes; while commonly used in commercial practice, the Hunter Colorimeter is not yet defined as an ASTM method.

Copper Corrosion

ASTM Test Method for Detection of Copper Corrosion from Petroleum Products by the Copper Strip Tarnish Test (D 130), and ASTM Test Method for Copper Corrosion of Industrial Aromatic Hydrocarbons (D 849), which is normally applied to hydrocarbon solvents, may be used to evaluate the copper corrosive tendencies if suspected to be sourced in plasticizer. The appearance of a copper strip, which has been immersed in the test fluid, under standard conditions, is compared with twelve special standard strips classified as follow:

1. Slight tarnish (1a,b) light orange, dark orange.
2. Moderate tarnish (2a,b,c,d,e) claret red, brassy, or gold.
3. Dark tarnish (3a,b) magenta, multicolored.
4. Corrosion (4a,b,c) transparent black, jet black.

The historical application of copper corrosion testing to plasticizers was an attempt to measure effects contributed by residual sulfur compounds due to sulfur-based catalysts, which may hydrolyze to acidic pH in the presence of moisture. Current commercial grade plasticizers do not typically contribute to copper corrosion. Commercial grade alkyl sulfonate esters of phenol [7] are plasticizers in which the sulfur is organically "combined" and not readily susceptible to hydrolyses.

Distillation Range

Most plasticizers have high boiling points or boiling ranges. This property can be used as a measure of its degree of permanence or resistance to loss through volatilization. Presence of lighter components can also be detected. The measurement of vapor pressure is a costly and time-consuming procedure. Thus, commercial liquids of high molecular weight—low vapor pressures—are typically characterized by boiling ranges in which one determines initial, mid, and final (or drypoint) boiling point temperatures. For fluids with dry point >140°C, ASTM Test Method for Distillation of Petroleum Products (D 86) is used. Fluids with dry point <140°C are measured using ASTM Test Method for Distillation Range of Volatile Organic Liquids (D 1078). For very high boiling fluids or where decomposition may occur, distillation may be done under vacuum regulated at 5 mm Hg. The initial and final boiling points or the mid boiling point are typically reported.

Gas chromatographic (GC) techniques are commonly applied as a fundamental measure of plasticizer chemical purity and isomer distribution. Direct relationships between GC traces and boiling ranges have not yet been established for plasticizers.

Both distillation range and GC analyses are means to relate vaporization characteristics of plasticizers to practical needs. The fundamental characteristic of vapor pressure may be measured by ASTM Test Method for Vapor Pressure-Temperature Relationship and Initial Decomposition Temperature of Liquids by Isoteniscope (D 2879). The log of plasticizer vapor pressure varies linearly with the reciprocal absolute temperature (degrees Kelvin) according to the Clausius-Clapeyron equation [8]

$$\ln\frac{P_1}{P_2} = \frac{\Delta H}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \tag{1}$$

where

P_1 and P_2 = vapor pressure, $g \cdot cm^2 \cdot s^{-2}$,
T_1 and T_2 = respective temperatures, K,
ΔH = molar heat of vaporization, $cal \cdot g^{-1}$, and
R = gas constant, 1.99 cal $°C^{-1} \cdot mol$.

Vapor pressure values are useful to estimate normal boiling points at 760 mm mercury and solubility parameters [*1*]. Sears and Darby have reported that the vapor pressure of binary plasticizer blends may be expected to fall between the values of the neat plasticizers, but cannot be predicted from a knowledge of the blend ratio and the neat vapor pressures.

Ester Value

Esters are the largest group of materials that are commercially useful as plasticizers. This is a result of reasonable costs and broad utility in a wide range of polymers having moderate to high polarity characteristics. Ester value can be used to estimate the purity or ester content of the plasticizer. ASTM Test Method for Ester Value of Lacquer Solvents and Thinners (D 1617) or ASTM Methods of Sampling and Testing Plasticizers Used in Plastics (D 1045) may be used for this determination. The methods involve saponification of the ester in a known excess amount of KOH. The excess amount of KOH is then determined by titration with standard sulfuric acid. The amount of KOH consumed in the saponification process is a measure of the ester content of the plasticizer.

A gas chromatography method, ASTM Test Method for Purity of Monomeric Plasticizers by Gas Chromatography (D 3465), may also be used to determine the purity of monomeric plasticizers. The GC method does not provide "ester values." It is useful to characterize major isomers present versus known standards and to ascertain trace quantities of nonparent organic compounds. GC instrumentation is costly and requires comparison of output traces against a library of known materials that have been characterized under a specific set of conditions using specific GC instruments and columns.

Flash Point

Most plasticizers are high flash materials. Either ASTM Test Method for Flash and Fire Points by Cleveland Open Cup (D 92) or ASTM Test Method for Flash Point by Pensky-Martens Closed Tester (D 93) may be used. Preference should be for the closed cup method; this yields a more conservative number and is consistent with Department of Transportation (DOT) regulations in the United States. DOT has revised the definitions and classifications of hazardous materials, effective 1 Oct. 1993, as follows:

	Flash Point
Not Regulated	≥93°C (200°F)
Combustible	61 to 92.5°C (142 to 199°F)
Flammable	≤60.5°C (141°F)

The "flash point" is defined as the minimum temperature at which a liquid gives off vapor within a test vessel in sufficient concentration to form an ignitable mixture with air near the surface of the liquid as determined by ASTM Test Method for Flash Point by Tag Closed Tester (D 56) or ASTM Test Methods for Flash Point of Liquids by Setaflash Closed Cup Apparatus (D 3278).

Flash point values are reported for commercially significant monomeric plasticizers in E. J. Wickson's *Handbook on PVC Formulating* [*7*]. While not a very good analytical tool, flash points will reflect presence of nonparent, low-flash-point contaminants.

Pour Point

Due to the high molecular weight and isomeric mixtures of plasticizers, few have distinct freezing points. The pour point can be useful information for handling plasticizers during cold seasons. Method of measurement is described in ASTM Test Methods for Pour Point of Petroleum Oils (D 97). Plasticizer pour point temperatures may also be estimated from viscosity/temperature plots as the temperature at which kinematic viscosity is 50 000 cSt. Most plasticizers have pour points of less than −30°C [*7*]; no known relationship exists between pour point and plasticizer performance properties in polymers under low-temperature conditions.

Refractive Index

The refractive index of a plasticizer is measured using ASTM Test Method for Refractive Index and Refractive Dispersion of Hydrocarbon Liquids (D 1218). Refractive index is often thought of as a means of identifying the plasticizer. This is an erroneous assumption. It may be used, however, to differentiate between classes of plasticizers, as, for example, between phthalates and adipates [*10*]. When used with other physical measurements, refractive index may be used as a supplemental test. Refractive index can also be used to check for product contamination, but it is only useful to distinctify commercial materials having very widely different refractive indices.

Residual Odor

Residual odor may be contributed by reaction by-products from manufacturing or by residual raw ingredients which are often more volatile and odorous than the plasticizer. When ASTM Test Method for Odor of Volatile Solvents and Diluents (D 1296) is used, tests at elevated temperatures (about 150°C) can be considered to improve detection. Since odor is a subjective characteristic, generalizations for plasticizers are limited to terms such as "mild and characteristic."

Sampling

To obtain representative samples of plasticizers for evaluation, ASTM Methods for Sampling and Testing Plasticizers Used in Plastics (D 1045) may be followed. ASTM Recommended Practice for Sampling of Industrial Chemicals (E 300) can also be used.

Density and Specific Gravity

Density is an important characteristic for design engineering of plasticizer storage and building facilities. Specific gravity is the density of the given reagent relative to that of water

at the specified temperature; it is generally used in the characterization of plasticizers or as a means to detect gross contamination. Specific gravity at 20/20°C is measured with ASTM Test Methods for Specific Gravity of Liquid Industrial Chemicals (D 891) and is commonly employed in industry. Commercial plasticizers typically fall within the range of 0.92 to 1.50 sp gr at 20/20°C. ASTM Test Method for Density and Relative Density of Liquids by Digital Density Meter (D 4052) is the recommended procedure to measure specific gravity of fluids that lie between 0.68 and 0.97; this method is applicable to hydrocarbons that are commonly used as plasticizer extenders.

Viscosity

Viscosity measures the fluid's resistance to flow; the thicker the fluid, the higher its viscosity and the greater its resistance to flow under gravity. In ASTM Test Method for Kinematic Viscosity of Transparent and Opaque Liquids (and the Calculation of Dynamic Viscosity) (D 445), time is measured in seconds for a fixed volume of the fluid to flow under gravity through the capillary of a calibrated viscometer at constant temperature. The kinematic viscosity of a plasticizer varies as a log log function versus the log of absolute temperature according to the following equation

$$\log \log \eta \cong A - B \log T \qquad (2)$$

where

η = kinematic viscosity, centistokes,
T = temperature, degrees Kelvin, and
A and B = constants.

This reflects the tremendous influence of temperature on viscosity and allows one to interpolate viscosity values at specified temperatures. The kinematic viscosity (centistokes) can be converted to its dynamic viscosity (centipoise) by multiplying by the true density of the fluid at the specified temperature: dynamic viscosity, cP = kinematic viscosity, cSt, times density.

Water

Residual water from manufacturing processes and moisture absorbed from the atmosphere can affect the quality and clarity of coatings. Water content can be measured using ASTM Test Method for Water in Volatile Solvents (Fischer Reagent Titration Method) (D 1364). Plasticizers are hydrophobic liquids and typically have a limited capacity to take up water and/or be dissolved into water. Higher-molecular-weight phthalates are practically insoluble in water with solubilities in the 0.1 to 1.2 mg/L (ppm) range with even less solubility in salt water [*6*].

Typical Properties

As shown in Table 1, commercial plasticizers fall into about seven chemical family groups (eight if we were to add a "miscellaneous" grouping). The major plasticizer types in use are phthalates, trimellitates, and aliphatic dibasic esters such as adipates. The families of esters are formed by reacting the parent acid with monomeric alcohols ranging from C_4H_9OH (butanol) to $C_{13}H_{27}OH$ (tridecanol); the alcohol may also vary in isomeric structure ranging from normal (unbranched) to very specific and/or randomly branched structures. Two alcohols have found wide usage in synthesis of commercial plasticizers—2-ethylhexanol and isononanol—a mixture of randomly branched (primarily methyl branched) nonyl isomers. Table 2 is a summary of typical properties of plasticizers derived from these two alcohols with the major parent acids—phthalic, trimellitic, and adipic [*11*].

METHODS OF IDENTIFICATION

A plasticizer may initially be characterized by its functional groups. While absolute identification is complicated without sophisticated chemical or instrumental methods, it is possible to identify the type of plasticizer by functional groups or presence of elements associated only with the plasticizer by the use of infrared analyses or wet chemistry. Most plasticizers are a member of one of the following families:

Plasticizer Type/Functional Group
Adipates
Chlorinated compounds
Epoxides (oxirane)
Phosphates
Phthalates
Polyesters
Trimellitates

Isolation of Plasticizers

Plasticizers may be separated from a lacquer or dried film by solvent extraction if it is to be analyzed. The lacquer is first dried to remove all solvents present. The dried solid is then solvent extracted (in an appropriate apparatus) with hot ethyl ether or another appropriate solvent that will extract the plasticizers while leaving most of the resins behind. The extractant is concentrated, and a small amount of methyl or ethyl alcohol is added. This will cause some of the dissolved resin to precipitate out. Next, filter and concentrate the extractant. ASTM Test Method for Acetone Extraction of Phenolic Molded or Laminated Products (D 494) may be applied.

Instrumental Methods

Modern instrumental analytical methods are able to separate, identify, and quantify components in composite mixtures. Rapidly falling costs of such instruments have enabled instrumental methods to be more widely available. These include gas chromatography (GC), high-performance liquid chromatography (HPLC), infrared spectroscopy (FTIR), and other emerging analytical instruments like supercritical fluid chromatography (SFC), GC/FTIR, and GC/MS (mass spectrometry).

Infrared Spectrophotometry

An infrared scan of the isolated plasticizer is by far the best way to identify the functional groups in the molecule. Mixtures of plasticizers can present problems due to masking effects. If one or more of the component plasticizers is known and its IR scan available, subtracting it from the IR scan of

TABLE 2—Typical physical properties of plasticizer esters made with isononyl and 2-ethylhexyl alcohols.

	Phthalate		Trimellitate		Adipate	
	DOP	DINP	TOTM	TINTM	DOA	DINA
Alkyl	2EH	INA	2EH	INA	2EH	INA

DINP di (isononyl) phthalate
TOTM tris(2-ethylhexyl) trimellitate
TINTM tris(isononyl) trimellitate
DOA di(2-ethylhexyl) adipate
DINA di(isononyl) adipate

the mixture may aid in identification of the other component. Other chromatographic techniques could be used to separate the components before scanning.

Liquid Chromatography

Column chromatography involves distribution of substances between liquid (mobile phase) and substrate (solid phase). Column and thin layer chromatography can be used. Instrumental methods using high-performance liquid chromatography (HPLC) with ultraviolet detection can be used for separation, identification, and quantification of plasticizers which possess a suitable chromophore.

Gas Chromatography

By comparing relative retention times and peak shapes with known samples, a plasticizer or mixture can often be identified and quantified. When coupled with IR (i.e., GC/FTIR), the IR spectrum of each chromatographic peak can assist in the identification of functional groups and hence plasticizer identity.

Qualitative Methods

For the detection of nitrogen, chlorine, sulphur, or phosphorus, the sample needs to be fused with metallic sodium. This preparation should be carried out in a fume hood and caution observed when handling metallic sodium. A small amount (about 3 mm^3) of metallic sodium is placed in a dry 6-in. (15.24-cm) test tube. The test tube should be held vertically by clamping it at the open end. The test tube is then heated until a cloud of sodium vapor begins to form. Remove the flame immediately. Add two to three drops of the plasticizer sample directly to the sodium vapor. When the test tube is cold, break off the end with the sodium in a mortar. Add several milliliters of alcohol to destroy unreacted sodium. Add about 20 mL of distilled or deionized water, grind up the sample, transfer to a beaker, bring to boil, and filter. The filtrate is then used for the chemical detection of the elements.

Sulfur

Add two to three drops of 10% solution of lead acetate to 2 mL of a 10% solution of sodium hydroxide. Add this mixture to 5 mL of the filtrate. A black precipitate of lead sulphide indicates the presence of sulphur. Positive identification suggests that the sample is either a sulphonamide or sulphate.

Nitrogen

Bring 2 mL of the filtrate to boil in a test tube. Add five drops of a 10% solution of NaOH and five drops of 10% ferrous sulphate solution. When cold, add, dropwise, a 10% solution of hydrochloric acid until the solution is acidic and the precipitate of ferrous hydroxide has dissolved. Avoid using an excessive amount of acid. A blue or green color or blue precipitate indicates presence of nitrogen. A positive test suggests that the plasticizer could be an amide.

Chlorine

Acidify 5 mL of the filtrate with several drops of dilute sulfuric acid and bring it to boil. Cool and acidify with nitric acid. Add several drops of a 10% silver nitrate solution. A white precipitate indicates the presence of a chlorinated compound.

Phosphorus

Boil 5 mL of the filtrate with 3 mL of concentrated nitric acid for 1 min. Cool and add twice the volume of 10% ammonium molybdate solution. Heat to about 60°C and set aside to cool. A yellow precipitate indicates the presence of phosphorus. Phosphate plasticizers will result in a positive test.

Phthalates

Add about 0.05 g of resorcinol and 0.05 g of phenol to separate 6-in. (15.24-cm) test tubes. Add to each test tube two to three drops of the isolated plasticizer and a drop of concen-

trated sulfuric acid. Heat the contents in an oil bath at 160°C for several minutes. Cool and add 2 mL of distilled water and 2 mL of 10% sodium hydroxide solution and stir. The presence of phthalate is indicated by a pronounced green fluorescence in the tube with resorcinol, and the tube with phenol will be red.

PERFORMANCE PROPERTIES

Compatibility

Compatibility is the ability of two or more substances to mix together without objectionable separation [*12*]. In the case of plasticizers, it is primarily a measure of the solvency or strength of positive interactions between the plasticizer and the polymer which attract them together.

Solvency is the extent (or amount) of interaction of plasticizer or solvent molecules at the surface of a polymer particle; a solid solution results when the polymer and plasticizer—and possibly additional reagents—become molecularly homogeneous. The degree to which a homogeneous solution, or miscibility, is stable is a function of the plasticizer/polymer interactions when in the presence of other reagents employed in the coating formulation; it must be recognized that the presence of these additional reagents can compete with the polymer/plasticizer interactions. The rule of thumb "like dissolves like" applies, but more specific knowledge is required to avoid results that appear to be anomalous.

Dried polymeric coatings may be considered as solid solutions; the limits of miscibility are impacted by all of the reagents that become components of the coating—those intentionally added, as well as inadvertent contaminates and/or degradation products formed in the coating process. When plasticizers are employed, they have a major effect on compatibility, primarily due to the level, or concentration, used in the polymer. If we accept the definition of a solution as a homogeneous mixture of two or more types of molecules, then "solvency" is a measure of a given solvent or plasticizer to homogenize and interact with a given polymer. Quantification of this "interaction" has been elusive; scales which have been devised are capable of measuring only gross differences. Observations of phase separation of plasticizer/polymer have been more finite than that predicted in many cases, while on the other hand, observations of symptoms (compatibility) are incapable of separating "solvency" from other interfering mechanisms that are concurrent, such as diffusibility.

Hansen publications [*13–14*] define the total solubility parameters of polymers, solvents, and other reagents as a function of three component parameters:

$$\lambda_T = (\lambda_d^2 + \lambda_p^2 + \lambda_h^2)^{1/2}, (\text{cal/cm}^3)^{1/2} \quad (3)$$

where

λ_T = total solubility parameter,
λ_d = dispersion parameter,
λ_p = polarity parameter, and
λ_h = hydrogen bonding parameter.

The location of polymers and other non-ionic reagents may be defined on this three-dimensional grid. Hansen states that it may be assumed that the closer a plasticizer lies to the center of the polymer solubility space of a polymer, the more compatible it will be with the given polymer. Many materials have been characterized in this fashion. Exxon Chemical Company has developed a computerized capability to define the location of various solvents and plasticizers relative to that of various polymers; it is called the CO-ACT® program and contains information on more than 1200 resins, solvents, and plasticizers [*15*].

Compatibility data for different plasticizer resin systems are available in various publications [*1,16–17*]. The plasticizers are usually presented as compatible, incompatible, or partially compatible with the resins. These data are often not useful due to incomplete description of the resin or a lack of standard approach in the test and reporting of observations. Where Hansen parameters are available for the plasticizers and resins, comparison of three-dimensional Hansen solubility parameters provide a better measure of compatibility as described earlier. Table 3 lists generalized examples of plasticizers and their compatibility with various coating resins.

Permanence

"Reactive" plasticizers are specialty types designed to self-polymerize or graft onto the polymeric resin during the curing process. But, in most cases, plasticizers do not chemically react with the polymer. They function by an overall solvating action that is less strong than that of a good solvent, but stronger than that of incompatible reagents such as lubricants. This interaction imparts a slight effect on plasticizer "permanence," or more properly "transience." One of two factors are generally the controlling influence over loss of plasticizer:

- Rate of diffusion of plasticizer from the resin bulk to the surface.
- Rate of loss of plasticizer from the surface.

The slowest rate of the two is the controlling factor under any specific set of conditions. Volatility and extraction by aqueous reagents are generally surface-controlled losses, while rate of diffusion controls loss under oil immersion and similar tests. The subject is very complex [*1–2*], but one may consider plasticizer vapor pressure as a key predictor of volatile loss, while diffusion-controlled losses are improved with plasticizers of higher molecular weight and branchiness in the chemical structure.

Resistance to washing is typically characterized as a function of thermal and/or humidity cycling exposures. This is a measure of the aging resistance of the plasticized polymeric coating.

Low-Temperature Properties

Some applications require flexibility and impact resistance at low temperatures. This property may be significantly improved at increased plasticizer levels, as well as being a function of the plasticizer type [*1*]. For example, at approximately 50 PHR, plasticizer in poly(vinyl chloride) phthalates of linear alcohols impart about −10°C improvement in low-temperature brittleness over branched, DOP-type, phthalate plasticizer. Dialkyl adipates, however, impart about −25°C improvement over the brittleness value of DOP-plasticized PVC as measured by ASTM Test Method for Brittleness Temperature of Plastics and Elastomers by Impact (D 746).

VC/VAc = Vinyl Chloride/Vinyl Acetate Copolymer: 90/10

PLASTICIZERS

Phthalates
DOP = di(2-ethylhexyl)
DIOP = di(isooctyl)
DINP = di(isononyl)
DIDP = di(isodecyl)

Trimellitates
TOTM = tris(2-ethylhexyl)
TINTM = tris(isononyl)

Acyclic Esters
DOA = di(2-ethylhexyl) adipate
DINA = di(isononyl) adipate
DOZ = di(2-ethylhexyl) azelate
DOS = di(2-ethylhexyl) sebacate

NOTE: Compatibility of plasticizers in specific polymers is a function of relative concentration (PHR), as well as the presence of other formulating reagents and residuals present in polymers. The above ratings are based on plasticizer levels typically used in coatings applications (<40 PHR).

Commercial coatings require the optimum choice of plasticizer type and concentration to meet required costs, hardness or modulus, permanence, and low-temperature properties.

Part 5: Solvents

18

Solvents

by Stephen A. Yuhas, Jr.[1]

SOLVENTS ARE SUBSTANCES, usually liquids, which are capable of dissolving other substances to bring them into liquid form. In paints and coatings, solvents dissolve the solid or semi-solid film-forming resins and reduce viscosity so that the paint can be applied as a uniform, thin film to a surface. Although solvents are transient components of a paint, they significantly affect not only the application characteristics of a paint, but also the appearance, physical properties, and durability of the coating.

The two most important performance requirements that must be considered in selecting the proper solvent for any end use are solvency and evaporation rate. These key properties control initial paint viscosity during application, coating viscosity at various stages of drying, and final coating appearance. Solvents must evaporate relatively quickly during initial drying to prevent excessive flow and sag, but must evaporate more slowly in the later stage to provide good leveling and adhesion.

Solvency and evaporation rate are often measured indirectly since direct measurements are not always feasible or convenient. In addition, there are numerous other solvent properties that must be considered for specific applications. These are often listed as requirements in the solvent specifications and include measures of purity, uniformity, safety, and compliance with air pollution regulations.

There are many different solvents used by the coatings industry. To facilitate their review and comparision, it is convenient to classify them chemically into three general categories: hydrocarbons, oxygenated, and others. Each category will be discussed separately in the sections that follow.

Solvents may also be classified according to the function they perform: active, latent, and diluent. An active solvent is a true solvent for the film-forming resin and has the major role in dissolving it. A latent solvent alone will not dissolve the resin, but behaves as an active solvent or has a synergistic effect when used in combination with an active solvent. A diluent usually has no solvency for the resin, but is tolerated by it in blends. Diluents are added to reduce cost and vehicle viscosity through dilution.

CLASSIFICATION BY CHEMICAL TYPE

Solvents can be broadly classified by chemical type into three categories:

1. *Hydrocarbon solvents*—organic compounds comprised of molecules consisting only of hydrogen and carbon atoms.
2. *Oxygenated solvents*—organic compounds comprised of molecules consisting of hydrogen, carbon, and oxygen atoms.
3. *Other solvents*—organic compounds consisting of hydrogen, carbon, and atoms other than oxygen, such as chlorine or nitrogen, or inorganic compounds such as water or supercritical carbon dioxide.

Hydrocarbon Solvents

The vast majority of hydrocarbon solvents are derived from petroleum, although a few are of vegetable origin. Therefore, hydrocarbon solvents may be regarded as being "natural products." Most are physically separated from petroleum by distillation and other refining processes. As a result, hydrocarbon solvents tend to be mixtures of organic compounds (rather than pure chemicals), and they may vary in composition depending on feedstock source.

Solvency of hydrocarbons is relatively weak compared with oxygenated and other solvents. Being of natural origin, they are good solvents for natural resins and natural-modified resins such as drying oils, varnishes, alkyds, asphalt, rosin, and petroleum resins. However, they are generally poor solvents for synthetic resins such as vinyls, epoxies, urethanes, acrylics, and nitrocellulose. Hydrocarbon solvents are usually used as low-cost diluents in solvent blends. Other distinguishing characteristics of hydrocarbon solvents are low specific gravity and complete water immiscibility.

Hydrocarbon solvents may be further subclassified into four subcategories: aliphatics, aromatics, naphthenes, and terpenes.

Aliphatic Hydrocarbons

Most aliphatic hydrocarbon solvents are manufactured by distilling the appropriate boiling range fractions from crude oil and subsequently treating them to improve odor and color stability. These saturated organic molecules are generally mixtures of straight chain or *normal*-paraffins and branched chain or *iso*-paraffins, with perhaps some cycloparaffins [*1*].

Unique, distinguishing characteristics of commodity aliphatic hydrocarbons are: very weak solvency, low odor, specific gravity, and cost. Although they are active solvents for some varnishes and alkyds, they are used primarily as low-cost diluents in solvent blends. Weak solvency is not necessarily a disadvantage of aliphatic hydrocarbons. They are preferred as carrier solvents in vinyl organosols and as reaction

[1]Chemical engineer, technical consultant, Solventures, Inc., 56 Wick Drive, Fords, NJ 08863.

Copyright© 1995 by ASTM International

diluents in certain polymer syntheses because of their low tendency to dissolve or swell polymers.

Examples of some typical aliphatic solvents used by the coatings industry are shown in Table 1 together with their ASTM specification references. Others are commercially available as aliphatic naphthas having producer-defined distillation ranges. The fastest-evaporating solvents—hexane, heptane, and lacquer diluent—are often used as the diluent component of fast-drying lacquers, where one of their important functions is to reduce cost.

Mineral spirits is the most commonly used aliphatic solvent. (Outside the United States, mineral spirits is often called white spirits.) It is the common "paint thinner" sold in retail stores and is used in architectural paints, varnishes, and stains. It has the right combination of moderate solvency and moderately slow evaporation rate to impart proper brushability, leveling, and wet edge.

Mineral spirits is a distillation fraction boiling between 300°F (149°C) and 400°F (204°C), with a minimum flash point of 100°F (38°C). Four types are defined in ASTM D 235, Specification for Mineral Spirits (Petroleum Spirits) (Hydrocarbon Drycleaning Solvent). "Low dry point" mineral spirits, referred to as Stoddard solvent, has a faster evaporation rate and is used as a dry-cleaning solvent.

VM&P naphthas have about the same solvency as mineral spirits, but have a much faster evaporation rate. They are distillation fractions having boiling ranges between 250°F (121°C) and 300°F (149°C). ASTM D 3735, Specification for VM&P naphthas, defines three types. They are used primarily in spray-applied, industrial finishes.

Several hydrocarbon solvent producers also manufacture and market complete lines of pure, isoparaffinic solvents, which are synthetically produced from pure petroleum components. Unique characteristics of the isoparaffins are that they have very weak solvency and are virtually odorless. Examples are odorless mineral spirits and odorless VM&P naphtha.

Aromatic Hydrocarbons

Aromatic hydrocarbons, which are cyclic, unsaturated compounds, are also made from petroleum. However, their manufacture requires additional processing steps. An aliphatic naphtha distillate from crude oil is processed through a catalytic reformer to rearrange the molecules into cyclic and polycyclic compounds, which are further dehydrogenated to aromatics. Various aromatic solvents are then separated by distillation [*1*].

There are only four aromatic solvents commonly used by the coatings industry: toluene, mixed xylenes, and two high-flash aromatic naphthas. Evaporation rates of these four major aromatic solvents range from fast to very slow. ASTM specification references and key properties are summarized in Table 2. Distinguishing characteristics of aromatic solvents, relative to hydrocarbon solvents, are stronger solvency and odor, high specific gravity, and higher cost.

Toluene is a pure chemical, methylbenzene. It is a fast-evaporating solvent used as an active solvent for certain resins, as a lacquer diluent, in spray paints, aerosols, and in a variety of industrial coatings.

Mixed xylenes are used as paint solvents and in thinners. Xylene is a mixture of three isomers: *ortho*-, *meta*-, and *para*xylene, plus ethylbenzene. Solvent xylene from different producers may vary in composition, resulting in slight differences in properties and performance [*2*]. Xylene has a moderate evaporation rate and is used primarily in industrial coatings.

The individual components of mixed xylene solvent are also isolated and marketed separately as chemical intermediates which are used by the coatings and chemical industries. Phthalic anhydride, used in the manufacture of alkyd resins, is produced from *ortho*xylene. Terephthalic acid, also used in the manufacture of resins, is produced from *para*xylene. Styrene is produced from ethylbenzene.

Two *high-flash aromatic naphthas* round out the aromatics most commonly used by the coatings industry.

Type I—Aromatic 100 has a flash point not less than 100°F (38°C).

Type II—Aromatic 150 has a flash point not less than 150°F (60°C).

Aromatic 100 consists mainly of C_9 aromatics, while Aromatic 150 is a mixture of predominantly C_{10} aromatics. Both are slow evaporating and are used in baked industrial coatings.

Naphthenic Hydrocarbons

Most of the aliphatic hydrocarbon solvents contain minor amounts of naphthenes, i.e., cycloparaffins, cyclic aliphatics. Properties of naphthenes, with respect to solvency, odor, and specific gravity, are intermediate between aliphatics and aromatics.

Purely naphthenic hydrocarbon solvents currently have very limited commercial availability. Cyclohexane, a pure naphthenic hydrocarbon, finds applications not as a solvent but as a chemical intermediate in the manufacture of nylon fiber and engineering resins, plasticizers, polyurethane, polyester, and epoxy resins. Properties are summarized in Table 3.

Terpenes

Terpene solvents are obtained from pine trees and to a much lesser extent as a by-product of the citrus industry. They are the oldest solvents used in coatings, predating ancient Egyptian civilization [*1,3*]. The main solvents in this group are turpentine, dipentene, and pine oil. Chemically, they are mixtures of C_{10} unsaturated hydrocarbon compounds. A good review of terpenes may be found in ASTM D 804, "Standard Definitions of Terms Relating to Naval Stores and Related Products."

Terpene solvents have volatiles similar to mineral spirits. However, they have only minor commercial significance today because they are more expensive than hydrocarbon solvents. Although their solvency is greater than that of aliphatic hydrocarbons, they have a much narrower range of solvency and evaporation rate and a stronger odor. Furthermore, because of their unsaturated structure, they are restricted in some areas by air pollution regulations.

There are four kinds of *turpentine*, as specified in ASTM D 13, Specification for Spirits of Turpentine, depending on the source and method of production [*1,4*].

Gum turpentine or *gum spirits* is produced by distilling the crude gum or oleoresin collected from living pine trees. It contains mostly α-pinene with lesser quantities of β-pinene and small amounts of other terpene hydrocarbons.

Steam-distilled wood turpentine is obtained from oleoresin within the wood of pine stumps or cuttings, either by direct steaming of the mechanically disintegrated wood or after solvent extraction of the oleoresin from the wood. It consists primarily of α-pinene, with small quantities of dipentene and other terpenes.

Sulfate wood turpentine is recovered during the conversion of wood to pulp by the sulfate (Kraft) paper-making process. It is a mixture of α- and β-pinene, with small amounts of other terpene hydrocarbons.

Destructively distilled wood turpentine is obtained by fractionation of certain oils recovered from the destructive distillation of pine wood. It is a complex mixture of a wide variety of aromatic hydrocarbons with only moderate quantities of terpenes being present.

Standard methods of sampling and testing turpentine are described in ASTM D 233, Methods of Sampling and Testing Turpentine.

Dipentene is obtained by fractional distillation from crude oils recovered in the several commercial methods of processing pine wood during the production of turpentine. It has somewhat stronger solvency and slower evaporation rate than turpentine. Standard test methods for sampling and testing dipentene are described in ASTM D 801, Methods of Sampling and Testing Dipentene.

Pine oil is a unique material separated during the four commercial turpentine production methods. Unlike the other hydrocarbon solvents, pine oil consists mainly of terpene alcohols, with a variety of small quantities of other oxygenated terpenes. Pine oil has strong solvent power due to the oxygen functionality. However, its evaporation rate is very slow. Pine oil is generally used in additive quantities, i.e., 5 wt% of the total solvent, to provide good coating flow out and wetting properties. Standard methods for sampling and testing pine oil are described in ASTM D 802.

d-Limonene is a relatively new commercial terpene hydrocarbon solvent recovered and purified from by-products of the citrus industry.

Typical properties of some selected terpene solvents are summarized in Table 4 [*5,6*].

TABLE 3—Typical properties of cyclohexane.

ASTM specification	D 3055
Specific gravity, 60/60°F	0.782
Distillation range, °C	174–178

Evaporation rate, *n*-butyl acetate = 100	40	18	5
Flash point, TCC, °F (°C)	95 (35)	120 (49)	130 (54)
Kauri-butanol value	56	62	>500
Aniline point, °F (°C)	70 (21)	32 (0)	<−4 (<−20)

are synthetically produced. Therefore, they are somewhat higher in cost. Most are pure, single-component chemical products, compared with hydrocarbon solvents which tend to be complex mixtures. Consequently, oxygenated solvents have very narrow distillation ranges, some as narrow as 1°C.

Relative to the hydrocarbons, oxygenated solvents have much stronger solvency and are used as active solvents for most synthetic resins. Their strong solvency, together with the wide range of volatilites available, makes them an extremely important group of solvents for the coatings industry. Other distinguishing characteristics include higher specific gravity and partial to complete water solubility.

There are four principal types of oxygenated solvents widely used in coatings: ketones, esters, glycol ethers (ether alcohols), and alcohols. Through blending, almost any desired combination of performance properties can be obtained.

Ketones

Ketones are characterized chemically by a carbonyl group bonded to two carbon atoms or alkyl groups in the molecule. This versatile class of solvents has powerful solvency and a wide range of evaporation rates, from very fast-evaporating acetone to slow-evaporating isophorone. Ketones are further characterized by their strong, sharp odors. They have narrow distillation ranges because of their high purity. Acetone is completely water miscible, while other ketones have varying degrees of water solubility. Properties of selected ketones, with their ASTM specification references, are summarized in Table 5. (Diacetone alcohol is included in this category since this ketone alcohol functions more as a ketone than an alcohol.)

Acetone is very fast-evaporating. It is often used in aerosols and sprayed coatings, particularly in nitrocellulose and acrylic lacquers, to effectively reduce viscosity for spray application and then quickly flash off during the spraying process. Methyl ethyl ketone (MEK) has a fast evaporation rate and methyl isobutyl ketone (MIBK) a moderate evaporation rate. They are extensively used as active solvents in synthetic resin lacquers and paints. The very slow evaporation rate of isophorone makes it useful in baked industrial coatings.

Esters

Esters used as solvents are alkyl acetates and propionates and glycol ether acetates. Several other types of ester solvents are also commercially available as specialty products. The alkyl esters cover a wide range of volatilities, mainly methyl through hexyl esters. Glycol ether acetates are slow-evaporating, and they are used as retarder solvents in solvent-based coatings and as coalescents in latex paints.

Esters have strong solvency, although generally slightly weaker than ketones of similar volatility. They are characterized by their pleasant, sweet, fruity odors. All esters have narrow distillation ranges since they are relatively pure compounds.

Typical properties of the most common ester solvents are summarized in Table 6. As with ketones, their solvencies follow a general pattern, diminishing with increasing molecular weight and with increasing branching of the molecule. Evaporation rate also decreases with increasing molecular weight, but increases with increased branching. *n*-Butyl acetate, one of the most important ester solvents, has a medium evaporation rate. It is used as a reference for expressing evaporation rates of other solvents.

Glycol Ethers

Glycol ethers are ether alcohols, having both ether and alcohol functionality. The ethylene glycol ethers, derived from ethylene oxide and alcohols, have been widely used in coatings. However, because of health hazard concerns associated with certain ethylene glycol ethers, they are being replaced in many applications by propylene glycol ethers which are derived from propylene oxide.

Glycol ethers have a truly unique combination of properties: strong solvency, slow evaporation rate, complete water miscibility, high flash point, and mild odor. They are often

[c]Propylene glycol monomethyl ether acetate.

used in small percentages in lacquers and lacquer thinners as retarder solvents to maintain coating flow and leveling after most of the other solvents have evaporated. In these applications, their water miscibility is beneficial in reducing moisture blush. Glycol ethers are also widely used as coupling solvents in water-based coatings to solubilize the water-reducible polymers.

Chemical terminology for the glycol ethers is cumbersome. For example, 2-ethoxyethanol is also referred to as ethylene glycol monoethyl ether. Therefore, they are often identified by their commercial brand names. Typical properties of selected glycol ethers are summarized in Table 7.

Alcohols

Alcohols are chemically characterized as organic compounds having a single hydroxyl group. This structure imparts some degree of water solubility to alcohols, complete for the lower members, methanol, ethanol, and propanol, and partial for the higher members of the family. Alcohols are further characterized physically as having mild, pleasant odors. Typical properties of selected alcohols are summarized in Table 8.

By themselves, alcohols are very poor solvents or nonsolvents for most polymers. There are few exceptions; ethanol is a solvent for shellac, poly(vinyl acetate), poly(vinyl butyrate), some phenolics, and natural resins. Alcohols find applications as latent solvents or co-solvents for nitrocellulose lacquers, melamine-formaldehyde and urea formaldehyde resins, and certain alkyds. They are also useful coupling solvents, with glycol ethers, to solubilize water-reducible resins. In addition to their use as solvents, latent solvents, and coupling solvents, alcohols are used as chemical raw materials for the manufacture of other solvents (e.g., ketones and esters), monomers, and synthetic polymers.

Methanol is the fastest evaporating alcohol. It is the only alcohol which has some solvency for nitrocellulose. Methanol, historically known as wood alcohol, is now rarely used as a solvent because of its relative toxicity.

Pure ethyl alcohol (ethanol) is restricted in use by law to beverages and to scientific and analytical purposes. It cannot be used without a federal government permit. Commercial ethyl alcohol, for solvent and chemical intermediate use, is denatured with any of a large number of government-approved substances to make it unfit for use in beverages. There are close to 100 approved denatured formulations available in both 95 vol% (190 proof) and anhydrous (200 proof) grades. Because of the large multiplicity of grades, ASTM specifications have not been established for ethyl alcohol. Isopropyl alcohol can replace ethyl alcohol in most coating solvent applications.

Butyl alcohols (butanols) differ in volatility and solvency among the four isomers, which are: normal, secondary, iso-, and tertiary. All have moderate volatility. Branching increases volatility and decreases solvency. *n*-Butanol is by far the most widely used isomer. *t*-Butanol is a solid at room temperature.

[a]Purity and identity of these pure compounds are determined by a combination of tests of specific gravity (ASTM D 268 or D 4052), boiling point, and distillation range (ASTM D 1078).

The higher-boiling alcohols are used in relatively small amounts in solvent blends, and they find applications mainly in baked industrial coatings.

Other Oxygenated Solvents

Specialty oxygenated solvents include furan solvents and organic carbonates. Currently, they are not specified by ASTM standards. Information about them may be obtained from their suppliers.

Furan solvents of commercial interest include furfuryl alcohol, tetrahydrofuran (THF), and tetrahydrofurfuryl alcohol. These solvents have a cyclic ether structure and are characterized by exceptionally strong solvency for some synthetic resins, especially vinyls.

Ethylene and propylene carbonates are cyclic organic esters which are good solvents for many organic and inorganic materials. The former is a solid at room temperature. Characteristics of these carbonates include high flash point, very slow evaporation rate, high specific gravity, and very low odor.

Other Solvents

Chlorinated Hydrocarbons

Chlorinated solvents obviously contain chlorine atoms in the molecules. This gives them unique features of non-flammability, i.e., no flash point, and very high specific gravity. Several chlorinated solvents specified by ASTM standards are summarized in Table 9.

Methylene chloride has long been the active ingredient in most paint removers. It has strong solvency to soften and swell cured paint films and a very fast evaporation rate.

1,1,1-trichloroethane (methylchloroform) has found solvent applications in coating formulations because it is considered to be non-photochemically reactive by many regulatory agencies, and therefore it does not have to be included in measuring volatile organic compound (VOC) content [*1*].

Trichloroethylene is widely used for metal cleaning in vapor degreasing operations. (See ASTM D 3698, Practice for Solvent Vapor Degreasing Operations.)

Use of chlorinated solvents is declining due to (a) global concerns about their damaging effects on the earth's protective ozone layer and (b) concerns about the toxicity and carcinogenicity of many chlorinated solvents.

Nitrated Hydrocarbons

Nitrogen-containing hydrocarbon solvents include nitroparaffins and N-methyl-2-pyrrolidone (NMP). These are not currently specified by ASTM standards.

There are four nitroparaffinic solvents commercially available: nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane (2NP). Of these, 2NP is of most interest to the coatings industry. It has an evaporation rate similar to that of *n*-butyl acetate, and it is reported to have fast solvent release from coating films.

NMP is a specialty solvent having strong solvency, high flash point, complete water solubility, and high specific gravity. It is reported to be biodegradable and have a low order of toxicity. Applications include paint strippers, water-based coatings, printing inks, and reaction solvent for high-temperature resins.

TABLE 9—Typical properties of selected chlorinated hydrocarbon solvents.

Solvent	ASTM Specification	Grade or Application	Specific Gravity, 20/20°C	Boiling Point, °C	Evaporation Rate, *n*-BuAc = 100
Methylene chloride	D 3506	Pentachlorophenol solutions	1.366	39	1450

Trichloroethylene	D 4080	Vapor degreasing	1.465	86	450
Perchloroethylene	D 4081	Drycleaning	1.625	121	210

Supercritical Carbon Dioxide [7]

It has long been known that certain gases under supercritical temperature and pressure conditions can behave as solvents. They have become useful in a variety of industrial and analytical separation processes, such as extraction, polymer fractionation, chromatography, and catalyst regeneration, and as a reaction medium.

Supercritical fluids have properties intermediate to those of normal liquids and gases. The supercritical fluid region on a phase diagram corresponds to temperatures and pressures near or above the critical point of the fluid where the properties of the liquid and gas are similar or identical, so that in effect only one fluid phase, which is simultaneously liquid-like and gas-like, exists (Fig. 1).

Supercritical carbon dioxide has many useful attributes which make it attractive as a diluent for spray-applied coatings. Carbon dioxide is environmentally compatible because it is not regarded as a volatile organic compound (VOC). It acts as a hydrocarbon diluent and replaces organic solvents to the extent of 10 to 30 vol% of a formulation. Low VOC coatings can be formulated with existing high-performance polymer systems, and 70 to 80% reductions in VOC are achievable. Using carbon dioxide as a coating solvent effects a net reduction in the amount of "green house" carbon dioxide that is otherwise produced as a result of coating operations.

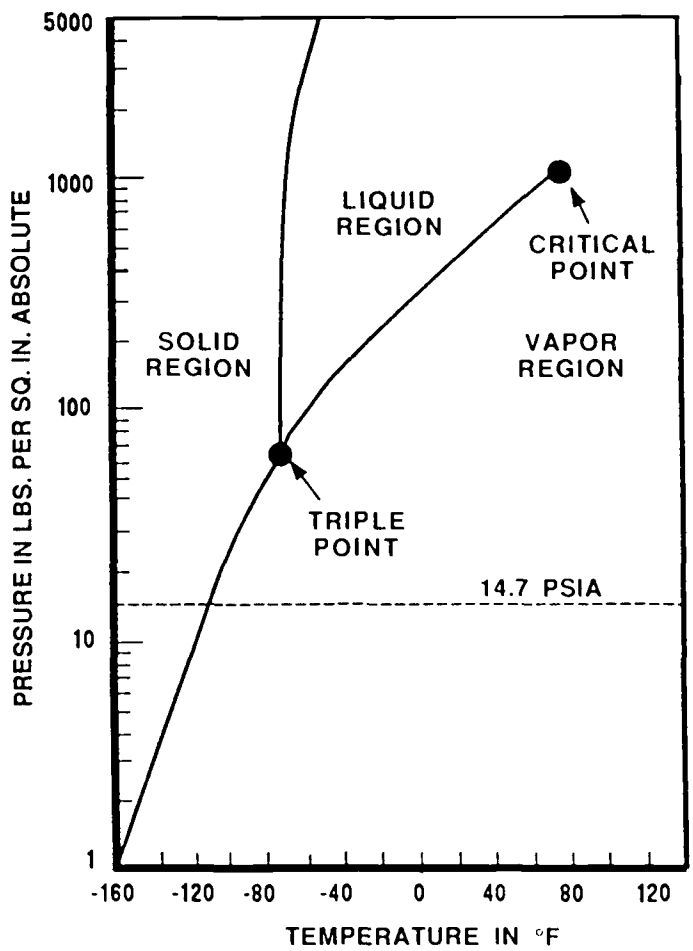

FIG. 1—Phase diagram for carbon dioxide [7].

The UNICARB®[2] process has been developed to utilize supercritical carbon dioxide in airless sprayed coating operations. It has numerous advantages in this application. The temperatures and pressures necessary to use supercritical carbon dioxide are well within the capabilities of present hot, airless spray systems.

Carbon dioxide has low toxicity, is non-flammable, inert, inexpensive, and readily available. Supercritical carbon dioxide has high solubility in most coating formulations, and it is a good viscosity reducer for polymer solutions. In the actual spraying process, it behaves as a highly volatile solvent, producing vigorous atomization that can remedy many of the defects of airless spraying, thereby achieving high quality coatings.

CLASSIFICATION BY FUNCTION

Solvents can be classified according to the function they perform in an end-use application: active solvents, latent solvents, and diluents.

Active Solvents

Active solvents are sometimes called "true solvents." They are the ones that really do the work to dissolve resins and other film formers. Active solvents are usually the more expensive ones with strong solvent power: ketones, esters, and glycol ethers. They are essential for dissolving film-forming resins and for effectively reducing viscosities of paints, varnishes, and lacquers for application.

Relative solvency of active solvents, particularly for lacquers, may be determined by ASTM method D 1720, Dilution Ratio of Active Solvents in Cellulose Nitrate Solution, and expressed in terms of toluene dilution ratio. Stronger solvents will tolerate more hydrocarbon diluent and still keep resins in solution. High toluene dilution ratio values indicate strong solvency. Typical values for selected active solvents may be compared in Tables 5 through 7.

Latent Solvents

By themselves, latent solvents are either poor solvents or nonsolvents for most coating resins. However, they possess a hidden or latent solvency which manifests itself when they are used in combination with active solvents. Latent solvents then behave as if they were strong active solvents. This synergism is used to advantage in formulating nitrocellulose lacquers in particular. Latent solvents are often alcohols, and they are intermediate in cost.

Diluents

Diluents are generally nonsolvents if used alone with synthetic resins. Their function is to participate in solvent blends to provide viscosity reduction through dilution of lacquers and paints and to reduce the cost of thinners and coating

[2]Union Carbide Chemicals and Plastics Co. Inc., 39 Old Ridgebury Road, Danbury, CT 06817-0001.

solvent blends. Diluents are usually low-cost hydrocarbon solvents.

There is usually a limit to how much diluent will be tolerated by coating resins in a solvent blend. If the limit is exceeded, the resins will start to gel or precipitate from solution. Aromatic hydrocarbon solvents are usually tolerated in greater amounts than are aliphatic hydrocarbons.

ASTM Method D 1720 may be used to determine the relative tolerances for hydrocarbon diluent when *n*-butyl acetate is used as the reference active solvent. In the test, the maximum ratio of hydrocarbon diluent to *n*-butyl acetate that will be tolerated by a solution of 8 g of nitrocellulose in a total of 100 mL of solvent and diluent is determined. This provides a measure of the suitability of the diluent for lacquer solvent formulations. For example, the toluene dilution ratio of *n*-butyl acetate is 2.8, while the VM&P naphtha dilution ratio is only 1.2, indicating a much greater tolerance for toluene than for VM&P naphtha.

Solvent Balance

In formulating coating solvents and thinners, careful attention must be paid to the proper balance of solvency and evaporation rate. Generally, expensive active solvents are kept to a minimum amount sufficient to provide adequate solvency and viscosity reduction. Diluent content is usually maximized to keep cost low.

Evaporation rate of each component must be considered in selecting appropriate active solvents and diluents depending on the method of coating application. As the applied coatings dry, the balance of active solvents and diluents remaining in the wet coating must be such that solvency for the coating resin remains sufficiently strong throughout the drying process. Otherwise, resin blush, i.e., precipitation or separation of the resin, can occur resulting in loss of gloss, incompatibility, haze, or other serious coating defects.

KEY PERFORMANCE REQUIREMENTS

Solvency

Solvency is the foremost performance requirement of a solvent. From a practical perspective, the term "solvency" to a coatings formulator refers to the ability of a solvent to (a) dissolve resins, (b) hold those resins in solution in the presence of diluents, and (c) efficiently reduce viscosity of resin solutions, lacquers, and paints. In general, relative solvency is measured indirectly by determining compatibility of specified resins or a chemical reagent with the solvent under test.

Three test methods are most often used for measuring and expressing relative solvent strength: kauri-butanol value, aniline point, and diluent dilution ratio. The first two test methods are used exclusively for hydrocarbon solvents and the latter test for only oxygenated solvents. Although these methods are somewhat archaic, the values obtained have been found to be useful in estimating general solvency for many coating resins.

Another method, a viscosity reduction test, provides a means of direct measurement of solvent power when a specific resin under consideration is employed. Solvents are directly compared by measuring the viscosities of solutions at different resin concentrations and plotting viscosity versus resin concentration.

Kauri-Butanol Value

Kauri-butanol value (KBV) is one measure of the solvent power of hydrocarbon solvents. High KBV indicates relatively strong solvency and often relatively high aromatics content as well. Typical KBVs may be compared in Tables 1 through 4.

KBV is a continuous scale and is sometimes used as an indicator of aromatics content; low aromatic (aliphatic) hydrocarbons have low KBVs and weak solvency, while highly aromatic hydrocarbons have high KBVs and relatively strong solvency. For example, odorless mineral spirits at the low end of the scale has a KBV of about 27, regular mineral spirits about 37, and aromatic hydrocarbons close to 100.

KBV is defined in ASTM Method D 1133, Kauri-Butanol Value of Hydrocarbon Solvents, as the volume in milliliters of the solvent at 25°C required to produce a defined degree of turbidity when titrated into a specified quantity of a standard clear solution of kauri resin in *n*-butyl alcohol. Kauri resin, a natural product, now archaic, was once used as a coating resin. However, standard test solutions are available from chemical supply companies. The kauri resin solution is standardized against toluene, which has an assigned value of 105, and a mixture of 75% *n*-heptane and 25% toluene on a volume basis, which has an assigned value of 40.

The procedure is to accurately weigh 20 g of standardized kauri-butanol solution into an Erlenmeyer flask and bring the flask and its contents to 25°C in a water bath. It is then titrated with the solvent being tested to a turbidity end point that occurs when the sharp outlines of 10-point print on a sheet placed under the flask are obscured or blurred but are not illegible. Turbidity at the end point is caused by precipitation of the kauri resin at incipient incompatibility.

This test is not applicable to oxygenated solvents.

Aniline Point

Aniline point (or mixed aniline point) is another measure of solvency of hydrocarbon solvents. In addition, it is often used to provide an estimate of the aromatics content of hydrocarbon mixtures. Aromatic hydrocarbons (strong solvents) exhibit the lowest aniline points and aliphatics (weak solvents) the highest. Naphthenes have values between those for aromatics and aliphatics. In homologous series, the aniline point increases with increasing molecular weight, i.e., decreasing solvency.

Aniline point is defined in ASTM Method D 611, Aniline Point and Mixed Aniline Point of Petroleum Products and Hydrocarbon Solvents, as the minimum equilibrium solution temperature for equal volumes of aniline and solvent. The reagent for this test is aniline, a clear liquid at room temperature. The procedure requires that equal volumes of aniline and hydrocarbon solvent are placed in a jacketed tube and mechanically mixed. The basic apparatus is shown in Fig. 2, although ASTM D 611 also describes alternative variations in the manual apparatus and an automatic apparatus as well.

Hydrocarbon solvents containing less than 50% aromatics will generally form an incompatible, turbid mixture at room temperature [*8*]. Therefore, the stirred mixture is heated at a

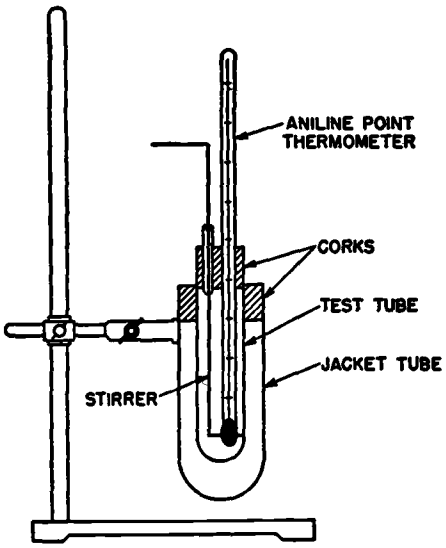

FIG. 2–Aniline point apparatus.

controlled rate until the two phases become miscible and clear. The stirred mixture is then allowed to cool at a controlled rate until it suddenly becomes cloudy throughout. The temperature at this end point is recorded as the aniline point of the solvent.

Hydrocarbon solvents containing more than 50% aromatics will generally form clear, miscible solutions with aniline at room temperature [*8*]. When this occurs, the stirred mixture must be cooled below room temperature at a controlled rate until the cloudy transition point suddenly appears. The temperature at this cloud point is the aniline point.

With hydrocarbons having high aromatics content, the aniline point may be far below room temperature and below the temperature at which aniline will crystallize from the aniline-sample mixture. To treat this circumstance, it becomes necessary to perform a "mixed aniline point" test. Instead of using equal volumes of aniline and sample, a mixture containing two volumes of aniline, one volume of sample, and one volume of *n*-heptane of specified purity is made. The test is then performed as described above, and the result is reported as the "mixed aniline point." Again, low values indicate strong solvency (the opposite of kauri-butanol values).

Unlike the continuous KBV scale, a disadvantage of the aniline point and mixed aniline point is that the two scales are not continuous. Therefore, it is difficult to directly compare high- and low-aromatic content solvents [*8*].

This test is not applicable to oxygenated solvents.

Diluent Dilution Ratio

The diluent dilution ratio test measures the solvency of oxygenated (active) solvents by determining their ability to hold in solution a difficult-to-dissolve resin, nitrocellulose, in the presence of hydrocarbon diluent. The test measures the maximum ratio of hydrocarbon diluent to oxygenated solvent that can be tolerated by the nitrocellulose solution. Strong oxygenated solvents provide a high tolerance for diluent and have high diluent dilution ratios. Typical values may be compared in Tables 5 through 7.

ASTM Method D 1720 defines diluent dilution ratio as the maximum number of unit volumes of a diluent that can be added to a unit volume of solvent to cause the first persistent heterogeneity (precipitation) in the solution at a concentration of 8 g of cellulose nitrate per 100 mL of combined solvent plus diluent at 25°C.

The procedure is to dissolve carefully dried nitrocellulose in the oxygenated (active) solvent, and with stirring, add hydrocarbon diluent by titration. The end point occurs at the first persistent appearance of resin precipitation or gelation. Additional active solvent is then added to redissolve the resin, and titration is continued to a second end point. The data are plotted to determine the ratio of diluent to active solvent at exactly 8 g of cellulose nitrate per 100 mL of total solvent.

Most often, toluene is used as the diluent in the test, and the result is expressed as the "toluene dilution ratio." However, other hydrocarbons, e.g., VM&P naphtha, may also be used, thereby producing different (lower) values expressed as "naphtha dilution ratios." Although cellulose nitrate is used as the "reagent" in this test, and the results are most meaningful for formulating nitrocellulose lacquers, it has been found from experience that the solvency ranking of oxygenated solvents according to their diluent dilution ratios applies to other coating resins as well.

As described in the Section entitled "Diluents," ASTM D 1720 may also be applied to compare and measure the suitability of specific diluents for use in lacquer solvent and thinner formulations by using *n*-butyl acetate as the reference active solvent in the test.

Dilution Limit

Some resins are soluble at high concentrations in a solvent but become incompatible and precipitate when diluted below a critical concentration, which is termed the dilution limit. Sometimes, this concentration is within the range of practical formulations. Therefore, it is important to know whether a dilution limit exists for a particular resin. To determine the dilution limit, a known weight of resin is dissolved in the solvent. Solvent is then added until precipitation, the first persistent cloudiness, appears. Dilution limit is expressed as the percent by weight of resin at the end point [*8*].

Viscosity Reduction

The relative solvency of different solvents for a given resin may be compared with each other or with a reference solvent by measuring the viscosities of different concentrations of the given resin in each of the solvents. The viscosities are then plotted as a function of resin concentration. An example is shown in Fig. 3 [*1*].

Viscosities of resin solutions can be measured precisely by ASTM Method D 445, Kinematic Viscosity of Transparent and Opaque Liquids, or by ASTM Method D 1725, Viscosity of Resin Solutions. A simpler, more widely used, but less precise method for determining resin solution viscosities is ASTM Method D 1545, Viscosity of Transparent Liquids by Bubble Time Method (Gardner-Holdt Viscosity).

At high resin concentrations, solution viscosity will depend on solvency of the solvent and solubility of the resin. However, at low resin concentrations, the solution viscosity becomes more influenced by viscosity of the pure (neat) solvent. Viscosities of selected solvents are listed in Table 10 [*17*].

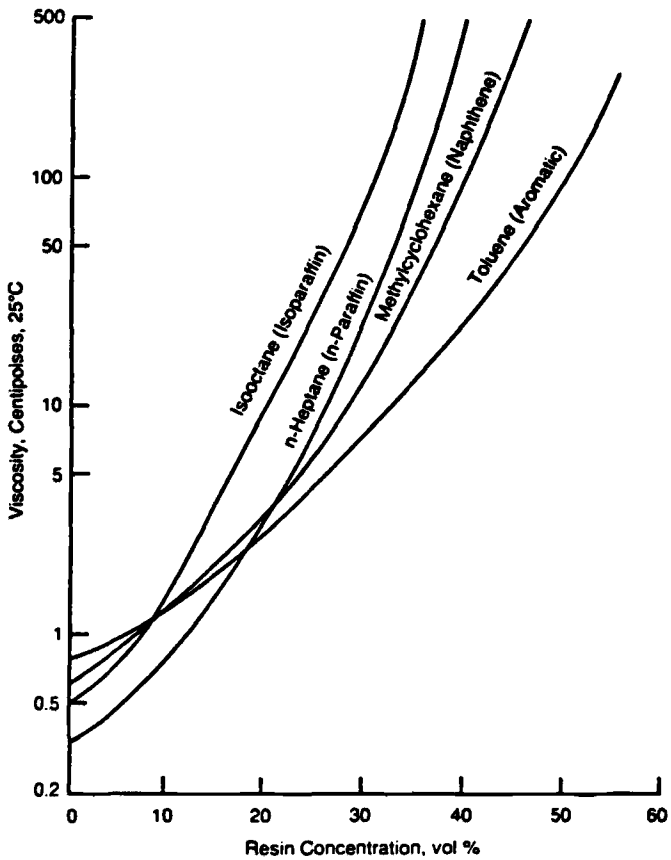

FIG. 3–Effect of solvent type on solution viscosity (medium oil alkyd in four hydrocarbon types) [*1*].

Solubility Parameters

Great strides have been made in developing theoretical models to describe solvency and to predict the capacity of a pure solvent or solvent blend to dissolve a given resin. The concept of solubility parameters was first proposed by Hildebrand [*9,10*], and it was applied to practical applications in the coatings industry by Burrell [*11*]. Further refinements and enhancements to the solvency model made by Burrell [*12*], Crowley [*13*], Hansen [*14,15*], and others have resulted in the evolution of a model that is workable, reasonably accurate in its predictions, and useful as a formulating tool.

The three-dimensional solubility parameter is the most widely used method for predicting miscibility/solvency between solvents and polymers. In this method, each polymer and each solvent is characterized by three solubility parameters: δ_d representing dispersion forces, δ_p representing polar forces, and δ_h representing hydrogen bonding forces. Therefore, polymers and solvents can be represented by points in a three-dimensional plot using the three solubility parameters.

Each polymer point may constitute the center of a sphere, the so-called "sphere of solubility," of radius R, known as the radius of interaction. Solvents whose points lie at a distance less than R from the center of the polymer's sphere, i.e., within the sphere, should dissolve the polymer. Conversely, solvents whose point coordinates lie outside of the sphere are not expected to dissolve the polymer [*16*]. A more thorough discussion of solubility parameters can be found in Chapter 35.

A very comprehensive source of solubility parameter information and data is the "CRC Handbook of Solubility Parameters and Other Cohesive Parameters" by A. F. M. Barton (CRC Press, 1983). A simpler, two-dimensional approach to solubility parameters, employing only the dispersion and hydrogen bonding parameters, is described in ASTM Method D 3132, Test for Solubility Range of Resins and Polymers. Most major solvent suppliers have developed computer programs, based on the solubility parameter concept, to aid in formulating solvent blends to optimize solvency, obtain desired performance requirements, and minimize cost.

Volatility

Volatility of a solvent describes its inherent tendency to transform from a liquid to a vapor. The fundamental controlling property is vapor pressure. Volatility is manifested by such properties as evaporation rate, boiling point, and flash point.

Vapor Pressure

All liquids have a tendency to vaporize and become gases, depending upon their relative vapor pressures. A solvent's

liquid vapor pressure is the pressure exerted by molecules at the liquid surface in their attempt to escape the liquid phase and penetrate their gaseous environment. In a physical sense, vapor pressure is the force exerted on the walls of a closed container by the vaporized portion of the liquid. Conversely, it is the force which must be exerted on the liquid to prevent it from vaporizing further. For a given liquid solvent, vapor pressure is a function purely of temperature. The more volatile a solvent, the higher the liquid vapor pressure at a specified temperature and the faster the vaporization, i.e., evaporation rate. A knowledge of the vapor pressure/temperature relationship is important in the safe design of solvent storage and distribution equipment to minimize solvent losses by vaporization.

Relative vapor pressures of pure solvents and blends are measured at 100°F (38°C) by ASTM Method D 323, Reid Vapor Pressure (RVP). The RVP apparatus consists of a double-chamber bomb fitted with a pressure gage. The lower chamber, which has one quarter the capacity of the upper chamber, is filled with the liquid solvent sample. The sample and its chamber are chilled to 0°C (32°F) to reduce premature evaporation, the bomb is sealed, and it is immersed in a 100°F (38°C) water bath. To assure full opportunity for vaporization, the bomb is removed from the bath periodically for a brief vigorous shaking. When an equilibrium temperature is reached and when the bomb pressure gage (which initially registered zero) has stabilized at maximum value, the pressure is recorded. After applying appropriate correction factors, the pressure is reported as Reid vapor pressure at 100°F (38°C).

Alternatively, vapor pressure of a solvent can be measured over a wide range of temperatures by ASTM Method D 2879, Vapor Pressure by Isoteniscope. This procedure utilizes a differential manometer, one leg of which is exposed to saturated vapor while the other is evacuated. Measurements are reported in absolute units. Absolute vapor pressures of selected solvents at 20°C are listed in Table 11 [*6,17*].

TABLE 11—Vapor pressures of typical commercial solvents.

Evaporation Rate

Evaporation rate of a solvent is second only to solvency in its importance to the coatings industry. Although solvents are transient ingredients of a coating, they perform vital functions but must ultimately leave the coating film by evaporation. During application of a coating, solvents play a role in controlling flow characteristics as the film forms. If solvent evaporation is too fast, the coating film will not level and flow out to form a smooth surface, the result being a rough, "orange peel" effect in spray-applied coatings, or brush marks if brush applied. Conversely, if solvent evaporation is too slow, the coating may run and sag on vertical surfaces, or solvents may become trapped in the film as it cures, thus impairing performance properties of the coating.

Proper solvent balance, the ratio of active solvent to diluent, is also important. If this balance becomes upset as a result of composition changes during evaporation, resin precipitation can occur, thereby causing a loss of film integrity. Therefore, solvent evaporation rate is a key factor in the formulation of coatings. Relative evaporation rates of selected solvents of various types may be compared in Fig. 4 and in Tables 1 through 9.

Evaporation rates of solvents are always expressed on a relative basis. They are not absolute values in practical situations because evaporation rates are dependent upon numerous environmental factors including temperature, airflow, humidity, exposed surface area, and the presence of resin and pigment. Humidity has no effect on the evaporation of hydrocarbon solvents, but it can significantly retard evaporation of oxygenated solvents which are completely or partially water miscible.

It is common practice to express evaporation rates relative to *n*-butyl acetate, a widely used, medium-evaporating solvent as a reference. Evaporation rate of *n*-butyl acetate is arbitrarily assigned a value of 100 (or sometimes 1.0 depending on the scale used). Solvents evaporating faster than *n*-butyl acetate have higher values for evaporation rate; those solvents evaporating slower have lower numerical values. Use of a reference standard compensates for differences in test procedure or environmental factors.

Numerous techniques have been used for measuring relative evaporation rates, some of them gravimetric, some volumetric. The ones currently most widely used are based on the gravimetric procedure and instrumentation (or some variation thereof) described in ASTM D 3539, Test Method for Evaporation Rates of Volatile Liquids by Shell Thin-Film Evaporometer. In this method, a measured volume of liquid

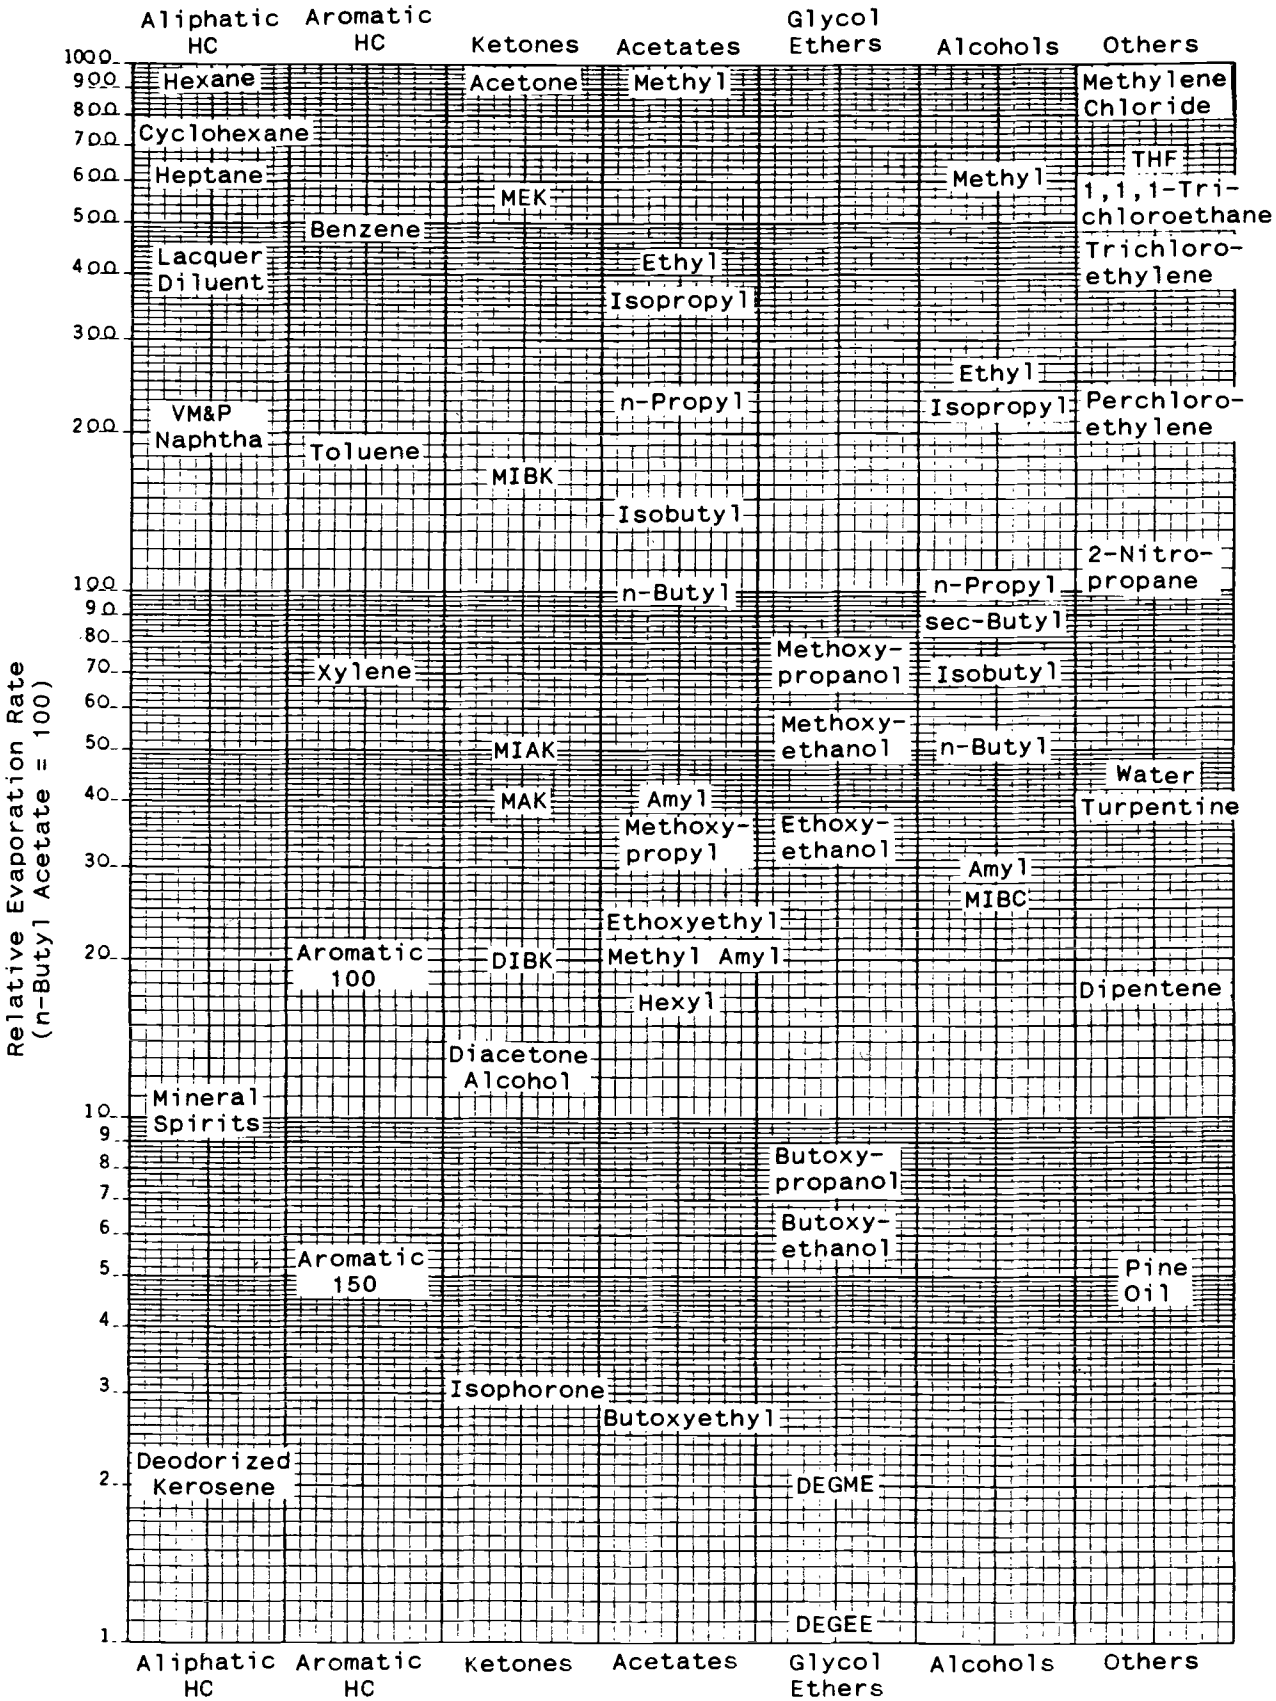

FIG. 4–Relative solvent evaporation rates.

solvent is spread on a known area of filter paper that is suspended from a sensitive balance in a controlled environment cabinet. Weight loss of the filter paper/solvent liquid is measured as a function of time as the solvent evaporates.

Early models of the apparatus use a Jolly spring as the gravimetric measuring device and require manual measurement of weight and time (Fig. 5). More recent models employ an electrobalance and automatically record weight loss versus time (Fig. 6). The Shell Thin-Film Evaporometer and the Chevron Research Evapograph operate under similar principles.

The basic procedure with both the manual and automatic instruments is similar. The evaporation chamber and sample are conditioned to 25°C (77°F). Airflow rate (21 L/min) and relative humidity (less than 5%) in the chamber are set. A filter paper, 90 mm in diameter, is horizontally suspended in the evaporation chamber from the weight-sensing device. The solvent sample (0.7 mL) is added from a hypodermic syringe and distributed over the entire area of the filter paper within a period of 10 s. Data are reported as time in seconds for 10% solvent weight increments through the evaporation cycle, and they are plotted as percent solvent evaporated versus elapsed time (for example, see Fig. 7) [*8,18*]).

The procedure is repeated using *n*-butyl acetate as the reference standard. Elapsed time for 90% evaporation of specimen and standard are determined. Evaporation *rate* of the solvent specimen is calculated as the ratio of 90% evaporation time for *n*-butyl acetate standard divided by the 90% evaporation time for the solvent specimen and normalized so that the evaporation rate of *n*-butyl acetate is 100 (or 1.0). The 90% evaporation time is generally used since some curvature of the plot usually occurs above that data point. Evaporation plots for pure solvents are nearly straight lines. Solvent mixtures or blends produce curved plots, the curvature becoming more extreme as differences in the evaporation rates of individual blend components become greater. Several solvent suppliers have developed computer programs to model and predict evaporation rates of solvent blends [*25–29*].

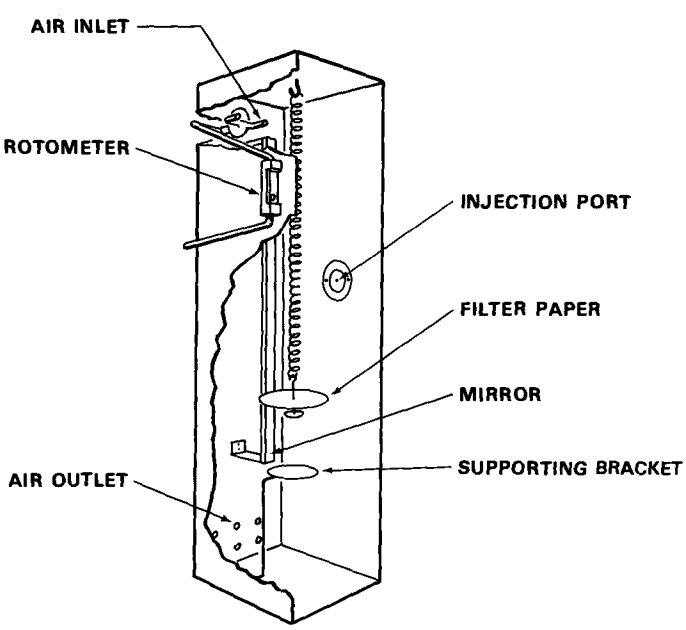

FIG. 5–Thin-film evaporometer.

The information presented so far has dealt with the evaporation of neat (pure) solvents. The presence of resin solute, e.g., in a lacquer or paint, retards solvent evaporation as illustrated in Fig. 8. In addition, some solvents are preferentially retained more than others by certain polymers due to solvent/polymer interactions arising from factors such as polarity and hydrogen bonding.

As solvent evaporation from a coating film progresses, it slows down markedly. The evaporation rate-limiting factor changes from neat solvent volatility to diffusion through the coating film. Diffusion-limited evaporation is much slower [*19*].

Actual evaporation of solvents from polymer films must be determined empirically. Although there are no standard test methods for doing so, various experimental procedures are reported in the literature [*8*]. Murdock and Wirkus [*20*], as well as Hays [*21*], tagged solvents with carbon-14 and measured residual radioactivity after the bulk of the solvent had evaporated. More recently, gas chromatography has been used effectively. Sletmoe modified a Shell thin-film evaporometer to permit sampling and subsequent analysis of evaporating vapor [*22*]. Lesnini evaporated the solvent from a series of solution aliquots and used a gas chromatograph to determine the type and amount of solvent remaining [*23*]. He dissolved the resin solution in a carrier solvent to ensure that a representative sample of the retained solvent was recovered for analysis.

A similar empirical procedure was used by a major solvent supplier to develop a database and appropriate algorithms for a solvency/evaporation rate computer program [*24,25*]. The program models solvency and evaporation rates of solvent blends from coating films, taking into account specific resin/solvent interactions. It calculates evaporation data for solvent blends evaporating from coating films and the compositions and solvency interaction radii of the solvent blends remaining in the film at any time.

Boiling Point/Distillation Range

Vapor pressure of a solvent increases as its temperature increases, as illustrated in the generalized graph in Fig. 9. If a solvent is heated to a high enough temperature, its vapor pressure will eventually rise to a value equal to 1 atm (e.g., 760 mm mercury pressure at sea level). At that point, the solvent will vaporize not only from the surface of the liquid, but vapor bubbles will form within the body of the liquid. This phenomenon is called "boiling," and the corresponding temperature at which it initially occurs is the "boiling point" [*30*]. When a solvent consists of a mixture of chemical components, as is the case with most hydrocarbon solvents, boiling occurs over a range of temperatures referred to as the "boiling range" or "distillation range." Single-component, pure solvents have single, unique boiling points or very narrow distillation ranges.

Distillation temperature or range is an important physical property which is listed in all solvent specifications. It is useful as an identification test (in combination with other tests, such as specific gravity), but will not differentiate between solvents of similar boiling point or range. Distillation range also gives an indication of solvent purity. This is partic-

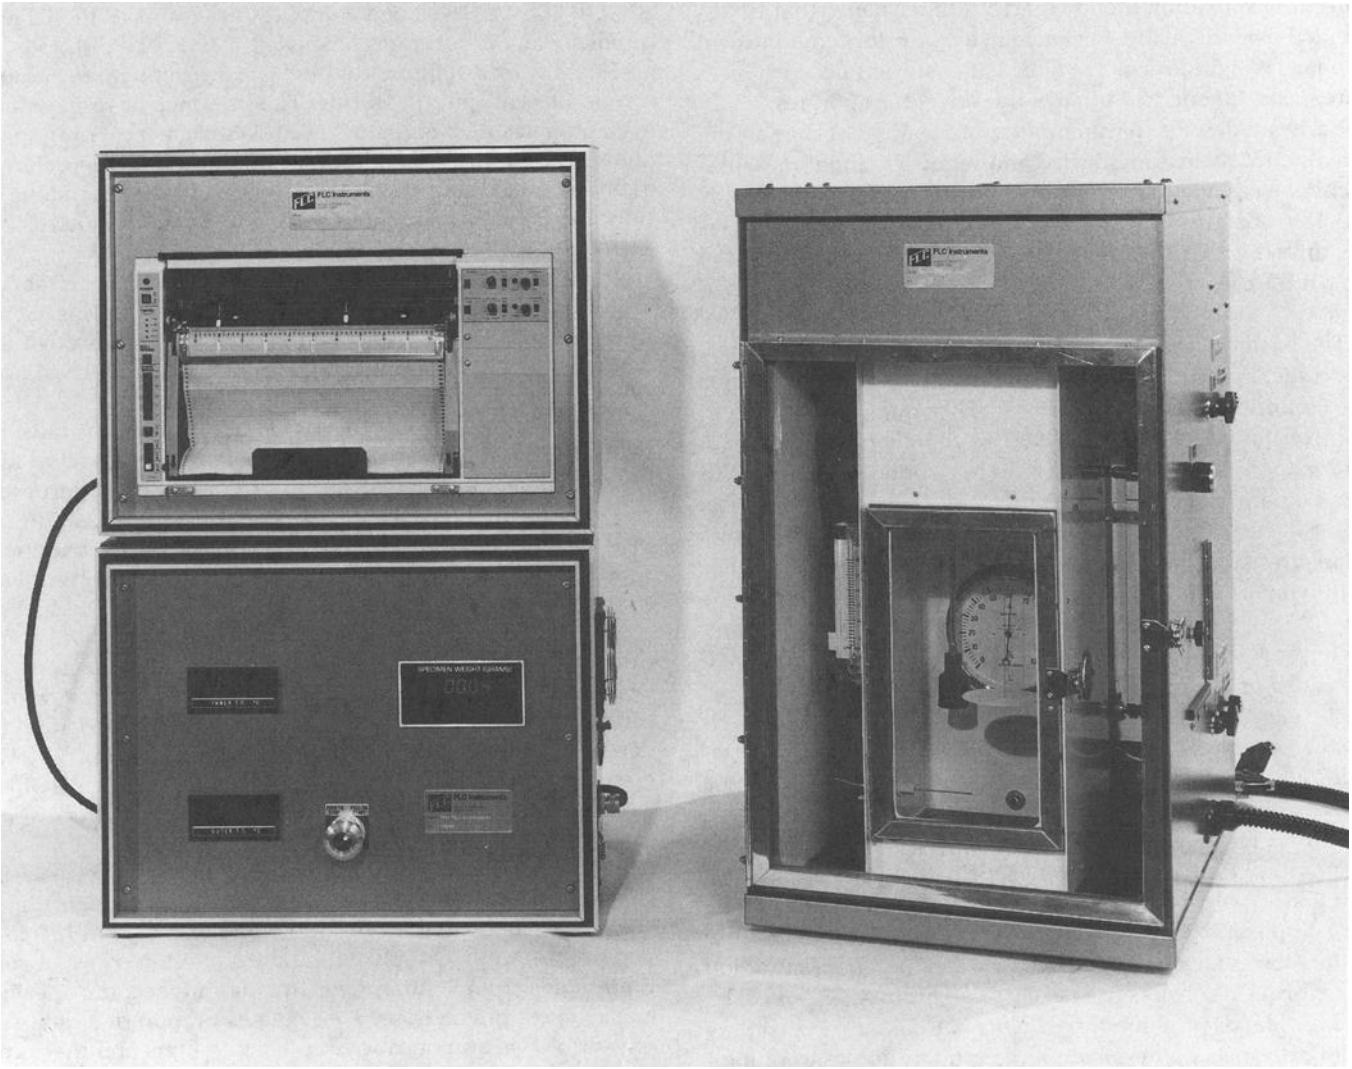

FIG. 6–Automatic thin-film evaporometer.

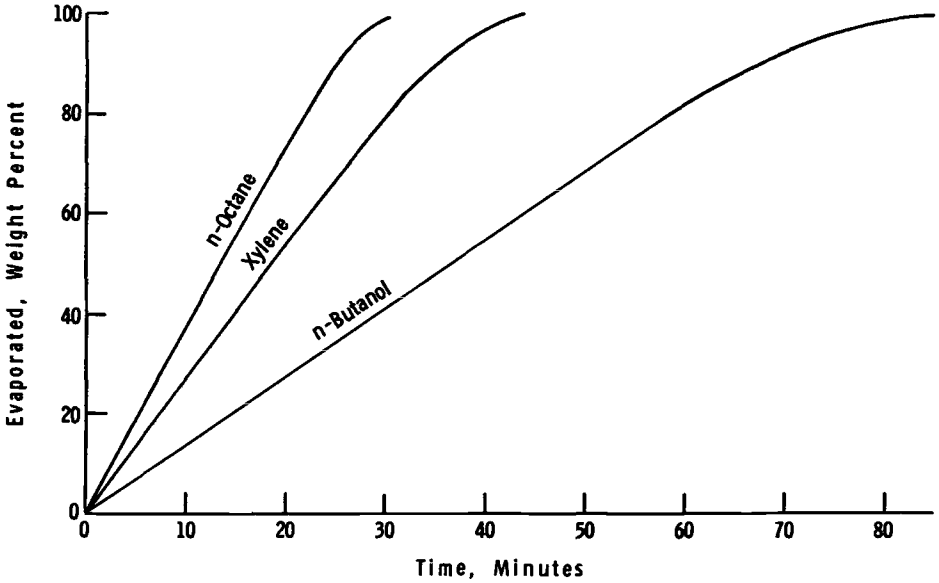

FIG. 7–Evaporation rates of typical solvents (Chevron Research Evapograph at 80°F).

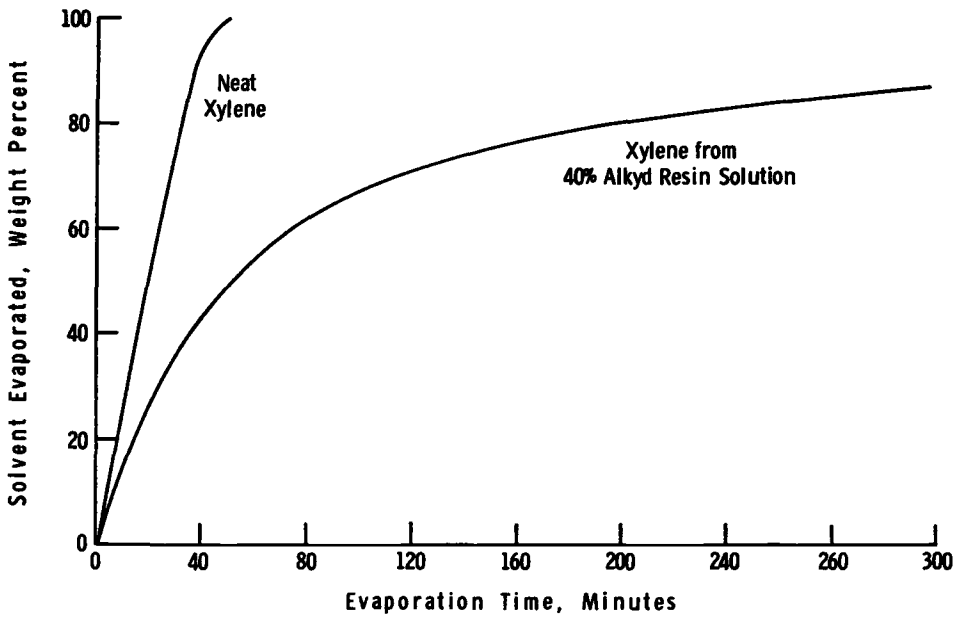

FIG. 8–Evaporation rate of xylene—Neat, and from a 40% solution of medium oil alkyd (Chevron Research Evapograph at 80°F).

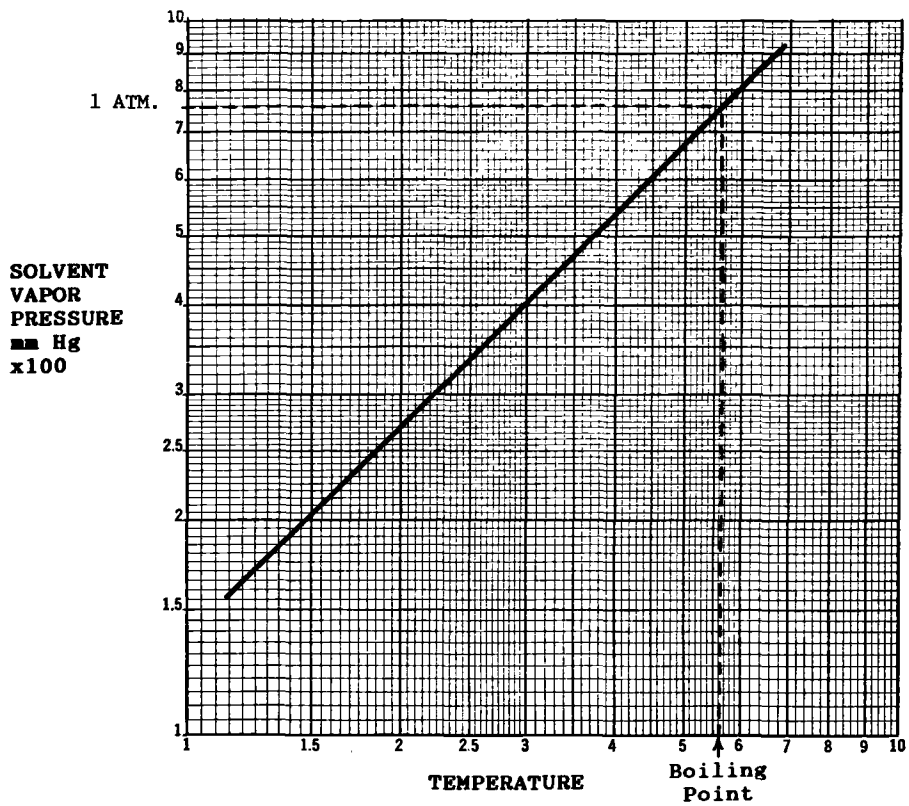

FIG. 9–Solvent vapor pressure versus temperature (idealized representation) [*30*].

ularly true for oxygenated solvents, which are relatively pure compounds. The more narrow the distillation range, the more pure is the solvent. Therefore, it is a useful test for detecting the presence of impurities or contaminants.

In addition, distillation temperature may be used to approximate the relative evaporation properties of one solvent versus another, although it does not provide precise information about evaporation rate. Evaporation/distillation temperature comparisons should not be made between dissimilar types of solvents since such predictions would be erroneous. However, for similar types of solvents, and for hydrocarbon solvents in particular, distillation data can be used effectively as a first approximation or gross measure of relative evaporation rate. For hydrocarbon solvents, the 50% distillation

point (i.e., the temperature at which 50% of the solvent has distilled) has been found to have a good correlation with evaporation rate [*8*].

The McArdle-Robertson evaporation index is based on the 50% distillation temperature [*31*]. It is intended primarily to apply to straight-run paraffinic naphthas having distillation ranges of not more than 40°C and to compare their relative evaporation times, as illustrated in Fig. 10.

There are three ASTM distillation test methods which are used for different kinds of solvents:

1. ASTM D 86, Distillation of Petroleum Products, is intended to be used for wide-boiling hydrocarbon solvents such as VM&P naphthas and mineral spirits.
2. ASTM D 850, Distillation of Industrial Aromatic Hydrocarbons and Related Materials, is intended for narrow-boiling aromatic solvents such as toluene, ethylbenzene, and xylenes.
3. ASTM D 1078, Distillation Range of Volatile Organic Liquids, is intended for narrow-boiling solvents, oxygenated solvents in particular, and also for certain hydrocarbon solvents, chlorinated solvents, and others.

The same solvent sample, tested by each of the three ASTM methods, may produce different distillation data due to variations in the equipment and procedures. It is important, therefore, when presenting distillation data or solvent specifications, to indicate the test method used.

The basic test procedure described in all three test methods is similar, although there are differences as noted in Table 12. The sample is heated in a glass distillation flask until it boils. Solvent vapors are cooled and condensed by passing them through a jacketed, water-cooled tube. Condensate is collected in a calibrated receiver. Distillation temperatures are registered on a thermometer immersed in the vapor in the neck of the distillation flask. Distillation temperatures are usually recorded at the initial boiling point, and when 5, 10, and each additional 10% up to 90%, and 95% of the sample have distilled over, and at the dry point. Typical distillation temperatures of selected commercial solvents are listed in Tables 1 through 9.

The basic assembly of the manual distillation apparatus is illustrated in Fig. 11. Automatic distillation equipment (Fig. 12) employing the same basic principles is available. The automatic equipment uses a thermocouple for temperature measurement and an automatic moving photocell sensing device to measure liquid level in the receiver. A recorder charts the volume of distillate recovered versus temperature.

There are specific terms to describe key temperatures in all ASTM distillations:

1. *Initial boiling point*—The temperature indicated by the distillation thermometer at the instant that the first drop of condensate falls from the condenser tube into the receiver.
2. *Dry point*—The temperature indicated at the instant that the last drop of liquid evaporates from the lowest point in the distillation flask.
3. *End point, final boiling point,* or *maximum temperature*—The maximum thermometer reading obtained during the test. This usually occurs after the evaporation of all liquid from the bottom of the distillation flask. If there are "heavies" in the sample, and there is no clean dry point, the end point is taken as the thermometer reading 5 min after the 95% distillation point.
4. *Decomposition Point*—The temperature reading that coincides with the first indication of decomposition of the liquid in the flask. Decomposition, if it occurs, is evidenced by smoke and fumes in the flask; the temperature ceases to rise and begins to fall.

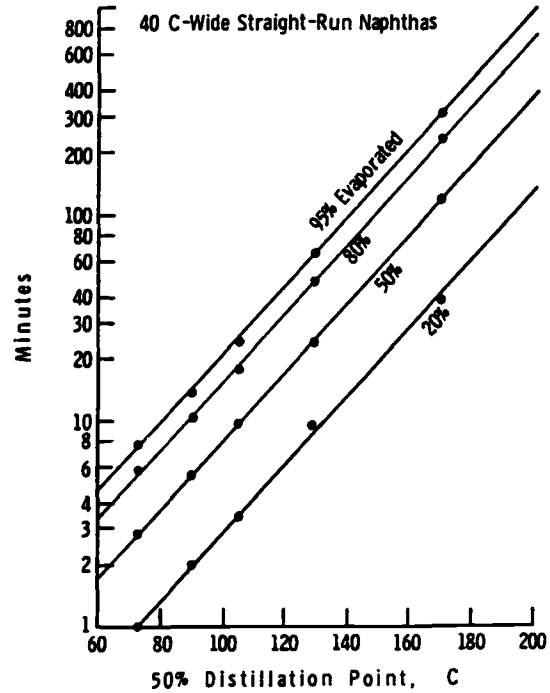

FIG. 10—McArdle-Robertson index for estimating evaporation rate from distillation temperatures (courtesy of *Industrial Chemistry*).

Two common sources of error or bias in distillation data are (a) improper placement of the thermometer in the distillation flask, and (b) failure to make appropriate corrections for barometric pressure. The thermometer must be positioned exactly as shown in Fig. 13. Higher placement will result in consistently lower temperature readings; lower placement may give higher readings.

Distillation temperature readings must be corrected for deviations from standard sea-level barometric pressure. Otherwise, tests run at high altitude or low barometric pressure will result in inaccurate, low distillation temperatures, while high barometric pressure will cause high distillation temperatures. Correction factors appropriate for specific solvents are listed in the ASTM test methods.

Flash Point

Flash point is another manifestation of volatility. The flash point of a liquid is defined as the lowest temperature at which the liquid gives off enough vapor to form an ignitable mixture with air to produce a flame when a source of ignition is brought close to the surface of the liquid under specified conditions of test at standard barometric pressure (760 mmHg, 101.3 kPa). Appropriate corrections must be made for barometric pressure deviations from standard pressure since flash point is dependent on vapor concentration, which is governed by vapor pressure.

TABLE 12—Comparison of ASTM distillation test methods for solvents.

Sample Type	ASTM D 86, Wide-Boiling Hydrocarbons	ASTM D 850, Narrow-Boiling Aromatics	ASTM D 1078, Narrow-Boiling Oxygenated (and others)
Sample size, mL	100	100	100
Distillation flask size, mL	125	200	200
Number of specified thermometers	2	8	14
Insulating shield hole size, mm	50	25–50[a]	38
Condenser temperature, °C	0–60[a]	10–20	0–50[a]
Rate of heat up to IBP, time, min	5–15[a]	5–10	5–15[a]
Rate of distillation, mL/min	4–5	5–7	4–5
95% point to EP, time, min	5	...	5

[a]Varies depending on boiling point and range of sample.

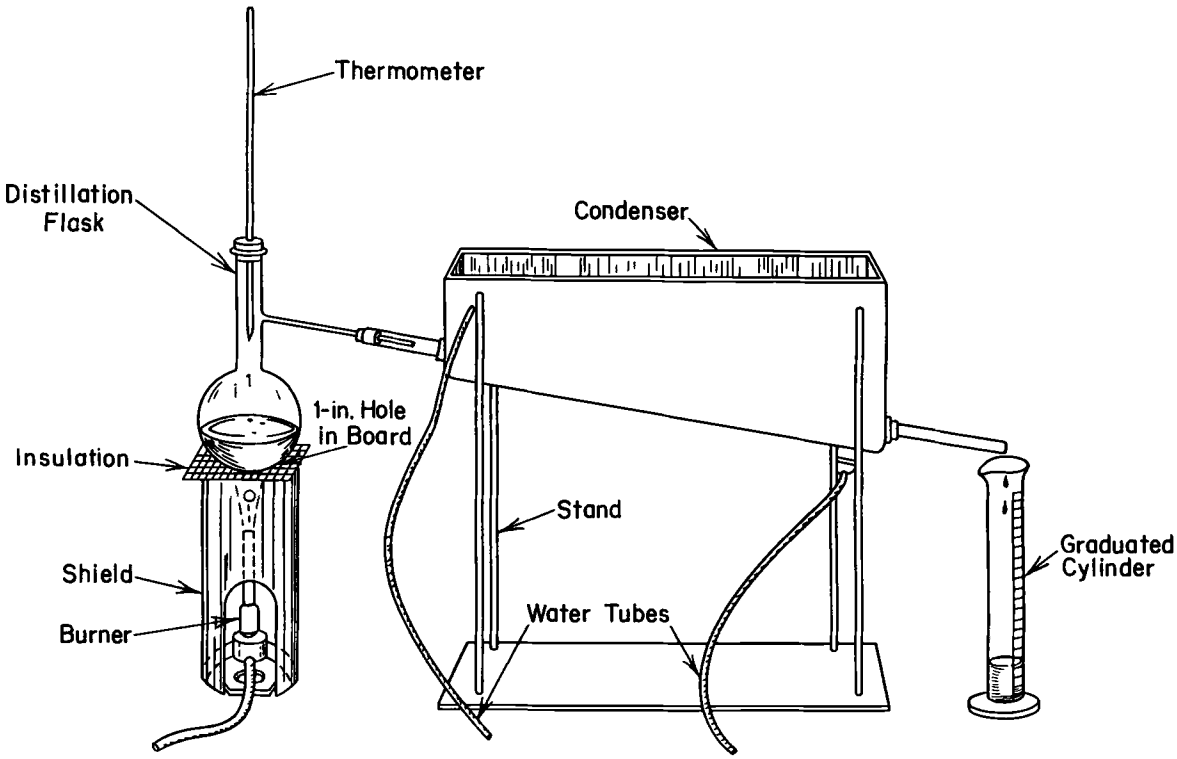

FIG. 11–Apparatus assembly for distillation test.

Similar to the vapor pressure/temperature relationship, solvent vapor pressure *concentration* in air is also a function of temperature, as shown in the generalized illustration in Fig. 14 [*30*]. At low temperatures, there is insufficient vapor concentration (fuel) available to ignite and produce a flame. In this temperature region below the flash point temperature, the solvent vapor cannot be ignited by a spark or flame.

As the temperature of the solvent is gradually increased, there is an accompanying increase in vapor concentration above the surface of the liquid. At a certain temperature, there will be sufficient vapor (fuel) to form a flammable (or explosive) mixture, and a fire will occur if a spark or flame is introduced. The temperature of the liquid at this point is called the "flash point," and the concentration of vapor at this temperature is called the "lower flammable limit" or "lower explosive limit" (LEL). Typical flash points of selected commercial solvents are listed in Tables 1 through 8.

At temperatures above the flash point, a flammable mixture of solvent vapor and air is present above the surface of the solvent. Just as "flash point" represents the lower temperature limit for ignition, there is also an upper limit beyond which the vapor/air mixture is too rich to ignite and burn. The vapor concentration at the upper temperature limit is called the "upper flammable limit" or "upper explosive limit" (UEL). *It must be emphasized that these phenomena apply only to equilibrium, closed systems.* For hydrocarbon solvents, the LEL is usually about 1 vol% solvent vapor in air, and the UEL is about 7 vol%, but for oxygenated solvents, these values can vary over a wide range.

Flash point is one indicator of the relative flammability hazard of solvents and solvent-containing products. The U.S. Department of Transportation (DOT) and the U.S. Department of Labor (OSHA) designate "flammable liquids" as those having flash points below 100°F (38°C). These require special packaging and handling. International cargo regulations specify a 140°F (60°C) flash point as the upper limit for "flammable liquids." In addition to being used to classify materials in government regulations, flash point limits are

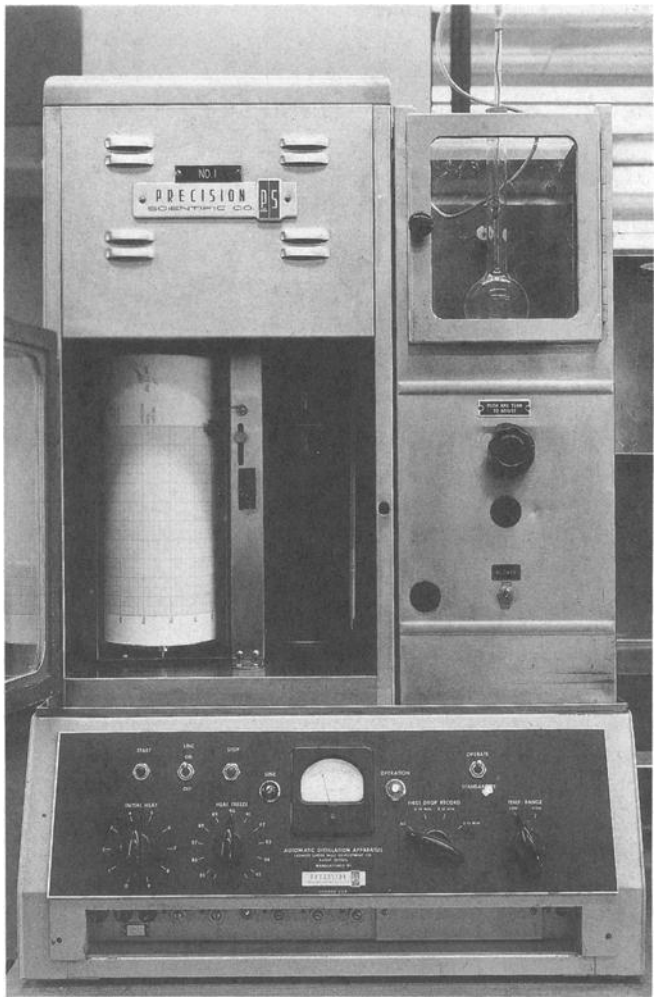

FIG. 12–Automatic distillation apparatus.

often listed as one of the requirements in solvent specifications, for hydrocarbon solvents in particular. Flash point may also be used to indicate the presence of impurities or contaminants in a given liquid, such as the presence of residual solvents in solvent-refined drying oils.

Flash point is roughly inversely proportional to volatility. The most volatile solvents tend to have the lowest flash points, which are indicative of the greatest fire hazard. With mixtures of miscible solvents, the component having the lowest flash point largely determines the flash point of the mixture when that component is present in substantial proportion, e.g., 5% or more. Mutually miscible mixtures of flammable/nonflammable liquids exhibit a direct, though often complex, relationship between flash point and the concentration of the flammable component, e.g., alcohols and water.

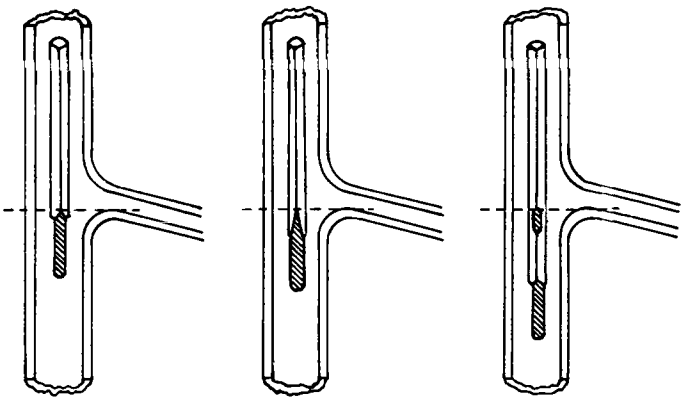

FIG. 13–Position of thermometer in distillation flask.

Chlorinated solvents, most of which are nonflammable, will have various effects in mixtures with flammable solvents. Some will suppress (i.e., raise or prevent) the flash point of flammable liquids because of the high vapor pressure of the nonflammable chlorinated solvent. However, some mixtures of chlorinated solvents and flammable liquids will lower the flash point below that of the flammable liquid, e.g., mineral spirits and methylene chloride [*32*].

It is good practice to actually measure the flash point of solvent blends because of the uncertainty of making predictions. There are several test methods commonly used.

Tag Open Cup—ASTM Method D 1310, Flash Point and Fire Points of Liquids by Tag Open-Cup Apparatus, may be used for determining the *open cup* flash points of liquids having flash points between zero and 325°F (−18 and 165°C). The sample is cooled to at least 20°F (11°C) below the expected flash point, and it is placed in an uncovered cup jacketed by a heat transfer fluid. The sample cup is filled to a depth of approximately ⅛ in. below the edge, and it is heated at a slow, constant rate. Temperature is measured by a thermometer immersed in the sample. A small test flame is passed at a uniform rate across the surface of the cup at 2°F (1°C) intervals of temperature rise until a flash of flame is observed. The sample temperature corresponding to the flash of flame is the "flash point" (Fig. 15).

"Fire point" can be determined with the same apparatus by continuing the test. Fire point is defined as the lowest temperature at which sustained burning of the sample takes place for at least 5 s.

Although the Tag Open Cup Flash Point test may appear to represent real life situations of open containers or accidental solvent spills, the test results could be misleading, especially for solvent blends. As the sample is slowly heated, the lightest, most volatile component in the blend may escape without being ignited. Therefore, *closed cup* test methods are now preferred by most regulatory agencies.

Tag Closed Cup—ASTM Method D 56, Flash Point by Tag Closed Cup Tester, uses an apparatus which confines solvent vapors in a closed cup (Fig. 16). It is intended for testing liquids (a) which contain no suspended solids, (b) which do not form a surface film under test conditions, (c) with viscosities below 9.5 cSt at 77°F (25°C) or below 5.5 cSt at 104°F (40°C), and (d) flash points below 200°F (93°C).

The 50-mL sample, cup, and heat transfer fluid in the cup jacket are cooled to 20°F (11°C) below the expected flash point. With the cup lid closed, the sample is heated at a specified slow, constant rate, as measured by a thermometer immersed in the sample. A small test flame of specified size is momentarily directed into the cup through an opening in the lid that is simultaneously opened at regular intervals of temperature rise; after each 1°F (0.5°C) for samples with flash points below 140°F (60°C) or 2°F (1°C) for samples with flash points above 140°F. The flash point is taken as the lowest temperature at which application of the test flame causes the vapor in the cup to ignite.

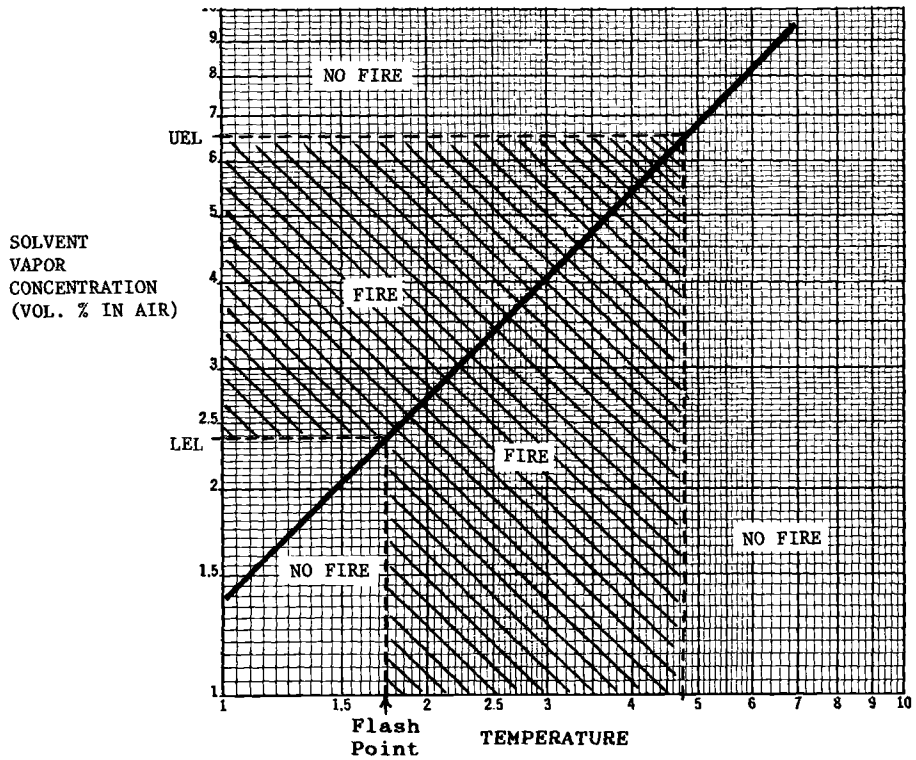

FIG. 14–Solvent vapor concentration versus temperature (idealized representation) [*30*].

Pensky-Martens—ASTM Method D 93, Flash Point by Pensky-Martens Closed-Cup Tester, is intended to be used for viscous liquids, suspensions of solids, and liquids that tend to form a surface film under test conditions. It differs from the Tag Closed Cup Test in that (a) it employs an air bath device instead of a liquid jacket around the test cup, and (b) the sample is mechanically stirred during the test (Figs. 17 and 18). This test method is particularly suited for samples such as resin solutions, paints, varnishes, lacquers, printing inks, and certain adhesives. Materials with flash points as high as 285°F (140°C) can be tested.

The sample and tester are first brought to a temperature of 60°F (15°C) or 20°F (11°C) lower than the expected flash point, whichever is lower. The sample is then heated at a slow, constant rate with continual stirring to provide uniform temperature throughout and to prevent formation of a surface film which would otherwise retard solvent vaporization. A small test flame is momentarily directed into the cup through a shuttered opening in the lid at regular temperature intervals with simultaneous interruption of stirring. The flash point is the lowest temperature at which application of the test flame causes vapor in the cup to ignite.

Setaflash—ASTM Method D 3278, Flash Point of Liquids by Setaflash-Closed-Cup Apparatus, describes procedures for (a) determining whether a material does or does not flash at a specified temperature, or (b) determining the lowest finite temperature at which a material does flash. The test methods are applicable to paints, enamels, lacquers, varnishes, and related products having a flash point between 32 and 230°F (0 and 110°C) and viscosity lower than 150 St at 77°F (25°C). These test methods are similar to international standards ISO 3679 and ISO 3680.

The Setaflash apparatus has certain advantages over other flash point measuring devices. It requires only a 2 to 4-mL sample instead of 50 to 70 mL. In the flash point verification mode of operation, test time is only 1 or 2 min (Fig. 19).

To perform a "flash/no flash" test, 2 mL of sample is introduced by means of a syringe through a leakproof entry port into the tightly closed Setaflash tester or, with very viscous materials, directly into the cup that has been brought to the required test temperature. As a "flash/no flash" test, the expected flash point temperature may be a specification or other operating requirement. After 1 min, a test flame is applied inside the cup and note is taken whether or not the specimen flashes. A fresh specimen must be used if a repeat test is necessary.

For a finite flash point measurement, the temperature is sequentially increased through the anticipated range, the test flame being applied at 9°F (5°C) intervals until a flash is observed. A true determination is then made using a fresh specimen, starting the test at the temperature of the last interval before the flash point of the material and making tests at increasing 1°F (0.5°C) intervals.

Equilibrium Flash Point—The Tag Closed Cup and Pensky-Martens flash point test methods depend on a definite rate of temperature increase to control the precision of the test method. However, the rate of heating may not in all cases give the accuracy expected because of the low thermal conductivity of some liquids such as paints, resin solutions, and related viscous materials. To reduce this effect, ASTM Method D 3941, Flash Point by the Equilibrium Method with a Closed-Cup Apparatus, uses a slow rate of heating to provide a uniform temperature throughout the specimen.

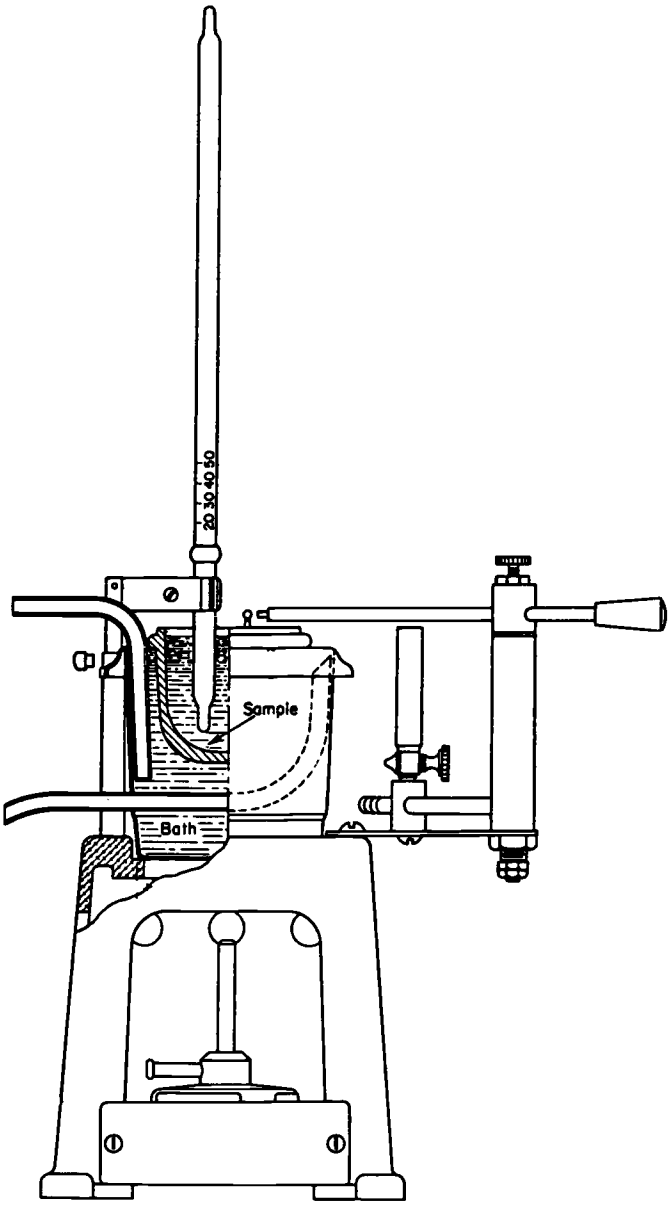

FIG. 15–Tag open-cup flash point tester.

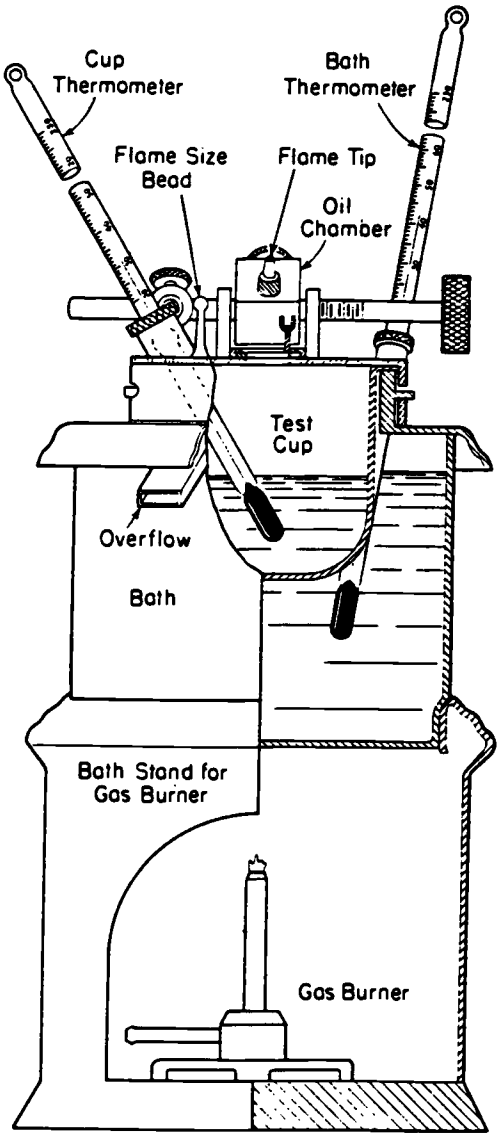

FIG. 16–Tag closed-cup flash point tester.

The specimen is heated in a closed cup of standard design in a suitable water bath at a rate of 1.0°F (0.5°C) in not less than 1.5 min so that the difference in temperature between the specimen in the cup and the bath never exceeds 3.5°F (2.0°C). Flash determinations are made at intervals of not less than 1.5 min. Since the specimen is heated at a reduced rate, a longer time interval between each determination is necessary to re-establish the saturation concentration of vapor in the air space above the specimen after each flash test.

Equilibrium Flash/No Flash—ASTM Method D 3934, Flash/No Flash Test—Equilibrium Method by Closed-Cup Apparatus, does not determine a finite flash point, but it verifies whether or not flashing occurs at a single specified temperature, which may be a product specification or agency requirement. The determination is made more accurate by ensuring that the flash test is carried out only when the material under test and the air/vapor mixture above it are in approximate equilibrium at the specified temperature.

Standard closed cups are used, i.e., Tag, Pensky-Martens, or Setaflash, and this test is run such that the air/vapor space above the specimen attains a saturation concentration of vapor before the test flame is applied. The specimen is held at the specified temperature for at least a 10-min period before the test flame is applied. This test method does not provide for the determination of the actual flash point, but only whether a specimen does or does not flash at a specified temperature.

PHYSICAL PROPERTIES

Density and Specific Gravity

Significance

Specific gravity is an inherent property which is listed as a requirement in all solvent specifications and is often used to set specifications. It is a good, simple, qualitative test when used with other tests to establish or confirm the identity of a solvent. In addition, it is useful for quality control, to provide

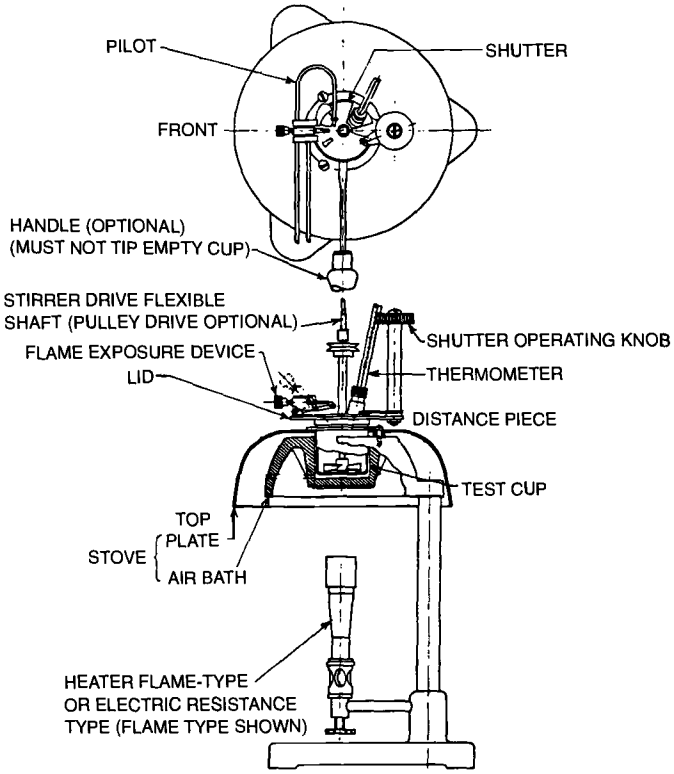

FIG. 17–Pensky-Martens closed-cup flash point tester.

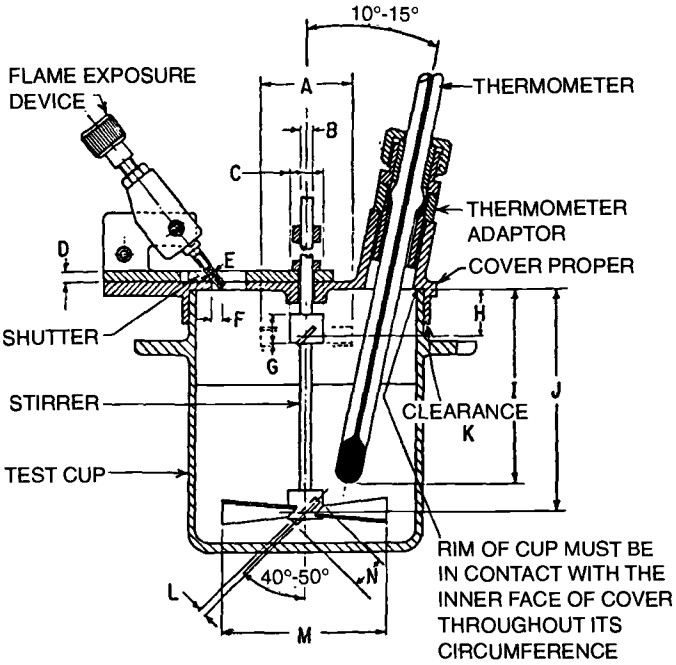

FIG. 18–Pensky-Martens flash point test cup and cover assembly.

a check on product uniformity, and to detect gross contamination.

Accurate specific gravity values are essential for the calculation of the volume occupied by a product whose weight is known or of the weight of a product when the volume is known. This information is necessary for accurately surveying large shipments by vessels, barges, railroad tank cars, or tank trucks to calculate costs and freight rates, and for inventory measurement and control.

It is customary to buy and sell hydrocarbon solvents on a volumetric basis (e.g., gallons, litres), converting measured values to volume at a standard temperature of 60°F (15.56°C). International transactions, however, are made on a gravimetric basis (e.g., metric tons) calculated at a standard 60°F temperature.

For oxygenated and other solvents, commercial transactions are customarily made on a gravimetric basis (e.g., pounds, kilograms, tons) converting measured values to weight at a standard temperature of 20°C (68°F). However, there is a trend toward changing the standard temperature to 25°C (77°F).

Finally, a knowledge of specific gravities of solvents and other paint components is important for the formulation of paints, varnishes, and lacquers. It is often necessary to make conversions between weight and volume bases and to calculate parameters such as pounds per gallon or kilograms per litre.

Typical specific gravities of selected commercial solvents are listed in Tables 1 through 9.

Definitions

The terminology relating to density and specific gravity is often confusing: density and apparent density, specific gravity and apparent specific gravity, mass and apparent mass versus weight. Definitions for these terms as they are applied in ASTM standards are contained in ASTM E 12, Definitions of Terms Relating to Density and Specific Gravity of Solids, Liquids, and Gases. Key definitions pertaining to liquid solvents are as follows.

density—the mass of a unit volume of a material at a specified temperature. The units shall be stated, such as grams per millilitre, grams per cubic centimetre, pounds per cubic foot, or other. The form of expression shall be

"density at x"

where x is the temperature of the material.

density, apparent—the weight in air of a unit volume of a material at a specified temperature. The units shall be stated. The form of expression shall be

"apparent density at x"

where x is the temperature of the material.

specific gravity—the ratio of the mass of a unit volume of a material at a stated temperature to the mass of the same volume of gas-free distilled water at a stated temperature. The form of the expression shall be

"specific gravity x/y°C"

where x is the temperature of the material and y is the temperature of the water. The term "relative density" with the same meaning as specific gravity is becoming more widely used than "specific gravity."

specific gravity, apparent—the ratio of the weight in air of a unit volume of a material at a stated temperature to the weight in air of equal density of an equal volume of gas-free distilled water at a stated temperature. The form of expression shall be

"apparent specific gravity x/y°C"

where x is the temperature of the material and y is the temperature of the water.

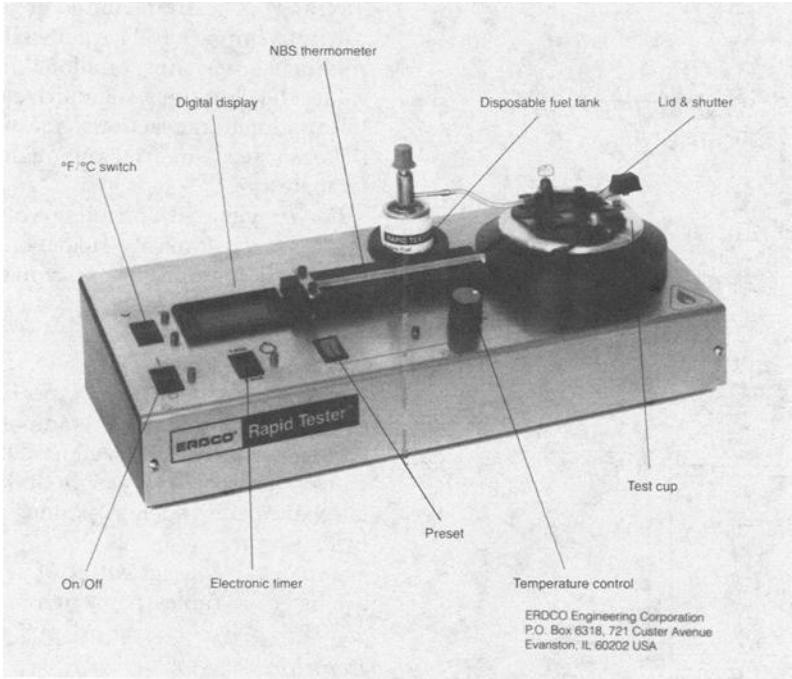

FIG. 19–Setaflash tester.

API gravity—a special function of relative density (specific gravity) 60/60°F (15.56/15.56°C) represented by:

$$\text{API gravity, degrees} = \frac{141.5}{\text{sp gr } 60/60°\text{F}} - 131.5$$

No statement of reference temperature is required, since 60°F is included in the definition. API gravity applies specifically to crude petroleum and to petroleum products such as hydrocarbon solvents. Gravities are determined at 60°F (15.56°C) or are converted to values at 60°F by means of standard tables. These tables are *not applicable* to nonhydrocarbons nor to essentially pure hydrocarbons such as the aromatics.

A brief discussion of these definitions may be useful. In scientific terminology, *mass* is a measure of the quantity of material in a body, and it is constant regardless of geographical location, altitude, or atmospheric conditions as long as no material is added or taken away. *Weight* is the force with which a body is attracted to the earth, and it varies from place to place with the acceleration of gravity.

When an equal-arm balance is used to compare an object with standards of mass ("weights"), the effects of variations in the acceleration of gravity are self-eliminating and need not be taken into account, but the apparent mass of the object is slightly different from the true mass because of the buoyant effects of the surrounding air. Mass can then be computed from apparent mass by applying a correction for air buoyancy. When a spring balance is used, an additional correction accounting for the local value of the acceleration of gravity is required for the computation of mass.

For many commercial and industrial processes the scientific distinction between mass, apparent mass, and weight is of no practical consequence and is therefore ignored. The term "weight" in general practice has been accepted as being the value secured when an object is weighed in air. This "weight" or "weight in air" is often converted to "weight in vacuo" by the application of an air buoyancy correction, and it is then considered synonymous with mass.

All of the definitions listed above are based on either "mass" or "weight in air," with the distinction being that air buoyancy corrections have been applied in the former case and not in the latter. Density and specific gravity are based on mass and should be similarly constant. Apparent density and apparent specific gravity are based on weight in air, and therefore they are subject to change with atmospheric conditions, locality, and altitude. These changes may be negligible, depending on the accuracy required for the particular application.

Hydrometer Methods

Hydrometer methods are the quickest, simplest means for measuring density, specific gravity (relative density), and API gravity, especially in the field. These methods are based on the principle that the specific gravity of a liquid varies directly with the depth of immersion of a body floating in it. The floating body, called a hydrometer, is graduated in units of density, specific gravity, or API gravity units. Hydrometers are useful when accuracy to three decimal places is adequate.

The sample is brought to the prescribed temperature, and it is transferred to a clear glass or plastic cylinder which is at approximately the same temperature. The appropriate hydrometer, having the scale of interest, is lowered into the sample and is allowed to float freely and settle. After temperature equilibrium has been reached, the hydrometer scale is read. Note is made of the hydrometer scale graduation nearest to the apparent intersection of the horizontal plane surface of the liquid (Fig. 20). Temperature of the sample is read from a separate thermometer or from a thermometer integrated into the design of the hydrometer.

Detailed descriptions of test methods for the proper use of hydrometers can be found in ASTM Method D 891 (Method

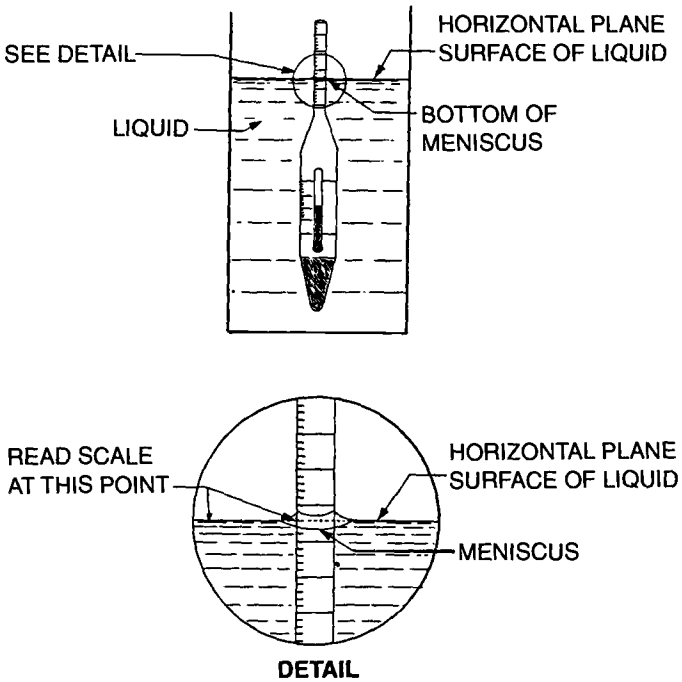

FIG. 20–Hydrometer and Meniscus detail.

A), Specific Gravity, Apparent, of Liquid Industrial Chemicals; ASTM Method D 287, API Gravity of Crude Petroleum and Petroleum Products (Hydrometer Method); and ASTM Method D 1298, Density, Relative Density (Specific Gravity), or API Gravity of Crude Petroleum and Liquid Petroleum Products by Hydrometer Method.

For hydrocarbon solvent naphthas, values can be measured on a hydrometer at convenient temperatures, the readings of density may then be reduced to 15°C, and readings of relative density (specific gravity) and API gravity at 60°F are obtained by means of international standard tables. By means of these tables, values determined in any one of the three systems of measurement are convertible to equivalent values in either of the other two systems so that measurements may be made in the units of local convenience.

Pycnometer Methods

Pycnometer methods for measuring specific gravity are more accurate and precise than hydrometer methods. They are used when accuracy to four or more decimal places is required. ASTM Method D 891 (Method B), Specific Gravity, Apparent, of Liquid Industrial Chemicals, describes the general test method for using a pycnometer.

A pycnometer is a tared vessel which is filled with water and weighed. It is then filled with the sample and weighed. Water, sample, and pycnometer are at a specified temperature. The ratio of the weight of sample to weight of water in air is the apparent specific gravity.

Bingham Pycnometer—A Bingham-type pycnometer may be used when density or specific gravity needs to be determined to five decimal places (Fig. 21). Its use is described in ASTM Method D 1217, Density and Relative Density (Specific Gravity) of Liquids by Bingham Pycnometer.

The pycnometer is first carefully calibrated by determining the weight of freshly boiled and cooled distilled water (distilled from alkaline permanganate through a tin condenser)

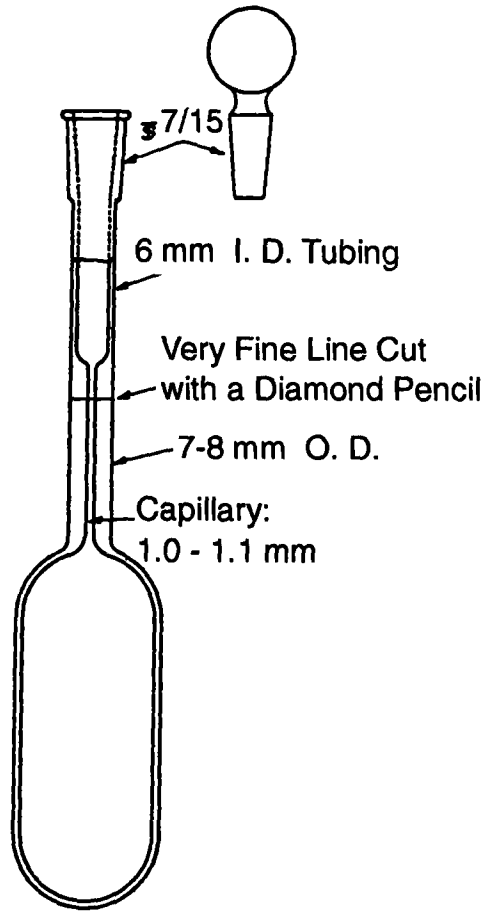

FIG. 21–Bingham-type pycnometer.

held by the pycnometer when equilibrated to volume at the bath temperature to be used for the determination. The liquid sample is introduced into the tared, clean, dry pycnometer, equilibrated to the desired temperature, and weighed. The relative density (specific gravity) or density is then calculated from this weight and the previously determined weight of water required to fill the pycnometer at the same temperature, both weights being corrected for the buoyancy of air.

Lipkin Bicapillary Pycnometer—The Lipkin bicapillary pycnometer is another type that is capable of high accuracy and precision when density or specific gravity needs to be determined to five decimal places [*33*]. Its use is described in ASTM Method D 941, Density and Relative Density (Specific Gravity) of Liquids by Lipkin Bicapillary Pycnometer.

The liquid sample is drawn into the pycnometer and weighed. It is then equilibrated at the test temperature, and the positions of the liquid levels in the capillaries are observed (Fig. 22). The density or relative density of the sample is then calculated from its weight, a calibration factor proportional to an equal volume of water, and a term that corrects for the buoyancy of air.

Digital Density Meter

A rapid, direct-reading, instrumental method for measuring density or specific gravity is by means of a digital density meter. Its use is described in ASTM Method D 4052, Density and Relative Density of Liquids by Digital Density Meter. A small amount of sample (several millilitres) is introduced

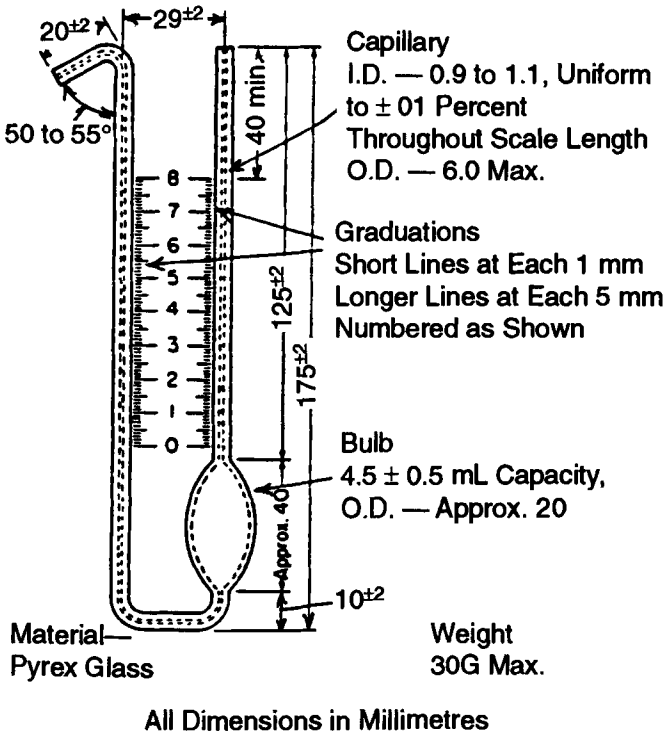

FIG. 22–Lipkin-type pycnometer.

into a vibrating quartz tube in the instrument at a preset temperature. Operation of the instrument is based on the principle that the oscillation of the quartz tube is damped as a function of the density of the sample within it. The instrument provides a digital readout of either density or specific gravity.

Calculations and Conversion Tables

ASTM Standard D 1250, Petroleum Measurement Tables, is a description of the tables which comprise Chapter 11, Section 1, of the *API Manual of Petroleum Measurement Standards* and which are distributed in three base systems of measurement: °API, °F, 60°F; relative density, °F, 60°F; and kilograms per cubic meter, °C, 15°C. These tables apply to crude petroleum and to all normally liquid petroleum products derived therefrom, which includes hydrocarbon solvent naphthas. They do *not* apply to oxygenated and other solvents nor to pure hydrocarbon solvents such as the aromatics.

ASTM Method D 1555, Calculation of Volume and Weight of Industrial Aromatic Hydrocarbons, contains tables for use in calculating the weights and volumes of the following solvents: benzene, toluene, mixed xylenes, *o-,m-,p*-xylene, cumene, ethylbenzene, high-flash aromatic naphthas, and cyclohexane. A method is given for calculating the volume at 60°F from an observed volume at any convenient temperature.

ASTM Method D 3505, Density or Relative Density of Pure Liquid Chemicals, describes the measurement of density or relative density using a Lipkin bicapillary pycnometer, and it provides methods for reporting results in the following units.

Density, g/cm^3 at 20°C
Density, g/mL at 20°C
Relative density, 20°C/4°C
Relative density, 60°F/60°F (15.56°C/15.56°C)
Commercial density, pounds (in air)/U.S. gal. at 60°F
Commercial density, pounds (in air)/U.K. gal. at 60°F

Tables of factors versus temperature are presented for benzene, toluene, mixed xylenes, *o-,m-,p*-xylene, and cyclohexane.

ASTM Method D 2935, Apparent Density of Industrial Aromatic Hydrocarbons, describes the measurement of apparent density in pounds (in air) per U.S. gallon at convenient temperature using a hydrometer and reporting values at any specified temperature. This method contains tables of "pounds in air per U.S. gallon" versus temperature. It applies only to the following solvents: benzene, toluene, mixed xylenes, *o-,m-,p*-xylenes, ethylbenzene, and cyclohexane.

ASTM Method E 201, Calculation of Volume and Weight of Industrial Chemical Liquids, presents tables for use in calculating the volume and weight of the following solvents: acetone, ethyl acetate (85 to 88 wt%), ethylene dichloride, ethylene glycol monomethyl ether, isobutyl alcohol, isopropyl alcohol (anhydrous), isopropyl alcohol (91 vol%), methyl ethyl ketone, methyl isobutyl ketone, and perchloroethylene.

A method is given for calculating the volume at 60°F from a volume observed at another convenient temperature. (Tables at 20°C can be calculated from the data and information provided.)

Also, a method is given for determining the weight in pounds per U.S. gallon (in air) at 60°F from an observed specific gravity and to compute therefrom the weight in pounds of a given volume of the liquid in U.S. gallons at 60°F.

Color

Most solvents are "water-white" or clear and essentially colorless. Color is an important specification requirement. If a solvent has color greater than the specification limit, it may be an indication of (a) inadequate processing, (b) contamination that might have occurred during storage and distribution, e.g., pickup of rust from tanks or pipes or color extracted from improper tank linings or loading hoses, or (c) oxidative degradation as a result of aging.

The property of color of a solvent varies in importance with the application for which the solvent is intended, the amount of color that can be tolerated being dependent on the color characteristics of the material in which it is used. For example, solvent color may undesirably contribute color to white paints or to fabrics if it is used for dry cleaning. Solvents that are off-specification in color are often found to be off-specification in other properties as well.

There are two visual test methods used for measuring the color of solvents; Platinum-Cobalt Color and Saybolt Color. Table 13 compares the approximate color values of the two scales.

Platinum-Cobalt Color

ASTM Method D 1209, Color of Clear Liquids (Platinum-Cobalt Scale), describes a procedure for the visual measurement of the color of nearly colorless liquids. It is used for all oxygenated solvents, most other solvents, and is gradually

TABLE 13—Approximate comparison of platinum-cobalt and Saybolt color scales.

	Platinum-Cobalt Color, ASTM D 1209	Saybolt Color, ASTM D 156

	100	+10
	150	+3
	180	0
	200	−3
	250	−8
Dark amber	300	−23

being used also for hydrocarbon solvents, where Saybolt Color still predominates.

For a number of years the term "water-white" was considered sufficient as a measurement of solvent color. Several expressions for defining "water-white" gradually appeared, and it became evident that a more precise color standard was needed. This was accomplished in 1952 with the adoption of ASTM Test Method D 1209 using the platinum-cobalt (Pt-Co) scale.

This test method is similar to the description given in "Standard Methods for the Examination of Water and Waste Water" [*34*] and is sometimes referred to as "APHA Color." The properties of these platinum-cobalt color standards were originally described by A. Hazen in 1892 in a paper entitled, "New Color Standard for Natural Waters" [*35*]. He assigned the number 5 (parts per ten thousand) to his platinum-cobalt stock solution.

Subsequently the American Public Health Association (APHA) in their first edition (1905) of "Standard Methods for the Examination of Water" used exactly the same concentration of reagents as did Hazen, and they assigned the color designation 500 (parts per million) to the same stock solution. (The parts per million nomenclature is not used since color is not referred directly to a weight relationship.)

The terms "Hazen Color" and "APHA Color" should not be used for solvents because they refer primarily to water. The recommended nomenclature for referring to the color of organic liquids is "Platinum-Cobalt Color, Test Method D 1209."

The method involves comparing visually the color of the solvent sample with colors of standard dilutions of the Pt-Co stock reference solution in Nessler tubes. The tubes are viewed vertically. The color standards are aqueous solutions of mixtures of cobalt chloride, potassium chloroplatinate, and hydrochloric acid. The scale runs from zero for pure water to 500 for the stock solution of 1.000 g of cobalt chloride, 1.245 g of potassium chloroplatinate, and 100 mL of hydrochloric acid made up to 1 L of solution. Most solvents have color values of less than 5 on the Pt-Co scale.

Saybolt Color

ASTM Method D 156, Saybolt Color of Petroleum Products, is used most often to measure the color of hydrocarbon solvents. This system of color measurement is not commonly employed outside of the petroleum industry.

In this method, a column of sample is viewed vertically, and its color is compared with that of a reference glass disk in the Saybolt chromometer. The height of the column of liquid is adjusted until the observed color intensity is equal to that of the colored glass disk. The depth of the liquid column is a measure of the Saybolt color, which is read directly from a scale on the instrument. The scale runs from +30 for colorless liquids to −30 for dark liquids.

Odor

Odor is an inherent, characteristic property of most solvents. Evaluation of the *characteristic odor* by a trained person is a quick and simple means of identifying a solvent (when combined with other tests) as well as for determining its suitability for an application from an odor point of view. *Residual odor* can be used to detect the presence of low-volatility materials that may be associated with manufacture, product degradation, or contamination during distribution.

ASTM Method D 1296, Odor of Volatile Solvents and Diluents, describes procedures for testing both the characteristic and residual odors of solvents. It involves dipping strips of filter paper into the sample and into a reference standard. To judge characteristic odor, an immediate comparison is made between the odor of the sample and reference standard on the filter paper. Residual odor is judged by permitting the papers to dry in air at room temperature and examining them at suitable time intervals for differences in odor.

Electrical Resistivity

Control of electrical resistivity is critical to the application of electrostatically sprayed coatings. It impacts the transfer efficiency (efficiency of paint application), coating appearance, and economics. Electrical resistivity of the paint must be properly adjusted to obtain optimum atomization characteristics and deposition. The adjustment is mainly accomplished through appropriate selection of solvents [*36*]. Nonpolar solvents, such as hydrocarbon solvents, have high electrical resistivity (low conductivity). Polar solvents such as ketones, alcohols, glycol ethers, and esters generally have low electrical resistivity (high conductivity), although some (e.g., higher molecular weight esters) have high resistivity. Typical values for commercial solvents are shown in Table 14.

An ASTM method, Electrical Resistivity of Liquid Paint and Related Materials is currently under development. It describes the use of two different test meters and probes, Ransburg and BYK-Gardner. Electrical resistivity values are often expressed in terms of "Ransburg megohms," which are read from the meter scale. Multiplication of these values by an appropriate cell constant, which is typically about 132, converts Ransburg megohms to specific resistivity in megohm-cm units.

Refractive Index

Refractive index is defined as the ratio of the speed of light through a vacuum to the speed of light through the sample. Although this property may have no fundamental signifi-

TABLE 14—Electrical resistance of typical commercial solvents.

	Ransburg Megohms

Methoxypropyl acetate	3

cance to the practical solvent user and is generally not a specification requirement, the test is useful because measurements can be made quickly and precisely. As with specific gravity, refractive index is characteristic (although not uniquely so) of different solvents, and it is very sensitive to differences in composition of solvent blends. Therefore, it is useful for distinguishing between aromatic and saturated hydrocarbon solvents and for checking purity and uniformity of batches.

ASTM Method D 1218, Refractive Index and Refractive Dispersion of Hydrocarbon Liquids, is designed to measure these properties with high precision. For routine examination or quality control, simpler instruments with less accuracy are satisfactory.

PURITY AND COMPOSITION

Gas Chromatography

Gas chromatography (GC), also referred to as gas-liquid chromatography (GLC), is commonly used for the analysis of purity and composition of solvents. GC is a powerful analytical tool, very sensitive, rapid and simple in execution. It is capable of furnishing accurate qualitative and quantitative information from extremely small amounts of sample [*37*].

In this analytical technique, a minute amount of solvent sample (microlitres) is injected by means of a hypodermic syringe into a heated injection port in the instrument, where it is instantly vaporized. The solvent vapors are carried into a GC column by means of an inert carrier gas: helium, hydrogen, or nitrogen. The carrier gas is the eluent which transports the solvent components in vapor form through the GC column, which is maintained at a certain constant or programmed temperature.

The GC column consists of a long, coiled tube, typically ⅛- to ¼-in. inside diameter and made of stainless steel, copper, or glass. The tube is packed with a powdered, porous substrate or support, which is coated with an absorbent, stationary liquid phase. Alternatively, and in more common use today, the GC column consists of a long, coiled capillary tube 1/16-in. or less in diameter, which does not contain the powdered packing support. Instead, the interior walls of the capillary tube are coated with the liquid stationary phase.

The stationary liquid phase has the ability to preferentially adsorb certain components of the vaporized solvent sample. It is selected on the basis of the analysis to be performed. The stationary phase can in some cases be a nonpolar liquid, for instance a hydrocarbon oil, but in other cases a better separation of solvent components can be obtained by employing a highly polar liquid.

Actual separation of solvent components is achieved by a continuously alternating process of adsorption and vaporization as the solvent vapors pass through the GC column. Differences in adsorption characteristics and volatilities cause the individual sample components to pass through the column at different rates. The components are eluted from the column as individual bands separated by zones of inert carrier gas.

At the end of the GC column, the carrier gas and sample components flow through a sensitive detector, which is capable of indicating the presence of the components qualitatively and quantitatively. The detector may be a thermal conductivity cell, a flame ionization detector, or an electron capture detector. There are also other less common types of detectors.

TABLE 15—ASTM gas chromatography methods for analyzing purity and composition of solvents.

Compound	Method	Compound	Method
Benzene	D 4492	Mineral spirits (aromatics content)	D 3257

Methyl isobutyl ketone	D 3329		

Any material other than the carrier gas going through the detector will cause a peak to be plotted on a recorder chart.

The time required for a component to flow through the column, under a given set of operating conditions, when compared to the time for known compounds, helps to identify the component. The amount of that component is proportional to the area under the recorder chart peak. Modern gas chromatographs often have a digital integrator which prints out the elution time and the area under the peak. Temperature, column length and size, type and amount of stationary liquid phase, carrier gas pressure and flow rate, and sample size are some of the variables that can be changed to effect desired separations.

Versatility of gas chromatography in solvent analysis is very great. Good ASTM references on gas chromatography include "ASTM Standards on Chromatography," second edition; ASTM Practice E 260, packed Column Gas Chromatography; and ASTM Practice E 355, Gas Chromatography Terms and Relationships. Specific ASTM GC methods for analyzing the purity and composition of solvents are listed in Table 15.

Liquid Chromatography

There are two ASTM methods which utilize a liquid chromatography procedure for measuring the volume percentages of aromatics, olefins, and saturated aliphatics (paraffins and naphthenes) which comprise a hydrocarbon solvent naphtha. Both methods involve the physical separation of these hydrocarbon types by passing the hydrocarbon sample through a tube packed with silica gel. The technique is based on the principle that polar compounds are adsorbed more strongly by silica gel than are nonpolar saturated compounds.

A hydrocarbon solvent sample is passed through a glass column packed with silica gel. Then, alcohol, which is more strongly adsorbed than any hydrocarbon, follows the sample through the column, desorbing and forcing the hydrocarbons out. Saturated compounds are eluted first, unsaturated compounds next, and then aromatics.

In ASTM Method D 936, Aromatic Hydrocarbons in Olefin-Free Gasolines by Silica Gel Adsorption, small samples of the emerging sample are periodically collected. The refractive index of each fraction is measured. From this information, the relative percentages of aliphatics and aromatics can be determined, as illustrated in Fig. 23. Precision is good, but the procedure is slow.

ASTM Method D 1319, Hydrocarbon Types in Liquid Petroleum Products by Fluorescent Indicator Adsorption (FIA), is a refinement of the silica gel adsorption procedure. A mixture of fluorescent dyes is added to the hydrocarbon solvent sample before it is put into the silica gel column. When all of the sample has been adsorbed on the silica gel, alcohol is added under pressure to desorb and force the sample down the column. The fluorescent dyes are also selectively separated with the sample fractions, and they make the boundaries of the aromatics, olefins, and saturates clearly visible under ultraviolet light. The zone of aromatics fluoresces violet, and the zone of olefins fluoresces a chartreuse color. The zone of paraffins plus naphthenes remains colorless. Volume percentage of each hydrocarbon type is determined by measuring the length of each zone in a long, narrow extension of the silica gel column.

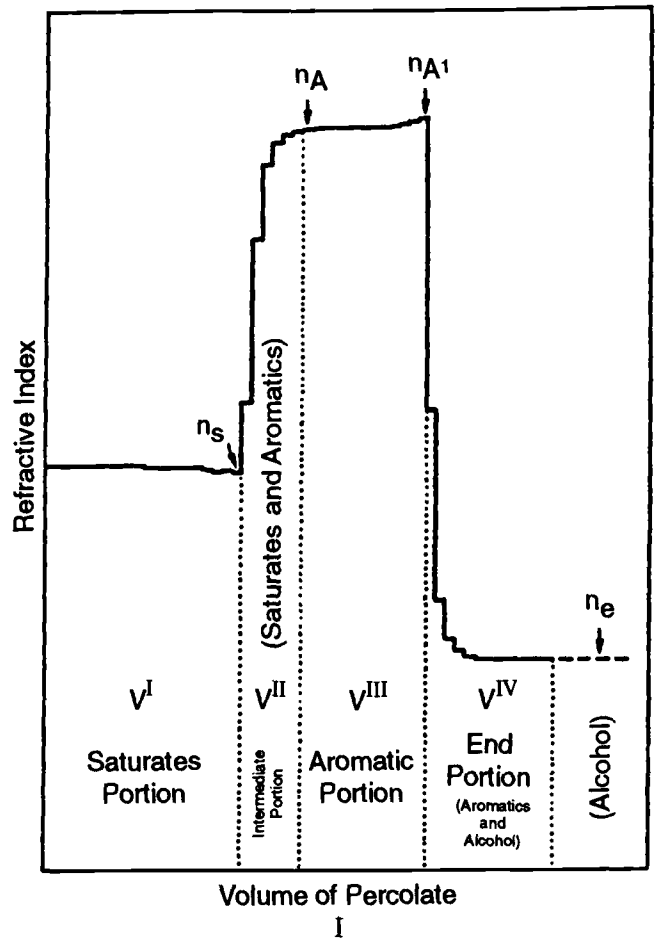

FIG. 23–Typical adsorptogram by ASTM Method D 936.

Purity of Ketones

ASTM Method D 2192, Purity of Aldehydes and Ketones, is an alternative to gas chromatography for measurement of the purity of ketone solvents. This is a wet chemical procedure and is applicable for testing ketones having greater than 98% purity.

The test is based on the reaction of ketones with hydroxylamine to form an oxime. Hydroxylamine hydrochloride is first converted in part to free hydroxylamine by reaction with a known amount of aqueous triethanolamine.

$$H_2NOH{\cdot}HCl + (HOCH_2CH_2)_3N \longrightarrow H_2NOH + (HOCH_2CH_2)_3N{\cdot}HCl$$

The free hydroxylamine then reacts with the ketone to form an oxime.

$$R_1R_2C = 0 + H_2NOH \longrightarrow R_1R_2C = NOH + H_2O$$

where R_1 and R_2 are alkyl groups.

The amount of hydroxylamine consumed, which is determined by titration of the excess base with standard sulfuric acid, using bromophenol blue indicator, is a measure of the ketone originally present. Water, alcohols, saturated esters,

and hydrocarbons do not react with the reagent, but large amounts of inert organic solvents are undesirable because of the possible effect on the indicator.

Purity of Esters

ASTM Method D 1617, Ester Value of Solvents and Thinners, is an alternative to gas chromatography for the measurement of purity of ester solvents. It may also be used for determining the ester content of lacquer thinners.

This is a wet chemical test and involves the reaction of the solvent sample with a measured excess of aqueous potassium hydroxide, using isopropanol as a mutual solvent if necessary

$$R_1COOR_2 + KOH \longrightarrow [R_1COO]^-K^+ + R_2OH$$

where R_1 and R_2 are alkyl groups. The amount of potassium hydroxide consumed, which is determined by titrating the excess with standard mineral acid, is a measure of the amount of ester originally present.

This test method has its greatest application where the solvent or thinner is not a pure ester. The type of ester present must be known to perform the calculations. The test may also be used for assessing compliance with ester specifications.

IMPURITIES

Acidity

Solvents may have residual acidity from manufacturing processes, or acidity may be present as a result of contamination or decomposition during storage or distribution. Acidity is undesirable since it may cause corrosion of storage tanks and lines. Also, it may cause reactions with basic pigments resulting in color changes.

ASTM Method D 847, Acidity of Benzene, Toluene, Xylenes, Solvent Naphthas, and Similar Industrial Aromatic Hydrocarbons, expresses acidity in terms of milligrams of sodium hydroxide consumed when 100 mL of sample are titrated using phenolphthalein indicator. If two drops or less of standard 0.1 *N* sodium hydroxide solution produce a persistent pink end point, the sample is reported to contain no free acid.

ASTM Method D 1613, Acidity in Volatile Solvents and Chemical Intermediates Used in Paint, Varnish, Lacquer, and Related Products, expresses total acidity in terms of weight percent acetic acid or as milligrams of sodium hydroxide required to neutralize one gram of sample. The test is performed by mixing 50 mL of sample with an equal volume of water (or with an equal volume of alcohol if the sample is not water soluble) and titrating with aqueous 0.05 *N* sodium hydroxide solution to the phenolphthalein end point.

Acid Wash Color

ASTM Method D 848, Acid Wash Color of Industrial Aromatic Hydrocarbons, is a test used for benzene, toluene, xylenes, refined solvent naphthas, and similar aromatic hydrocarbons. Acid wash color is a measure of chemical reactivity of trace impurities rather than a measure of the color of the sample itself.

The test is performed by agitating a sample with sulfuric acid under prescribed conditions. The color of the acid layer is compared with colors of aqueous reference solutions containing various concentrations of cobalt chloride, ferric chloride, potassium chromate, and potassium dichromate. The color scale ranges from zero for distilled water to 14 for the darkest reference color standard. The color developed in the acid layer gives an indication of impurities in the aromatic hydrocarbon which if sulfonated would cause the material to be discolored.

Alkalinity

ASTM Method D 1614, Alkalinity in Acetone, specifically covers the determination in acetone of alkalinity calculated as ammonia (NH_3). The sample is added to an equal volume of water previously neutralized to the methyl red indicator end point. If alkalinity is detected, it is titrated with 0.05 *N* sulfuric acid and is reported as weight percent ammonia.

Benzene Content

Benzene is classed as a toxic and carcinogenic compound. A knowledge of the concentration of benzene may be an aid in evaluating the possible health hazards to persons handling and using solvents, but the ASTM test methods are not intended to evaluate such hazards. In addition, benzene content is an important specification requirement for aromatic hydrocarbons used as chemical intermediates.

ASTM Method D 4367, Benzene in Hydrocarbon Solvents by Gas Chromatography, may be used to determine benzene content of hydrocarbon solvents at levels from 0.01 to 1 vol%. An internal standard, methyl ethyl ketone (MEK), is added to the solvent sample, which is then introduced into a gas chromatograph equipped with two columns connected in series. The specimen passes first through a column packed with a nonpolar stationary liquid phase, methyl silicone, which separates components by boiling point. After octane has eluted, the flow through the nonpolar column is reversed, flushing out components higher boiling than octane. The octane and lighter components then pass through a column with a highly polar phase, 1,2,3-tris(2-cyanoethoxy)propane, which separates the aromatic and nonaromatic compounds. The eluted components are detected by a conventional detector and are recorded on a strip chart. Peak areas are measured, and the concentration of benzene is calculated by reference to the internal standard.

ASTM Method D 4534, Benzene Content of Cyclic Products by Gas Chromatography, applies to cyclohexane, toluene, individual C_8 aromatics, cumene, and styrene. Benzene may be determined over a range from 5 to 300 mg/kg (5 to 300 ppm). The test is performed with a gas chromatograph equipped with a flame ionization or other detector and a column containing a polar stationary liquid phase such as tetracyanoethylated pentaerythritol. A reproducible volume of sample is injected. Quantitative results are obtained from the measured area of the recorded benzene peak by using a factor obtained from the analysis of a blend of known benzene content.

Nonaromatic Hydrocarbons in Aromatics

ASTM Method D 2360, Trace Impurities in Monocyclic Aromatic Hydrocarbons by Gas Chromatography, covers the determination of total nonaromatic hydrocarbons and trace monocyclic aromatic hydrocarbons at levels of 0.0005 to 1 percent by weight in high-purity benzene, toluene, and mixed xylenes by gas chromatography. This inspection is of particular importance when these high-purity aromatics are used as chemical intermediates.

This test method is performed using an internal standard, *n*-butylbenzene, added to the specimen which is then introduced into a gas chromatographic column. The sample passes through the column, which contains a polyethylene glycol stationary liquid phase, and it is separated into nonaromatic and aromatic components. The components are detected by a flame ionization detector as they elute from the column and appear as peaks on the chromatogram. Peak areas are measured, and the concentration of the composite nonaromatics and each trace aromatic component is calculated with reference to the internal standard.

Nonvolatile Residue

ASTM Method D 1353, Nonvolatile Matter in Volatile Solvents for Use in Paint, Varnish, Lacquer, and Related Products, describes the analytical measurement of residual matter in solvents that are intended to be 100% volatile at 105 ± 5°C. Volatile solvents are used in the manufacture and application of paint, varnish, lacquer, and other related products, and the presence of any residue may affect the product quality or efficiency of the process.

Nonvolatile residues may consist of oil contamination, dissolved solids, rust, sand, or dirt. Trace oil contamination, which could cause cleaning solvents to leave an objectionable deposit of oily residue, often will not be detected by any other specification test.

This test is performed by evaporating to dryness 100 mL of solvent in a carefully cleaned, dried, and tared evaporating dish of platinum, aluminum, ceramic, or glass, first on a steam bath and then in an oven at 105 ± 5°C. Weight of any residue remaining in the dish is determined, and the result is reported as milligrams of nonvolatile residue per 100 mL.

Olefins Content

Olefins are undesirable impurities in hydrocarbon solvents. They are unsaturated, reactive compounds that tend to oxidize, causing solvent discoloration and objectionable noncharacteristic odor. The level of olefins present can be determined by reacting them with bromine. The amount of bromine that will react is a measure of the olefin content.

ASTM Method D 1159, Bromine Number of Petroleum Distillates and Commercial Aliphatic Olefins by Electrometric Titration, is used for testing materials which have fairly high olefin contents. Bromine number is defined as the number of grams of bromine that will react with 100 g of sample.

The test is performed by first dissolving the hydrocarbon sample in a titration solvent composed of specified proportions of glacial acetic acid, carbon tetrachloride, methanol, sulfuric acid, and mercuric chloride. The dissolved sample is then titrated at 0 to 5°C with a bromide-bromate solution. (The titration is run at low temperature since addition of bromine to olefinic molecules proceeds rapidly and completely at temperatures down to or below 0°C, while competing reactions with aromatics and compounds of sulfur, nitrogen, or oxygen, if present, are minimized.) End point of the titration is indicated by a dead-stop electrometric titration apparatus. Bromine number is calculated from the weight of sample and from the volume of bromide-bromate reagent titrated. Values are generally in the range of 1 to 100.

Hydrocarbon solvents usually have a bromine number of less than one. Therefore, for greater accuracy, precision, and discrimination, it is more appropriate to use ASTM Method D 1492, Bromine Index of Aromatic Hydrocarbons by Coulometric Titration, or ASTM Method D 2710, Bromine Index of Petroleum Hydrocarbons by Electrometric Titration. Bromine index is defined as the number of *milligrams* of bromine consumed by 100 grams of sample (as compared with bromine number which is expressed as *grams* of bromine consumed by 100 grams of sample). Although the test procedures differ, bromine index is the more sensitive test and may be assumed to be numerically equal to 1000 times the bromine number.

In the coulometric titration method, the specimen is added to an electrolyte solution consisting of glacial acetic acid, methanol, potassium bromide, and mercuric acetate, and it is titrated with electrolytically generated bromine at room temperature. End point is determined by a dead-stop method when excess bromine is detected. The time of titration and generation current are proportional to the bromine generated and consumed by the sample.

Sulfur Content

Crude petroleum usually contains traces of sulfur compounds, the greater proportion of which are generally removed during refining since they might otherwise cause objectionable corrosive tendencies and foul odors in refined products such as hydrocarbon solvents. There are several test methods which directly measure sulfur content or which indicate their presence indirectly.

Copper Strip Corrosion

ASTM Method D 130, Detection of Copper Corrosion from Petroleum Products by the Copper Strip Tarnish Test, indicates the presence of corrosive compounds (such as sulfur compounds) in hydrocarbon solvents and other petroleum products by their effect on a highly polished test strip of copper. The polished copper strip is immersed in the solvent sample in a test tube and heated for 3 h at 100°C. At the end of this period, the copper strip is removed, washed, and compared with ASTM Copper Strip Corrosion Standards. Rating classifications range from "1a—slight tarnish," light orange, almost the same as the freshly polished strip, to "4c—corrosion," jet black.

ASTM Method D 849, Copper Corrosion of Industrial Aromatic Hydrocarbons, is similar to ASTM D 130 but applies specifically to aromatic hydrocarbons. The sample and polished copper strip are placed in a flask fitted with a condenser and are placed in a boiling water bath for 30 min. At the end

of this period, the copper strip is removed and compared with the ASTM Copper Strip Corrosion Standards. Aromatic solvents are reported to pass the test if the copper strip ratings are "1a" or "1b," indicating only "slight tarnish"; all other ratings are considered failures.

Doctor Test

The Doctor Test is a very sensitive qualitative test for detecting hydrogen sulfide and mercaptan sulfur in hydrocarbon solvent naphthas. It is described in section 6.1.10 of ASTM Specification D 235 for Mineral Spirits.

The test is performed by vigorously shaking together in a test tube the solvent being tested and an aqueous sodium plumbite solution. A small amount of pure, dry flowers of sulfur is added so that practically all of it floats on the interface between the solvent and the sodium plumbite solution after shaking. If the solvent is discolored or if the yellow color of the sulfur film is noticeably masked or discolored and blackened, the test is considered positive and the solvent is reported as "sour." If the solvent remains unchanged in color and the sulfur film is bright yellow or only slightly discolored with gray or flecked with black, the test is considered negative and the solvent is reported as "sweet."

Sulfur by Lamp Method

ASTM Method D 1266, Sulfur in Petroleum Products (Lamp Method), is used for quantitatively measuring total sulfur content of solvents. The sample is burned in a wick lamp in an artificial atmosphere of 70% carbon dioxide and 30% oxygen to prevent formation of nitrogen oxides. A solution of hydrogen peroxide is used to absorb the oxides of sulfur which are formed during combustion and to oxidize them to sulfuric acid. After flushing with air to remove dissolved carbon dioxide, the absorbent is titrated with a standard solution of sodium hydroxide. Sulfur is calculated as percent by weight from the weight of sample burned and the volume of sodium hydroxide reagent required to titrate the acid in the absorbent. Alternatively, the sample may be burned in air, in which case the sulfur as sulfate in the absorbent is reacted with barium chloride to precipitate barium sulfate, and the sulfur content is determined gravimetrically.

Trace Sulfur by Coulometry

ASTM Method D 3961, Trace Quantities of Sulfur in Liquid Aromatic Hydrocarbons by Oxidative Microcoulometry, is a highly sensitive quantitative test for the determination of sulfur content in the range of from 0.5 to 100 mg/kg (0.5 to 100 ppm). The test may be extended to higher sulfur concentrations by appropriate sample dilution. Although the test method applies specifically to aromatic hydrocarbons, it may also be used for other solvents.

The test is performed by injecting a measured liquid sample into a quartz combustion tube in an electric furnace maintained at about 800°C and having a flowing stream of gas consisting of about 80% oxygen and 20% inert gas. Oxidative pyrolysis converts the sulfur to sulfur dioxide which then flows into a titration cell where it reacts with triiodide ion present in the electrolyte.

$$I_3^- + SO_2 + H_2O \longrightarrow SO_3 + 3I^- + 2H^+$$

The triiodide thus consumed is coulometrically replaced.

$$3I^- \longrightarrow I_3^- + 2e^-$$

These microequivalents of triiodide generated are equal to the microequivalents of sulfur dioxide entering the titration cell. The sample result is compared with that of known calibration standards, and appropriate calculations are made to report the sulfur concentration.

Water Content

Dissolved water can have adverse effects on solvent end-use applications. For example, it can reduce solvency. Water can cause reactions with isocyanates during polyurethane preparation and with moisture-cure polyurethane paints and varnishes causing polymerization and gelation during storage. Metallic pigments can react with water to generate hydrogen gas, which can expand and burst paint cans. Dissolved water can act as a catalyst poison when a solvent is used as a reaction diluent for polyolefin polymerization.

Karl Fischer Reagent Method

ASTM Method D 1364, Water in Volatile Solvents (Fischer Reagent Titration Method), is a quantitative test. It is based on reactions involving the reduction of iodine by sulfur dioxide in the presence of water. These reactions can be used quantitatively when pyridine and an alcohol are present to react with the sulfur trioxide and hydroiodic acid produced in the reagent.

$$H_2O + I_2 + SO_2 + 3C_5H_5N \longrightarrow 2C_5H_5N{\cdot}HI + C_5H_5N{\cdot}SO_3$$

$$C_5H_5N{\cdot}SO_3 + ROH \longrightarrow C_5H_5N{\cdot}HSO_4R$$

To determine water content, Fischer reagent (a solution of iodine, pyridine, and sulfur dioxide in the molar ratio of 1:10:3) dissolved in anhydrous 2-methoxyethanol is added to a solution of the sample in anhydrous pyridine-ethylene glycol (1:4) until all water present has been consumed. This is evidenced colorimetrically by the persistence of an orange-red end-point color or electrometrically by an indication on a galvanometer or similar current-indicating device which records the depolarization of a pair of noble-metal electrodes. The reagent is standardized by titration of measured amounts of water.

Alternatively, automatic instruments are commercially available which operate on a coulometric principle according to ASTM Method E 1064, Water Content of Liquid Organic Chemicals by Coulometric Karl Fischer Titration. A measured quantity of sample is introduced into a titration cell containing reagent which undergoes the Karl Fischer reactions. Iodine is coulometrically regenerated, the amount of current required being proportional to the water content of the sample.

Heptane Miscibility Test

Oxygenated solvents are capable of dissolving sizable amounts of water. They can be checked qualitatively for water content by ASTM D 1476, Heptane Miscibility of Lacquer Solvents. Heptane is water immiscible and has a very low tolerance for water in solvent blends. The test is performed by mixing the solvent sample under test with heptane

in a 1:19 proportion and agitating. A clear solution indicates miscibility and low water content (less than about 0.5 wt%) in the solvent sample. A turbid solution indicates immiscibility and the presence of high water content in the solvent sample.

Water Solubility

Certain oxygenated solvents are completely miscible, e.g., methanol, isopropanol, acetone. This property can provide a qualitative means for indicating the presence or absence of water-insoluble contaminants, such as oils, paraffins, olefins, aromatics, high molecular weight alcohols, ketones, etc. Water-insoluble materials in the solvents may interfere with many of their end-uses.

ASTM Method D 1722, Water Miscibility of Water-Soluble Solvents, covers the determination of the miscibility of water-soluble solvents with water. The sample is diluted to 10 volumes of water in a glass graduated cylinder. The resulting mixture is viewed through the length of the column of liquid toward a dark background while being transversely illuminated. The sample is reported to pass the test if there is no evidence of cloudiness or turbidity initially and after 30 min.

Part 6: Pigments

19

White Pigments

by Juergen H. Braun[1]

INTRODUCTION

ALMOST EVERYTHING MAN-MADE that is white or light in color contains white pigment in its surface: houses inside and outside, industrial articles, plastics, glazes, rubber, printed surfaces, many paper products, and even some foods. Only papers and textiles can be white without pigment.

Virtually all this whiteness and lightness is supplied by titanium dioxide (TiO_2) pigments. Void pigments make a minor contribution. The classic white pigments—lithopone, zinc sulfide, and the white leads—have essentially disappeared from commerce because TiO_2 pigments perform much better, are much cheaper, and are nontoxic. Zinc oxide is still added to some paints as a mildewstat, but not as a white pigment.

TiO_2 pigments are manufactured by a major, globally distributed industry. Its products are sold for many applications; however, more than half of all white pigment goes into paints. In many coatings, white pigment is the single most expensive ingredient. To select the right pigment grade and use it well is an important challenge to the paint manufacturer.

This chapter will familiarize coating manufacturers with white pigments and help them understand their options for selection, utilization, and testing. Toward this objective, I will first outline the commerce and manufacture of white pigments and then discuss their function, the substances that serve this function, and the commodities available. I will distinguish between product characteristics that describe the pigment itself and product performance, which are properties of paint films, that is, systems composed of pigment and binder.

Commerce

The white pigment market is served almost exclusively by titanium dioxide pigments. Globally, six billion pounds are produced annually at a value of six billion dollars. The value of TiO_2 pigments exceeds by far the combined value of all color pigments.

Five manufacturers share two thirds of the world market. Most of these producers operate several large plants located in industrialized countries. The largest of these plants makes about two million pounds of pigment a day. Their products are of similar quality. A few small plants operate in the lesser developed countries making the product at somewhat lower quality for regional consumption.

In the United States and other developed countries, one half of the TiO_2 pigment is used in coatings, one quarter in paper, and 15% in plastics. All other end uses, pigmentary (inks, floor coverings, elastomers, roofing granules, fibers, fabrics, sealants, foods, etc.) and nonpigmentary (ceramics, welding rods, etc.), account for the remaining 10%. In less developed countries, most of the TiO_2 pigments go into paints and plastics.

Manufacture

TiO_2 particles, the active ingredient of pigment, are made by two processes:

1. The old sulfate route dissolves the ore in sulfuric acid, purifies the aqueous solution of titanyl sulfate, precipitates a hydrous titania gel, and calcines the gel to crystallize it into aggregates of pigment particles, which, in turn, must be ground.
2. The newer, "greener" chloride route chlorinates the ore and purifies the $TiCl_4$ intermediate by distillation and chemical treatments. $TiCl_4$ is then flame oxidized to pigmentary TiO_2 particles and chlorine. The chlorine is recycled.

Sulfate processes are low-tech, labor-intensive operations in batch mode. Chloride processes are high-tech, automated, continuous operations. Sulfate and chloride products do not differ much in performance except that chloride TiO_2 is purer and thus brighter.

Waste disposal is a significant factor and constraint. The sulfate process generates vast quantities of dilute sulfuric acid and iron(II)sulfate from its ilmenite ($FeTiO_3$) ingredient.[2] The chloride process makes iron(III)chloride by-product in much lesser quantities that are dependent on ore composition: rutile (TiO_2), anatase (TiO_2), leucoxene (TiO_2/$FeTiO_3$), and ilmenite ($FeTiO_3$).

After the primary pigment particles are made by either process, their surfaces are treated to adapt the pigment to a variety of end uses. These treatments are carried out in aqueous suspension followed by drying, grinding, and dry treatment operations. Pigments are also converted into slurry grades.

[1]Consultant, 614 Loveville Road, Building E, Apartment 1-H, Hockessin, DE 19707-1616.

[2]The iron-free minerals, rutile and anatase, do not dissolve in sulfuric acid and cannot be used as such in sulfate processes.

Copyright© 1995 by ASTM International

By either process, manufacture involves five steps:

1. Digestion of the ore.
2. Purification of the intermediate.
3. Crystallization of pigment particles.
4. Treatment of the pigment surface.
5. A variety of finishing operations.

Research and Development

For 50 years, the TiO_2 industry has been large, competitive, and profitable enough to dedicate sizable science and engineering resources to product improvement. These efforts have been remarkably successful. *Today's TiO_2 pigments are complex structures composed of an optically active core with shells that adapt the pigment to specific end uses.* Each feature is carefully designed into each pigment grade, optimizing it for its specific application. Their optical performance approaches the light-scattering effectiveness calculated from concepts of theoretical physics.

Experts in pigment technology, with the help of specialists in optics, surface chemistry, fine-particle technology, and chemistry have resolved many of the compromises between often conflicting requirements. End users can contribute to progress by suggesting new opportunities. Solving pigment problems does, however, require expertise in pigment technology.

THE FUNCTION OF PIGMENTS

Most coatings have two functions, aesthetic and protective. More often than not, manufactured surfaces are visually unattractive and therefore coated for aesthetic appeal. The coating hides the substrate's discolors and contrasts and provides a visually pleasing appearance or identification. Pigments[3] are not directly involved in the protective function of coatings.

Pigments supply the hiding and color of a coating. They are incorporated in surfaces to make them look bright or dark, colorful or drab, white or black, either more appealing or more appropriate to whatever the intended service. Toward that end, pigments must hide the unattractiveness of a substrate. Thus, pigments serve the human eye. They interact with visible light and cause surfaces to be seen in colors[4]: chromatic colors like red, blue, and green or achromatic colors like black, gray, and white.

To understand this primary aesthetic function of pigments, let us consider the interactions of visible light with matter at or near surfaces. Involved are two mechanisms of optics: light scattering and light absorption.

White or bright hiding is achieved by light scattering, an optical mechanism by which a ray of light is scattered as it hits an interface. White pigments are substances selected to scatter light very well.

Hiding also can be achieved by the absorption of light that is involved in colored and black surfaces and pigments. Optical absorption is decisively more efficient than optical scattering. Thus, less color or black than white pigment is required for hiding. Dark and black paint films can therefore be thinner than their white and light counterparts.[5]

Table 1 relates appearance characteristics of surfaces to the optical phenomena that cause them. If all light is absorbed by a surface, none scattered, the surface is perceived as black. If all light is scattered, none absorbed, the surface is seen as white. If a portion of the light is scattered and another portion absorbed, the surface is gray. If the absorption and scattering is wavelength dependent, for example, if red light is absorbed and green light is scattered, the surface is colored by the scattered green portion of the light. Even though common usage refers to objects as colored, i.e., red cars, green mountains, almost always only their surfaces matter.[6]

The return of light from a surface is caused by reflection at the surface and scattering from beneath with pigment causing the scattering. The optical action itself occurs at or in pigment particles, not on but within the surface. Light reflected at the surface does not usually change its color.[7]

Light scattered and returned from inside the coatings makes a surface look white or, if color pigments are involved, gives color to the surface. It is the white pigment in the coatings that does most of the light scattering.

Light scattering can be explained quantitatively from optical theories. Geometric optics give a graphic but superficial picture that accounts well for effects of refractive indices of potential pigments but unreliably for effects of pigment particle size. Wave optics and electromagnetic theory provide a more accurate but quite abstract model, accounting for particle size but not for effects of particle shape, orientation, and crowding.

The optimum particle size at which a population of white pigment particles scatters a maximum amount of light is about[8] 0.2 μm for green and white light. Blue light is scattered more efficiently by smaller particles, red light by larger ones. For pigments of high refractive indices, the theoretical curve of optical effectiveness versus particle size has a sharp peak (Fig. 1). For pigments of lower refractive indices, the peak broadens but the optimal size near 0.2 μm does not change much.

The pronounced wavelength dependence of optimum scattering causes a subtle color effect by white pigments in colored coatings. Their color shifts toward red if the white pigment is larger than optimal. Color shifts toward blue if the white pigment is smaller. This "undertone" is visible in col-

[3]Anticorrosive "pigments" do not meet Webster's definition of a pigment as "a substance that imparts black or white or color to other materials."

[4]In most technical contexts of color and colorants, white, gray, and black are considered colors.

[5]The transparency of white clothes, in particular wet, white clothes, illustrates the relative hiding effectiveness of white and color.

[6]This comes about because visible light and thus human vision penetrates pure gasses to a depth of about 10^{+6} m, pure liquids to about 10^{+2} m, dielectric solids to about 10^{-3} m, and metals to about 10^{-9} m, a range of 15 orders of magnitude.

[7]Exceptions are the colored metals—gold, copper, and their alloys—and extremely strong colorants, for example, copper phthalocyanine and hematite.

[8]The uncertainty is not in the optical calculation but reflects difficulties in defining the size of particles other then spheres. What, for example, is larger, a large snake or a small monkey? It depends on the perspective of the observer.

TABLE 1—Optics and appearance.

If the Pigment in the Coating		Then the Coating

All	None	None	Black
None	All	All	White
Some	Some	Some	Gray
Some,in specific wave bands		Colored	

ored coatings and in white coatings at incomplete hiding. In gray coatings the effect can be quite obvious and at times objectionable.

Pigments can act by themselves but are usually used in combinations: white pigment with a small amount of color or black pigment, white pigment with one or more color pigments, combinations of color pigments, color pigments with some black pigment, etc. Some types of pigment particles scatter light, others absorb it. White pigments deliver white appearance by scattering all light (see Table 1). Black pigments absorb all light. Color pigments create color by absorption of light of specific wave bands. Sometimes, though, the wavelength-specific absorption by color pigments is augmented by wavelength-specific scattering.

Pigments, because they are particulates, can affect surface texture and texture-related appearance characteristics: gloss and sheen.

Pigments do the optical, that is, the aesthetic work; they provide the color and the hiding. Binder keeps the pigment on the substrate and does the mechanical and the chemical work that protects the substrate from the environment. The less effective the pigment in its optical function, the thicker the coating must be to hide and provide the desired color. Thick coatings, however, cost more than thin ones. Since the cost of binder increases proportionally to film thickness, film costs are inversely proportional to the effectiveness of the pigment. Economics discriminate severely against pigments of low optical effectiveness.

The economics of hiding are illustrated by Fig. 2, a plot of the cost of hiding as a function of pigment volume concentration for the case of a typical white paint applied to hide color contrasts of a substrate. The film is composed of a TiO_2 pigment at $1 per pound and a density of 4 g/mL dispersed in a resin at $1 per pound and a density of 1 g/mL. Hiding cost has a distinct minimum. At too low a pigment volume concentration, the film must be thick to hide. The cost of hiding increases because additional resin is required to deliver the film thickness. At too high a pigment volume concentration, the white pigment is used inefficiently, also increasing cost, albeit at a lower rate.

THE SUBSTANCE OF WHITE PIGMENT

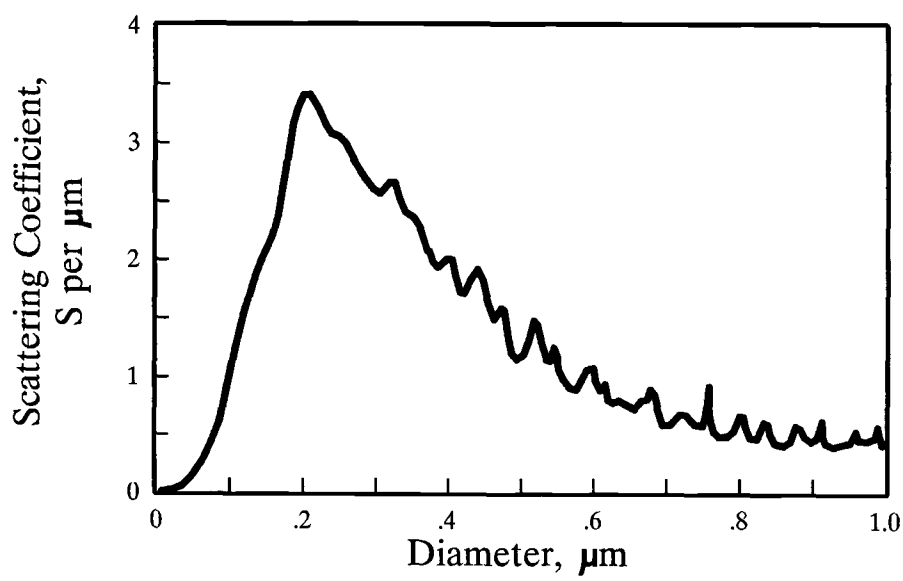
White pigments translate light scattering into hiding power, brightness, and opacity of thin films. The films, in turn, hide the color and contrasts of the substrate.

To serve as an effective white pigment, a substance must meet requirements that limit the selection to less than one dozen from among the thousands upon thousands of natural and man-made chemicals. A potential white pigment must:

- have an extremely high refractive index

In addition the substance must be:

- stable
- almost colorless
- suitable for manufacture in optimized, colloidal particle size
- a solid
- insoluble in water and organic solvents
- safe in manufacture, end use, and as a waste



Calculations: W. D. Ross, Du Pont Company

FIG. 1–Scattering by spheres of rutile in resin. From Braun, J. H., *Introduction to Pigments*, monograph in the Federation Series on Coatings Technology, Federation of Societies for Coatings Technology (United States), 1993.

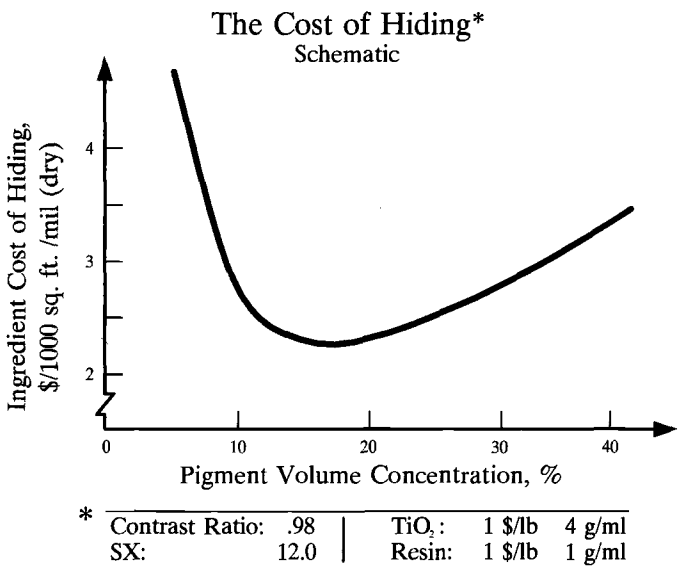


FIG. 2–The cost of hiding. From Braun, J. H., *Introduction to Pigments,* monograph in the Federation Series on Coatings Technology, Federation of Societies for Coatings Technology (United States), 1993.

Of these, the requirement of an extremely high refractive index, larger than 2.0, is essential and is most restrictive. Most materials with high refractive indices are hydrolytically unstable. A combined requirement for extreme refractive index plus stability eliminates all but a few substances.

High density is a disadvantage for a pigment. Pigments function by volume yet are sold by weight. Thus, a high-density pigment contains fewer particles per pound to do its optical work than a low-density pigment.

Because of its optical performance, safety, and cost, titanium dioxide has become the only white pigment of commercial significance. In the foreseeable future, it is quite unlikely that a better white pigment will be found to replace TiO_2 because its performance advantage results from a combination of a uniquely high refractive index with other essential characteristics.

TiO_2 has the highest refractive index of all ordinary, colorless, and stable substances, significantly higher even than diamond. Refractive indices of most compounds such as TiO_2 have been measured and can even be calculated from pure theory. No colorless substance, neither real nor hypothetical, has been found[9] that has a higher refractive index than TiO_2.

Before the commercialization of titanium dioxide, lithopone ($BaSO_4/ZnS$), zinc oxide, zinc sulfide, and white lead [lead(II)hydroxy carbonate] served as white pigments. All have lower refractive indices, scatter less effectively, and are much less cost effective.

Not only particulates but also air voids in coatings scatter light as if they were particles. But air voids are far less effective than TiO_2. Voids thus contribute to hiding but at direct or indirect costs. In coatings below their critical pigment volume concentration, voids scatter light and hide as such. But because they do not hide as well as TiO_2, films must be thicker, increasing binder cost. In coatings above the critical pigment volume concentration, extenders create a network of interconnected voids. These pores enhance the hiding effectiveness of the pigments. This indirect hiding contribution of voids is cheap to achieve in a paint but comes at the expense of mechanical and chemical film qualities. Pores (1) concentrate mechanical stresses to where they initiate fracture and (2) conduct aggressive chemicals from the surface into the depth of the paint film. The hiding improvements and the quality detriments of coatings above their critical pigment volume concentration can be quite large.

TiO_2 PIGMENTS

Titanium dioxide has obsoleted all other white pigments because TiO_2 is cheaper to use and much safer than other pigments. TiO_2 pigments are the most effective scatterers of visible light. They hide better and provide more lightness. They are more stable and less toxic.

Figures 3 and 4 show what TiO_2 pigments "look" like. Figure 3 is a transmission electron micrograph of an uncoated TiO_2 pigment grade dispersed in a dispersant by conventional techniques of grid preparation. Single crystals, twins, aggregates, and small agglomerates are visible. Weakly bonded agglomerates, though, are not distinguishable from strongly bonded aggregates because micrographs do not show strength of bonding. Figure 4 shows a set of electron scanning micrographs of dry pigment in bulk and as an individual floc. Visible are masses and individual crystallites, single and twinned. At highest magnification, scanning electron micros-

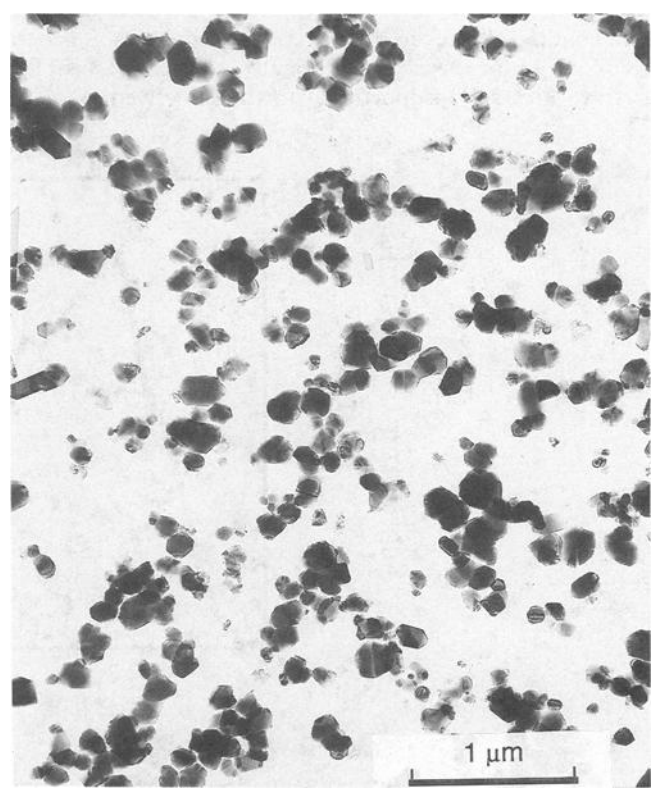

FIG. 3–Transmission electron micrograph of TiO_2 pigment.

[9]Extreme pressure phases of TiO_2 could be expected to have higher densities combined with higher refractive indices.

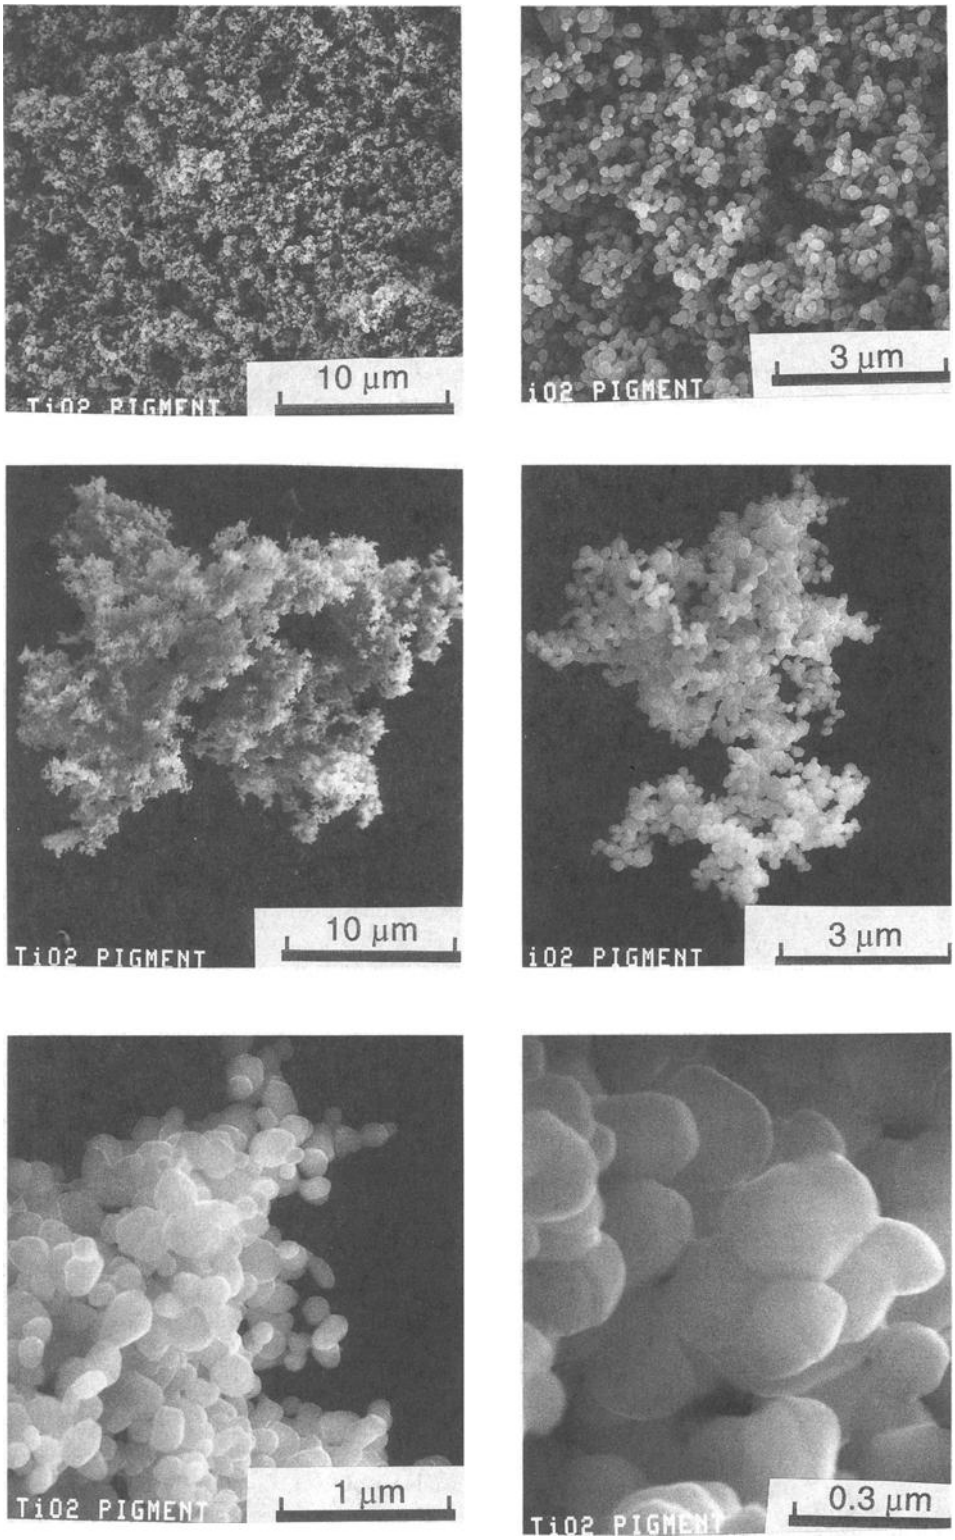

FIG. 4—Scanning electron micrographs of TiO_2 pigment.

copy shows crystals significantly more rounded than they actually are.

TiO_2 pigments are made in two crystal phases, rutile and anatase, that differ in lattice structures, refractive indices, and densities. Anatase was the first commercial titanium dioxide pigment but, for the coatings industry, has now been replaced by rutile because, in organic media, rutile has an 18% scattering advantage over anatase.

For the sake of clarity I will distinguish between characteristics and performance of a pigment. Composition, for example, is a characteristic of a pigment that is essentially independent of its environment. By contrast, hiding power

describes the performance of a system, a pigment within a paint film. Hiding is a film characteristic that depends on pigment volume concentration and a host of formulation and application parameters of the paint in which the pigment was evaluated.

Characteristics are properties of the commodity: composition, density, particle size, etc. They can be measured on the commodity, either dry powder or slurry. Granted, some product characteristics are affected by the ambiance in which they are measured but only in secondary ways. Particle size is an example of a characteristic affected by method of measurement.

At the state of the art it does not appear possible to establish rigid links between pigment characteristics and performance. Thus, the pigment commodity cannot be defined exclusively in terms of its characteristics. Certain characteristics can be measured reliably. Their results bear on but do not guarantee performance. Clearly, complete specifications for pigments must include both product characteristics as well as product performance measures.

A few generalizations of the connection between pigment characteristics and product performance are appropriate:

- High gloss pigments: (1) pack densely as indicated by measures of oil absorption, liquid demand, and interstitial space; (2) contain few agglomerates larger than about 0.5 μm[10]; and (3) have hydrous oxides contents that are low and TiO_2 contents that are correspondingly high [*1*].
- Pigments intended for high-pigment volume concentration paints contain up to 20 wt% hydrous oxides because fluffy oxides act as very efficient extenders. TiO_2 contents are correspondingly low.
- Satisfactory outdoor durability precludes the presence of more than about 1 wt% anatase phase with the rutile [*2*].
- Product fractions smaller than about 0.1 μm and larger than about 0.4 μm constitute losses to optical performance because particles that are too large or too small scatter light inefficiently.
- Impurity metal ions within the rutile crystals can degrade brightness dependent on the nature of the metal ion. Certain ions degrade color in concentrations as low as 0.000 01 wt%. Effects of ion contaminants on characteristics other than brightness are generally insignificant. Hydrous oxide coatings can tolerate a much higher concentration of impurity metal ions in the coating without much effect.
- Hydrous oxide coatings on pigment have ion-exchange characteristics. Their exchangeable ion content affects pigment performance in applications that are sensitive to pH (acid-catalyzed coatings) or the presence of electrolyte (electrocoatings).
- Pigment surface area affects oil absorption.

Some of these effects are sufficiently well quantified for translation into specifications.

Pigment Characteristics

TiO_2 pigment has to meet stringent specifications of crystal phase, particle size, surface characteristics, and purity. As with all chemicals, every product characteristic has some effect on every performance quality. Some specific characteristics, however, dictate equally specific performance attributes. These crucial relationships are described.

Refractive index and density are paramount to optical function, but they are not subject to manipulation. Crystal phase impacts weathering and light-scattering performance. Particle size controls light scattering and has effects on color. Surface characteristics are designed into the product through chemical treatments reflected by commodity composition. The treatments improve dispersibility, durability, and gloss performance. High purity of the pigment makes for brightness.

TiO_2 Crystallites

The active ingredients of a TiO_2 pigment commodity are its TiO_2 crystallites. Other components of the commodity affect the commodity density but do not affect the crystallite density nor the refractive index of the pigment. Neither the refractive index nor the density of any chemical can be manipulated independently by conventional technology.[11]

Two crystal phases of titanium dioxide serve as pigments: rutile and anatase. They differ in refractive indices, densities, and weathering performance because rutile and anatase differ by the arrangement of the titanium and oxygen ions within the crystals (Fig. 5). Rutile crystals are elongated, are denser, and have higher refractive indices.[12] Because of their higher refractive indices, rutile pigments scatter light more effectively than anatase products. They are also much less prone to chalk.

Rutile absorbs slightly more violet light than anatase and is slightly more yellow in bulk. However, little, if any, of this yellowness extends into pigment applications.

TiO_2 is a UV-energized oxidation catalyst of organic polymer. Anatase surface is about ten times more reactive than rutile surface. It takes only 10% anatase in rutile to reduce to one half the life expectancy of a paint film. Thus, for all exterior applications, the phase purity of rutile pigments is quite important.

During paint manufacture or usage, titanium dioxide cannot undergo transitions of crystal phase, that is, it cannot change its lattice structure. This contrasts to most organic pigments, many of which phase convert readily, usually with dramatic loss of optical performance. For example, an unstabilized α-copper phthalocyanine pigment, upon exposure to an aromatic solvent, grows into long needles of β-copper phthalocyanine, losing most of its color strength in the process.

Phase Analysis One percent or more of anatase in rutile pigment is considered undesirable because it increases the catalytic reactivity of the pigment. Fortunately, the phase analysis of TiO_2 pigment is cheap, convenient, and reliable.

Phase purity of pigment is usually measured by X-ray diffraction, for example, ASTM Test Method for the Ratio of Anatase to Rutile by X-ray Diffraction (D 3720-90). Conventional diffractometers can detect 1% of pigmentary anatase in 99% rutile by using peak intensity ratios or instrument

[10]Particle size measured as Stoke's settling diameters by sedimentation methods.

[11]Density and refractive indices of inorganic oxides can be increased together, but only at extreme pressures and astronomic cost.

[12]Actually, TiO_2 crystals have two principal refractive indices each. These two refractive indices do not differ much. They enter all relevant considerations of pigment as an appropriately weighted average.

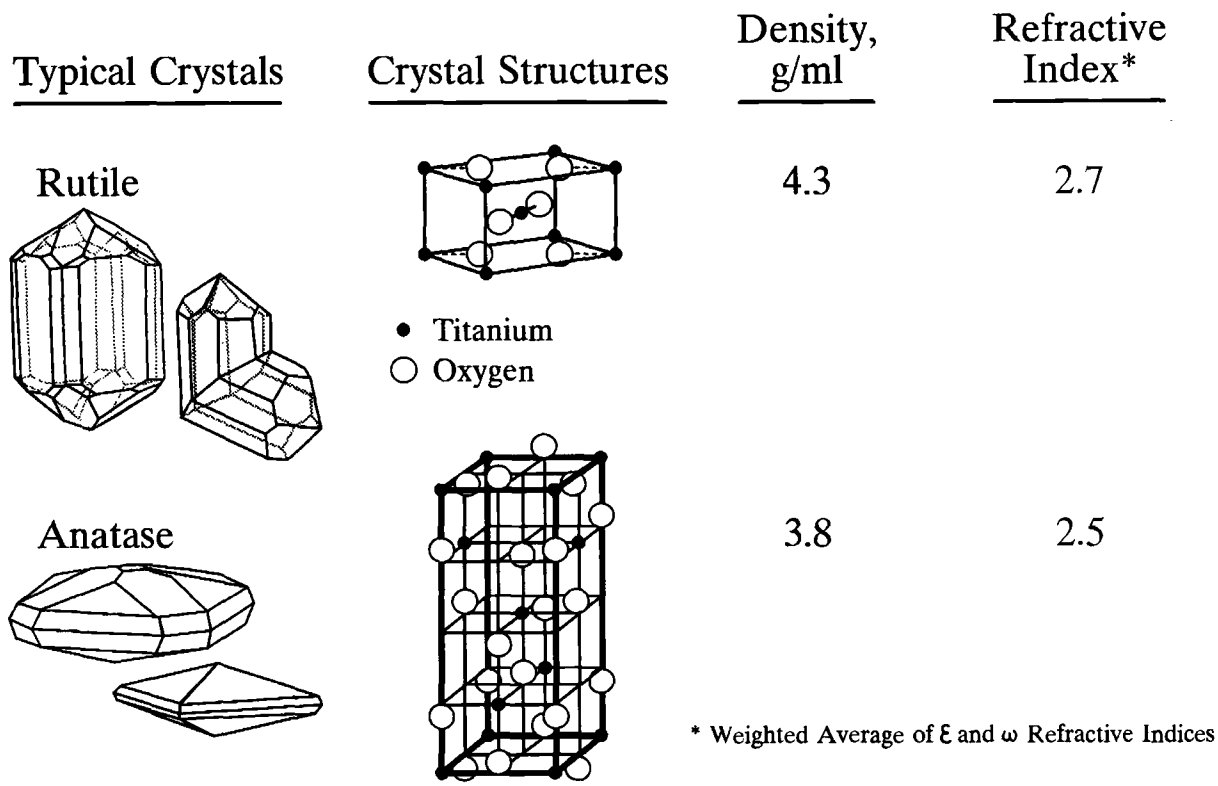

FIG. 5–Titanium dioxide crystals. From Braun, J. H., *Introduction to Pigments*, monograph in the Federation Series on Coatings Technology, Federation of Societies for Coatings Technology (United States), 1993.

counts. With careful attention to instrument alignment and sample preparation, a bit less anatase can be detected. Other, more complex techniques are more sensitive. However, why bother since less than 1 wt% anatase does not contribute much to the catalytic activity of the pigment.

The hydrous and anhydrous oxides contributed by pigment treatment are not detectable by X-ray diffraction because they are either truly amorphous or subcrystalline, that is, too small and/or too disorganized. Their diffraction lines are diffuse and drowned in the TiO_2 signal.

Pigment Particle Size

TiO_2 pigment particles are submicroscopic, so small that one pigment particle is to the size of a man as the size of a man is to the size of the earth. Thus, intuitive judgments based on macroscopic experiences are often misleading.

The particle size of pigment grades is tailored to the required optical performance. Pigment size depends critically on definition of "particle." For paint optics, the particle is the object a light beam meets in the paint film. Its size is a composite of primary particles, aggregates, agglomerates, flocs, and even of casual contact of any of these assemblies. Primary particles are individual single crystals and crystallographic twins.[13] They average from 0.1 to 0.3 μm in median diameter by weight with a geometric standard deviation of about 1.4.[14] Aggregates are associations of crystallites sharing grain boundaries and are thus strongly bonded. Agglomerates are associations of crystallites and aggregates bonded by relatively weak forces. Flocs are weakly bonded associations of crystallites, aggregates, and agglomerates formed spontaneously in a liquid or even in air.

The shear forces of paint application can disperse flocs. However, they are likely to reassociate. Paint grinding breaks most agglomerates if (1) the mill base is formulated to proper viscosity and (2) the mill is operated well. Aggregates can be broken only by high-intensity mills. Crystallites cannot ordinarily be broken. Aggregates and crystals, once broken, do not reassemble because aggregate bonding and crystal growth require thermal activation to many hundred degrees centigrade. TiO_2 pigments do not degrade in conventional paint and plastics processing.

The inclusion of casual contact in the definition of "particle" is important because it links size to concentration. At low pigment concentration, the frequency of particle overlap in a beam of light is low and the casual contact contribution to effective size is small. At high concentration, casual contacts are abundant and contribute significantly to the particle size as seen by a light beam penetrating a paint film.

Optimal scattering performance calls for optimal particle size. Particles that are too small in the extreme, molecular dispersions, scatter almost no light; particles too large, macroscopic crystals, are transparent. The particle size at which a population of TiO_2 particles scatters a maximum amount of light is about 0.2 μm for green[15] and white light. Blue light is scattered more effectively by particles closer to about 0.16

[13]Two or more single crystals intergrown according to some deducible law of symmetry.

[14]Geometric standard deviation = $\frac{1}{2}(D_{84}/D_{50} + D_{50}/D_{16})$, with D =

[15]For whiteness and brightness, green light matters most because

μm, red light by particles of about 0.23 μm. This optically effective particle size is likely to differ from the size measured by analysis.

Particle-size distributions of commercial TiO_2 pigments are narrower than those of many so-called monodisperse particulates (Fig. 6). Population statistics approach "log-normal" character, that is, a logarithmic transform converts the size distribution curve to "normal" (Gaussian) probabilities. Appropriately ground, pigment dispersions contain less than 5 wt% of particles smaller than 0.10 and larger than 1.0 μm. The mean particle size of pigment grades is tailored to the required light scattering performance. Pigment grades composed of small particles are made for applications at low-pigment volume concentration.

The pronounced wavelength dependence of optimum scattering causes a subtle color effect caused by white pigments in colored coatings. Their color shifts toward red if the white pigment is larger than optimal or toward blue if the white pigment is smaller. This "undertone" is visible only in gray and colored coatings and in white at incomplete hiding. In gray coatings the effect can be quite obvious, sometimes objectionable, sometimes desirable. Small size TiO_2 grades with blue undertone are used to make colors look "cleaner," i.e., less yellowish.[16]

Large particles in a paint film are detrimental to gloss. Thus, the coarse tail of the size distribution of TiO_2 pigments impacts gloss performance [*1*]. Figure 7 shows what particle size range impacts which performance characteristic.

Paint grind gages reveal the presence of minute quantities of grit, clumps composed of tens of thousands of primary particles. Grind gages do not respond to pigmentary particle sizes. For TiO_2 pigments, the presence of grit has no detectable optical effects.

Particle size control is one of the manufacturing secrets of the TiO_2 industry. Additives and process conditions during crystallization and grinding operations are crucial to particle size and product performance in both chloride and sulfate processes.

Particle Size Analysis—Up front a warning: *Particle-size analysis and the interpretation of analytical data calls for specialized expertise.* Potential pitfalls are so numerous that serious misinterpretation is the rule rather than the exception, particularly in the interpretation of electron micrographs.

Problems arise in several ways. Two definitions of "particle," be it clump, agglomerate, aggregate, or crystallite, are vitally important: (1) the particle of the analysis and (2) the particle that matters within the intended application. The analytical particle is almost never the same as the particle in a paint film that interacts with light:

- Dispersion is a true grinding operation that reduces particle size. In spite of this, grinding must be an integral part of the analytical procedure. Otherwise, the softest and largest clumps become valid members of population statistics.
- In sample preparation, dispersive work expended upon minute samples can add up to enormous energy concentrations that can break crystallites that cannot be broken en masse.

[16]Because dirt is colored by iron and thus reddish gray, a reddish or yellowish cast is perceived as "dirty."

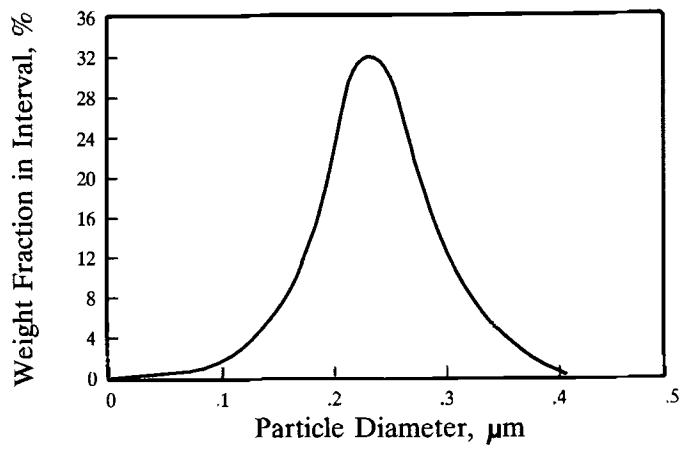

FIG. 6–Particle size distribution of TiO_2 pigment. From Braun, J. H., *Introduction to Pigments,* monograph in the Federation Series on Coatings Technology, Federation of Societies for Coatings Technology (United States), 1993.

- Sampling statistics is a frequent problem considering small quantities or low concentrations of pigment in samples.
- In microscopy, transmission images bear little resemblance to ordinary visual perceptions based on observation of surfaces. Scanning micrographs, by contrast, correspond to human vision. Differences become apparent when comparing Figs. 3 and 4.
- In light-scattering methods, the extreme refractive index of TiO_2 affects computational interpretation.
- No certified standards are available pertaining to the size range of pigments.

Numerous methods have been used for the size analysis of pigments: Andreasan pipette, disk centrifuges, transmission electron microscopy, light-scattering measurements, field flow fractionation, etc. They are too complex and far too costly for routine analysis.

Lately two methods have advanced TiO_2 technology because reproducible results can be obtained routinely: X-ray sedimentation and the X-ray disk centrifuge. Both are usually combined with ultrasonic dispersion.

X-ray sedimentation measures the Stokes' diameters of particles settling in water by gravity. Settling causes density differences in the suspension that are detected by absorption of X-rays. Brownian motion interferes with settling and distorts the small end of the size distribution curve of the particle population. The X-ray disk centrifuge substitutes centrifugal force for gravity, thus avoiding misrepresentation of small particle fractions.

Commodity Composition

The TiO_2 in the pigment is its optically active ingredient. Other components adapt it to its end use. The commercial products have compositions that fall into one of three categories: (1) uncoated pigments, (2) coated pigments, and (3) slurries.

Uncoated pigments contain 98% or more titanium dioxide; some contain up to about 1% aluminum oxide (anhydrous), and other products contain less than about 0.5% aluminum oxide with some other inorganic, anhydrous oxides. Organic additives and their decomposition products may be present

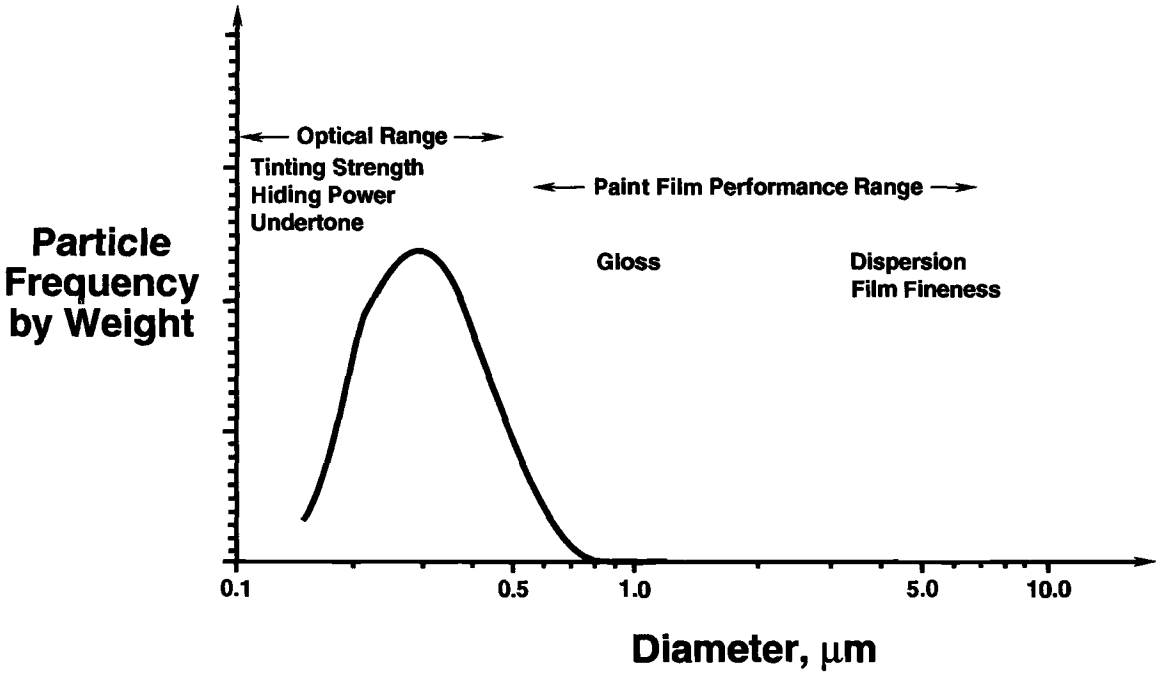

FIG. 7–TiO_2 aggregate size distribution. From Braun, J. H. and Fields, D. P., "Gloss of Paint Films, II," *Journal of Coatings Technology*, Vol. 66, No. 828, 1994, p. 93.

in concentrations of fractional weight percents. Uncoated pigments are used in plastics and paper. In coatings, wet-treated pigments are preferred because they are easier to disperse into liquids of low or moderate viscosity.

Minor constituents, either carried over from the ore or added in the manufacturing process, can be important in determining pigmentary properties because they can control crystallite size. Sulfate pigments retain up to 0.3% niobium pentoxide and 0.3% phosphorus pentoxide from the ore. They also contain up to 0.2% alumina, added to compensate for the presence of niobium. Compensation minimizes discoloration by the semiconductor imbalance that pentavalent and trivalent cations can cause in the rutile lattice.

Chloride process pigments contain practically no unwanted impurities because the titanium tetrachloride intermediate can be purified effectively. They contain about 1% pyrogenic alumina added for better process control and for photochemical stability improvement.

Trace constituents are generally unimportant except for transition metals such as iron, chromium, vanadium, etc., which degrade color by semiconductor mechanisms.

Besides inorganic constituents, most uncoated and many coated pigments contain up to 0.5% of an organic grinding aid to improve flow in the fluid energy mill to achieve a more uniform grind. The grinding aids are usually polyhydroxyl compounds (for example, trimethylol propane, triethanolamine, etc.) that can undergo some pyrolytic degradation in the mill.

For use in coatings, i.e., to be dispersible by the conventional paint-making equipment, TiO_2 pigments are "coated." In aqueous suspension, hydrous aluminum oxides are precipitated onto the surfaces of pigment particles. Interior grades contain a coating of up to 5% hydrous alumina for ease of dispersion. Durable grades have another coating that usually consists of about 2% silica and sometimes also oxides of zirconium, boron, zinc, cerium, and tin, usually in concentrations of less than 1%.

Rutile pigments are made suitable for extreme exposure by encapsulating individual particles in glassy silica sheaths. Silica surface treatments on TiO_2 pigments were once considered detrimental to gloss performance. Silica on pigment, however, comes in two distinct modifications, either "fluffy" or "dense." Fluffy silica does indeed reduce gloss and is precipitated onto pigments intended for dry hiding paints to increase oil absorption. Dense silica is used to encapsulate the TiO_2 particle in a distinct shell to make the pigment durable in severe exposure.

Special high oil absorption products are made for paints formulated for dry flat hiding, that is, above the critical pigment volume concentration. They contain fluffy coatings, 5 to 15% hydrous silica and 2 to 6% hydrous alumina, for better spacing and improved optical efficiency in vehicle-starved formulations. The fluffy silica increases oil absorption and water demand by the pigment. Gloss is reduced.

Slurry products for coatings applications are usually based on coated pigments. In addition to the coated product, they contain organic dispersants and stabilizers. Predispersed pigments, sold as aqueous slurries, contain from 60 to almost 80% titanium dioxide by weight. They are stabilized with low concentrations of organic chemicals.

Odorless amines are added for pH control. Together with preservatives, about 1% of organic material is present. Pigment loading in slurry is limited by the concentration at which the slurry becomes too thick to be pumped. Slurries of lightly treated grades are available at higher solids contents than slurries of heavily treated, dry flat grades. The slurries can be shear thickening. Effects can be severe.

The pigment industry describes its products and the hydrous oxides they contain in terms of their analytical equivalents, alumina (Al_2O_3), silica (SiO_2), and water (H_2O) or mois-

ture content. Such description does not imply structure or chemical characteristis of the components but reflects analytical results. The actual components of pigment coatings are hydrous oxides: boehmite (γ-AlOOH), diaspor (α-AlOOH), hydrargillite [γ-$Al(OH)_3$], etc.

Product descriptions in terms of analytical results are preferred because they can be verified. By contrast, the precise structural analysis of colloidal coatings on pigment surfaces is always difficult and often beyond the capability of even the most sophisticated analytical techniques. Results are usually ambiguous. But because coatings are precipitated from aqueous solution, the alumina coatings on coated TiO_2 pigments contain structural water, i.e., they are hydrous.

Wet treatments have profound effects on dispersibility and durability. In dry hiding paints, they affect hiding through oil absorption and spacing. Brightness is not usually affected.

Process details of wet treatment are guarded secrets of the TiO_2 industry. The patent literature provides little guidance because the most and least effective processes can be described by equally factual performance claims.

Elemental Analysis—Chemical analysis of pigments presents no particular problems. The quality of the data meets the requirements of pigment and coatings technologies. For routine analyses, conventional, wet analytical methods, for example, ASTM Test Methods for Chemical Analysis of White Titanium Pigments (D 1394-76), have been replaced by instrumental techniques for cost savings, not data quality. Aluminum and silicon contents are usually determined by X-ray fluorescence techniques. Water content is analyzed as weight loss of volatiles by thermogravimetric analysis (TGA).

Pigment Surface

Because pigment particles are so very small, their surfaces are enormously large. One pound of untreated TiO_2 has a surface of about one acre. Thus, surface characteristics have a profound impact on a pigment's interactions with all the other components of paints. Furthermore, pigment surfaces are complex composites reflecting the nature of the commodity.

The rutile component of most TiO_2 pigments contributes 0 to 10 m^2/g of surface area. Inorganic treatments with hydrous aluminas and silicas can more than double the total surface area of a pigment. Most pigment surfaces are composites of Ti—O, Ti—OH, Al—O, and Al—OH groups. Many pigment surfaces include Si—O and Si—OH units. Silica-encapsulated grades have few if any Ti—O and Ti—OH surfaces.

The surface areas themselves are not homogeneous. Usually they are composites to which TiO_2 contributes 0 to 10 m^2/g TiO_2 and 5 to 10 m^2/g pigment, hydrous aluminas with about 200 m^2/g $Al_2O_3 \cdot xH_2O$ and 2 to 8 m^2/g pigment, silicic acid with about 150 m^2/g $SiO_2 \cdot xH_2O$ and 0 to 10 m^2/g pigment, silica glass 5 to 10 m^2/g SiO_2 and 5 to 10 m^2/g pigment, etc. The chemical and physical characteristics of the surface are specific to the component. Granted, the components share important similarities. They are all hydrophilic oxides with high-energy surfaces.

Even the surfaces of titanium dioxide crystallites themselves are not just composed of titanium and oxygen ions. In the sulfate process, while the rutile crystallites grow, insoluble components accumulate on their surfaces. Those components are either impurities present in the ore and not removed in the purification process or additives designed to control crystal structure and growth and to regulate agglomeration. This fortuitous surface is not necessarily suitable for a given end-use application; thus, crystallite surfaces are modified by treatments.

The surfaces of TiO_2 pigments are wetted readily. They are usually hydrophilic and disperse spontaneously into water. The energy of wetting is high, aiding dispersion into organic liquids. The ease of wetting of TiO_2 pigments contrasts with wetting problems of organic color pigments, most of which are hydrophobic and have a low negative free energy of wetting. Water does not wet them without the help of surfactants. Suitable organic solvents may wet organic pigments but often only sluggishly.

Since unmodified pigments tend to cake and flow poorly, they are treated with up to 0.5% of a grinding aid, usually organic polyhydroxyl compounds, to improve dry flow. These organic materials remain on the pigment surface. Silicone treatment can be used to make dry pigment flow like sand, but the pigment becomes hydrophobic and unsuitable for most coatings applications.

Surface Analyses—Surface analysis of pigments involves three interrelated subjects: surface area, surface composition, and surface chemistry. For data interpretation, sample density data are also required. Methods and results tend to be more interesting to the scientist than the practitioner.

Instrumental surface area determinations are now routine. Nitrogen adsorption is used widely. Reliability of results is satisfactory. Data are affected by the composite character of pigments and its response to sample preparation.

The modern methods of surface analysis, Microprobe, ESCA, etc., have been used to study pigment surfaces and have yielded interesting results and valuable insights. Costs and technical complexity preclude their widespread and routine uses.

Surface adsorption by pigments has been explored extensively by surface calorimetry and in terms of adsorption isotherms, etc. Ambiguities introduced by the composite character of the surfaces have their impacts.

The density of a pigment can be measured precisely and quickly by a helium densitometer. However, for fine powders of known composition, calculated densities are often more reliable than measured values. Density calculation requires knowledge of the pigment composition and the density data for the pure component oxides. It is decisively important to include in the calculation the total water content: absorbed moisture plus the structural water of the hydrous oxides.

Pigment Packing

The packing density of pigment particles affects paint film performance. This density is an inverse measure of interstitial volume, a reflection of the way pigment particles aggregate and agglomerate into either stringy assemblies that haystack loosely or compact clumps that pack densely.

Effects of packing density on performance are profound. Packing characteristics determine the critical pigment volume concentration of a pigment. Through the critical pigment volume concentration, pigment packing affects virtually all characteristics of paint films [*3*]. Fluffy pigments have

a low critical pigment volume concentration; particulates that pack densely have high critical pigment volume concentrations. In effect, the critical pigment volume concentration itself is a measure of the interstitial volume of wetted pigment particles. Adsorption layers are also involved, but in most instances their contribution is minor.

Practitioners of coatings technology have long been aware of the importance of packing. They used oil absorption of a pigment as one of its most important descriptors. Oil absorption is still used today because it reveals so much about the pigment even though linseed oil has lost its importance as a binder.

Oil absorption is primarily a measure of wet packing complicated by the involvement of adsorption layers, dispersion work, and flocculation. The measure predates the insights of Asbeck/Van Loo into structure and performance of paint films.[17] Thus, the connection between oil absorption—the practical measure—and the scientific concept—critical pigment volume concentrations—is unnecessarily convoluted. Oil absorption of different pigments cannot be compared because the measure is based on weights, not volumes. Critical pigment volume concentration, by contrast, is based on volumes and lends itself readily to comparisons of particulates that differ in densities.

At its best, when oil absorptions of similar pigments of identical densities are measured by an experienced individual who uses a standardized procedure to his personal end point, oil absorption values become a reasonably precise measure of the packing of pigment particles in oil.

For wetted particles, pigment packing is not affected much by the nature of the liquid, water, oil, or solvent provided the particles are not flocculated. In practice, surfactants must be added or be present as a natural component of the system as it is in raw linseed oil. "Liquid absorption" values agree pretty well with each other if they are based on relative volumes of a pigment in a variety of liquids.

Incidentally, oil absorption values correlate inversely with the bulk density of a given pigment. The fluffier the pigment packs in air, the more loosely it packs in liquids.

Packing Measures—In spite of its many shortcomings, oil absorption is the only measure of packing that is widely accepted. The test is a titration of raw linseed oil into dry pigment powder to an end point at which the mass cakes. Two procedures are in common use: ASTM Test Method for Oil Absorption of Pigments by Spatula Rub-out (D 281-84), and ASTM Test Method for Oil Absortion of Pigments by Gardner-Coleman Method (D 1483-84).

Precision of oil absorption data is poor unless all measurements in the data set are made by one experienced individual. For tests by different laboratories, the spatula method has a coefficient of variation of 12%, with 5.3% for the Gardner-Coleman method. Data obtained by two analysts tend to differ because the end point of the titration is more difficult to define than to reproduce.

[17]Asbeck and Van Loo recognized that the characteristics of paint films involve volume rather than weight considerations, no small matter when densities of paint film components can range from 0.9 to 6 g/mL.

Contaminants

Extraneous metal ions within rutile crystallites can degrade the brightness of pigment. Nickel and chromium can be detrimental in concentrations as low as a few parts per million. Involved are semiconductor mechanisms. Substitution of extraneous ions for Ti^{4+} in the TiO_2 lattices discolors the crystals usually towards gray or yellow.

Impurities and co-products introduced by the treatment chemicals are far less detrimental to brightness. Co-products can, however, affect specialized performance requirements. Certain ions can, for example, inhibit cure of acid or base-catalyzed coatings or cause film defects in electrocoatings.

Purity and brightness of TiO_2 crystallites are process related. TiO_2 crystallites made by the chloride process are purer and brighter than sulfate products.

The co-product content of a pigment commodity is usually not a matter of poor operating practice but set by complex compromises between conflicting performance requirements.

Trace Analyses—Trace impurities in pigments are analyzed by conventional emission spectroscopic and X-ray fluorescence methods. Results are considered reliable though not particularly precise.

Color

Titanium dioxide is a virtually colorless dielectric with some semiconductor characteristics due to small amounts of contaminants. Rutile absorbs in the violet end of the visible spectrum. Figure 8 shows schematically the reflectances of

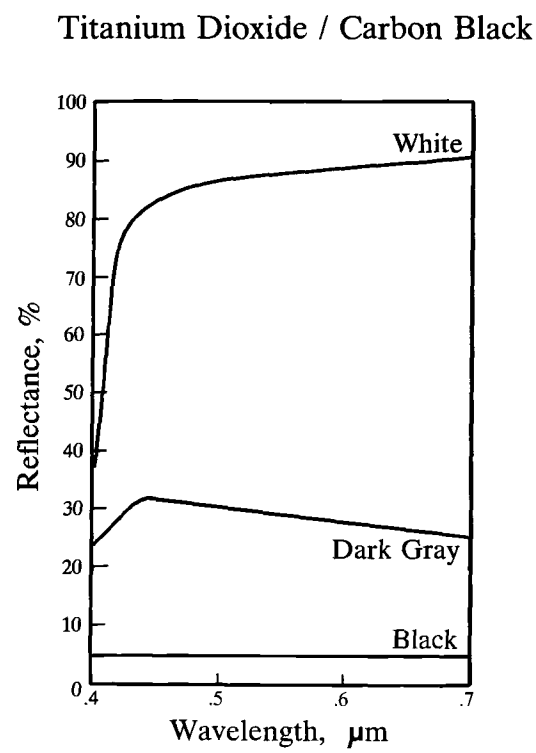

FIG. 8–Reflectances of white, gray, and black paints. From Braun, J. H., *Introduction to Pigments*, monograph in the Federation Series on Coatings Technology, Federation of Societies for Coatings Technology (United States), 1993.

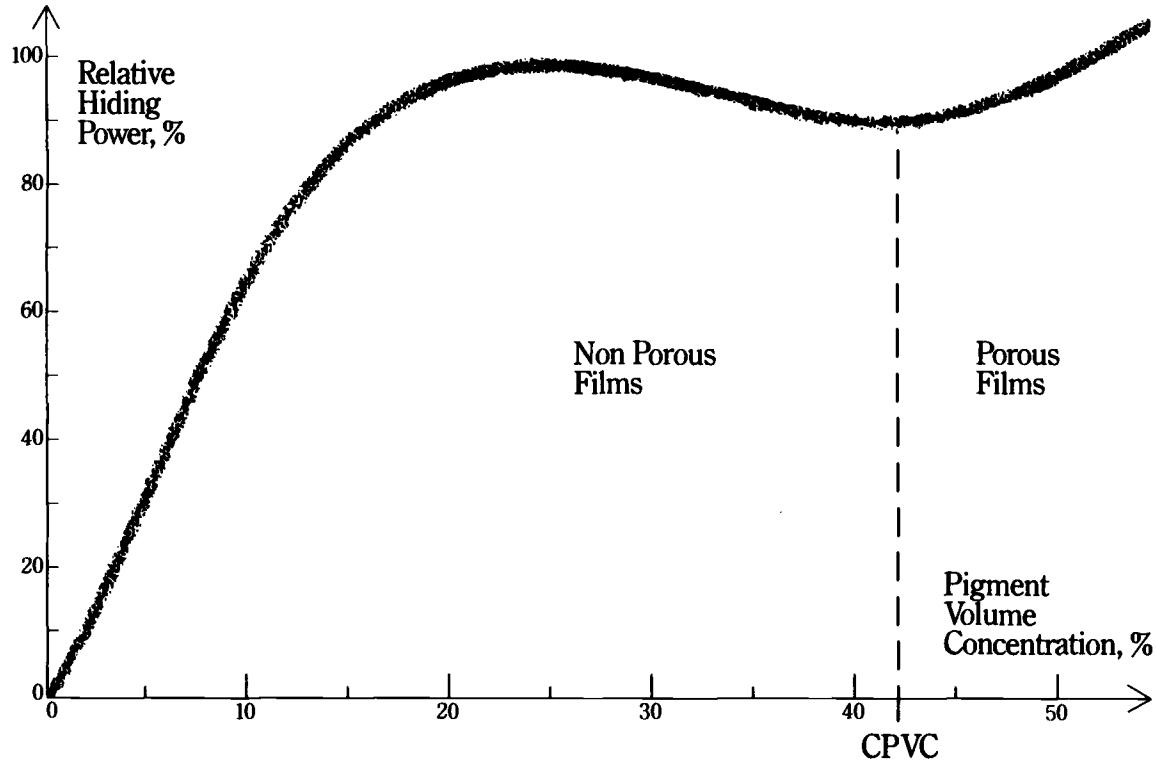

FIG. 9–Hiding power of paint films. From Braun, J. H., *Introduction to Pigments*, monograph in the Federation Series on Coatings Technology, Federation of Societies for Coatings Technology (United States), 1993.

white, gray, and black paints pigmented with only TiO_2, with TiO_2 and carbon black, and with only carbon black, respectively. Absorption of far violet light imparts a slight yellow hue to large crystals. The anatase absorption edge is at a shorter wavelength than rutile, shifted almost completely into UV wave lengths. Thus, anatase crystals are slightly less yellow. All this does not matter much in coatings. For high-purity pigment, dry powder color does not correlate with end use color because most polymers contribute far more yellowness than the pigment.

Pigment brightness matters less in most coatings applications than one might presume. Most coatings, even white ones, are toned, that is, their brightness is reduced intentionally by addition of carbon black or color pigments. Purity, thus brightness, is important only for white coatings that are usually not toned: coatings for light fixtures, many coil coatings, most inks, and ink-similar paints.

Chloride process pigments are intrinsically brighter and whiter than their sulfate counterparts. Typically, chloride process pigments average 99.5% L*[18] lightness,[19] and 98.5% sulfate pigments.[20] The difference between chloride and sulfate pigments, an L* lightness difference of 1%, is about ten times larger than the least visible difference.

TiO_2 particle size has a significant effect on the color of tinted coatings and thin white films. Smaller particles scatter blue light more efficiently. As a result, pigment of a smaller average particle size will shade bluer both tinted coatings and white coatings at incomplete hiding. Pigment of larger average particle size will shade redder in the same systems. Most TiO_2 grades for coatings applications are neutral in this particle-size-related undertone. Products intended for very low end-use concentrations are often bluish. Red undertone pigments are not in demand.

Color Measurement—Color measurements of pigment are performed on dry pressed pellets. Modern spectrophotometers provide data with more than sufficient precision for most purposes of pigment quality control. Most of these instruments can report their results in any of several color coordinates. The L*a*b*[21] system seems particularly well suited to describe variations on the theme of white.

Hazards

TiO_2 pigment is a benign chemical. Its hazards, and the relative lack thereof, are detailed in Material Safety Data Sheets that must accompany any U.S. shipment. TiO_2 presents no pronounced health hazards; it is neither corrosive nor acutely toxic and does not appear to be a significant carcinogen nor embryo toxin in the workplace. As a dry powder, TiO_2 can become a nuisance dust that may require control.

TiO_2 pigment cannot burn nor explode, neither as a dry powder nor as aqueous slurry. Neither the dry pigment nor the slurry is corrosive nor reactive. The hazards of pigment

dispersions in organic liquids reflect the characteristics of the liquids.

Pigment Performance

The TiO_2 industry sells light scattering for the price of TiO_2 because there is no better and cheaper way to achieve effective hiding by thin films that are white or light in color. Thus, optical effectiveness is the primary performance characteristic of the pigment. However, TiO_2 pigment is well optimized and functions near its theoretical potential. Between products developed for similar end use, light scattering differences are too small to matter or be measured. Thus, secondary performance characteristics can be commercially decisive.

Hiding and Opacity

Pigment sells by weight but scatters light, that is, functions, by its volume. The particle size of TiO_2 for white pigment applications was optimized for the scattering of visible light, first experimentally, later confirmed by theory. Commercial grades perform near theoretical potential. A rutile particle of about 0.2 μm diameter is optimal for green light, the wave lengths of greatest sensitivity of the human eye.

Figure 1 illustrates the relationship between scattering power and particle diameter. The Mie theory can specify the optimal diameter for the scattering of an electromagnetic wave by a dielectric particle with great precision, but the result is limited to single spheres. This complex and abstract theory must be translated (1) from a sphere into a real particle of elongated, angular shape, (2) from a single, isolated particle to assemblies of massive numbers, and (3) from mono-size particles to particle-size distributions. The task is formidable, yet significant progress has already been made.

Figure 9 illustrates the effects of pigment concentration on hiding a paint film. At first, hiding increases in direct proportion to concentration. Then, the crowding of pigment particles causes the increase to diminish, to reach a maximum, and to decrease toward the critical pigment volume concentration. Beyond the critical pigment volume concentration, dry hiding, that is, light scattering at air/pigment interfaces, causes hiding to increase again.

Crowding of pigment particles diminishes light scattering substantially [4] (Fig. 10). Effects become apparent at pigment volume concentrations above about 8 vol%. More than half of a pigment's scattering effectiveness can be lost between 8 vol% and the critical pigment volume concentration. A simple optical model explains the effects [5]. Improvements in pigment effectiveness achieved through control of crowding are likely to be fairly insignificant [6].

The optics within paint films are quantified by the Kubelka-Munk theory that combines for thin films the effects of light scattering (usually by white pigment) and light absorption (usually by color pigment). The model serves exceedingly well in spite of some theoretical limitations. Kubelka-Munk equations provide a basis or an explanation for most performance measurements: hiding, opacity, and tinting strength.

Measurements of Light Scattering—Until recently, pigments and paint films were evaluated by visual comparisons, for example, ASTM Test Method for Relative Tinting Strength of White Pigments by Visual Observation (D 332-87). The eye was more sensitive than available instruments, and the mathematics of Kubelka-Munk was too complex for routine calculations.

Two developments make quantitative evaluation of pigments now appropriate: (1) optical instruments have become more sensitive and more reliable than the eye, and (2) the least of computers can calculate results on the spot.

Light scattering and light absorption of paint films can be quantified independently using light reflectance or transmission measurements of thin[22] films drawn over black and white substrates. In addition, film thickness or film weight and composition must be measured. ASTM Test Method for Hiding Power of Paints by Reflectometer (D 2805-88), describes such a test.

[22]Thin enough to show obvious contrast between regions drawn over black and white backgrounds but thick enough to look uniform rather than mottled.

Relatively cheap and very reliable spectrophotometers can measure reflectances in any specific and narrow wave band. By measurements, wave band by wave band across the spectrum of visible light, applicability of hiding power measurements is extended from black and white to color. Paints of different hues can be compared and results expressed separately for performances of white and color pigments. Computer programs are available for data evaluation.

Tinting strength tests, ASTM Test Method of Relative Tinting Strength of White Pigments by Reflectance Measurement (D 2745-89), measure the relative light scattering of a white pigment by overwhelming the slight intrinsic absorptions of binder and pigment with a massive absorption by a standardized addition of colorant. Measured are thick films of infinite hiding.[23] The same test serves for the evaluation of color pigment. Here, the slight intrinsic scattering of the color pigment is drowned by the massive scattering from standardized addition of a white pigment.

Absorption of light within the paint film increases the hiding power of the film. The effect is quite pronounced. It can be caused by pigment or binder. When caused by a TiO_2 pigment of low brightness, this low-purity product can get undeserved credit for a hiding power advantage over purer products. Also, off-color extenders and colored polymers can boost hiding power incidentally or deliberately. This hiding improvement comes at the expense of brightness.

Dispersibility

To make a paint, dry powder has to be distributed in liquid composed of binder and solvent. The process is called dispersion or paint grinding.

The ease with which a powder can be dispersed in a liquid depends primarily on its particle size. As pigments go, TiO_2 at 0.2 μm size is large and easy to disperse, almost as easy as extenders, much easier than most color pigments. For all but glossy coatings, TiO_2 can be stirred into liquids with high-speed agitators. High-gloss finishes require more powerful equipment: media, roll, or ball mills.

Dispersing involves four distinct stages during which most of the energy of grinding converts to heat:

1. *Liquid replaces air-solid interfaces with liquid-solid interfaces.*

   The ease of wetting depends on (a) energy characteristics of the surface of the solid and (b) the chemical affinity between solid and liquid. TiO_2's high-energy surface wets well. By contrast, the low-energy surfaces of organic color pigments wet only with difficulty.

2. *Bonds between particles are broken.*

   TiO_2 crystals are not broken in ordinary mills. Bonds *between* crystals range in strength from strong within aggregates to weak within agglomerates. Weak aggregates can be broken in the high-energy mills of pigment and plastics technologies, not, though, by equipment common in coating technology. Agglomerates break in high-speed dispersers.

3. *Particles are distributed throughout the liquid.*

   The more viscous the liquid, the more power is required to mix and distribute and the more effective the grind.

4. *The distribution of particles has to be stabilized against reversible flocculation.*

   Nonaqueous systems flocculate by Brownian motion and are stabilized against flocculation by surfactants that provide steric hindrance. Aqueous dispersions flocculate by: (1) electrostatic attraction and by (2) Brownian collisions. They are charge stabilized by ionic dispersants.

Rheology matters decisively. Grinding in a shear-thickening rheology regime, dilatent grinding, is highly effective. By contrast, shear-thinning rheology of the grind charge absorbs energy into reversible bonding, wasting much of it as heat. High viscosity helps the energy transfer from mill to particulate. Thus, other parameters equal, grinding "viscous" is more effective than grinding "thin," and grinding "well cooled" is more effective than grinding "hot."

Flocculation degrades optical performance. White pigments can lose only a moderate fraction of hiding, rarely as much as 30%. By contrast, color pigments can lose most of their color.

Excessive or inappropriate grinding does not degrade TiO_2. Nor does optical performance improve with grinding because most of the pigment is dispersed very early in the grind cycle. A few parts per million of undispersed grit, however, can degrade film fineness from "excellent" to "inadequate."

Measurement of Dispersibility—This author knows of no reliable and useful measurement of dispersibility. Granted, it is possible to use standardized procedures to establish a ranking of pigment samples against specific performance requirements. Such a ranking cannot be quantified and does not translate from one application to the other.

In one such scheme, a paint is made by a minutely standardized, low-shear dispersion procedure. The paint is then tested for grit by one of several conventional fineness gages.

The "residual grit" aspect of dispersion is usually evaluated by fineness-of-dispersion gages, for example, ASTM Fineness of Dispersion of Pigment-Vehicle Systems (Method D 1270). The gages are shallow, tapered channels precision machined into steel blocks. A paint sample is scraped into the channel. The surface of the paint wedge is then examined to see at what depth the diameters of largest agglomerates exceed the depth of the channel. This point is visible as a transition from smooth to streaked paint surface.

Pigment Effects on Paint Film Durability

Durability is the continuance of decorative and protective performance of paint films and their components under the influence of weathering. Lack of weathering resistance manifests itself as: (1) oxidation of polymer ultimately to carbon dioxide and water; (2) discoloration and fading of color pigments; and (3) chalking of the TiO_2 with concomitant erosion and gloss loss. Instability of substrates introduces additional degradation effects.

For paint films with TiO_2, concerns involve the weathering resistance of the films themselves. Exposure to sunlight, moisture, and oxygen changes the appearance of paint films. Some films chalk and eventually erode to their substrates; others discolor and fade well before chalking becomes a problem.

[23]Thick enough so that a further increase in thickness does not affect reflectance.

Degradation of coatings occurs because paint films are slowly oxidized by air. Sunlight triggers the degradation reactions. In the dark, paint films can last for centuries, even millennia. In light, durability depends on binders, pigments, and the conditions of exposure. High humidity, particularly condensation, aggravates degradation.

Only the ultraviolet (UV) portion of sunlight causes degradation directly because it has an energy content sufficient to break chemical bonds. The degradation of UV-A and UV-B light[24] is irreversible for polymers and for all organic and some inorganic pigments. A few inorganic pigments are thermodynamically stable. Titanium dioxide is stable, but its catalytic characteristics are activated by UV above 3.08 eV. In effect, the band gap of TiO_2[25] is within the energy levels present in sunlight. All white pigments share some of this attribute. Extenders are stable and inert. Their band gaps are too large to be activated by the UV components of sunlight.

Titanium dioxide affects the durability of paint films in two distinct and opposing ways: (1) As a strong UV absorber, TiO_2 protects the paint film, and (2) as an UV-activated oxidation catalyst, TiO_2 degrades binders [7].

Three characteristics of TiO_2 are functionally disparate but are manifestations of a single fundamental characteristic of dielectric matter: (1) its unique refractive index, which makes TiO_2 the best white pigment; (2) its extreme UV absorptivity; and (3) UV catalytic activity of the TiO_2 surface.

Light of more than 3.08 eV, water, and oxygen are all essential for the TiO_2-catalyzed degradation of binder. Their reactions combine into a cycle that generates two free radicals from each active UV photon [8].

$$H_2O + O_2 + h\nu_{(UV)} \xrightarrow{TiO_2} \cdot OH + \cdot HO_2$$

The hydroxyl and peroxyl free radicals are highly reactive agents that oxidize and thus degrade essentially any organic polymer

$$2 \cdot HO + 2 \cdot HO_2 + CH_4 \longrightarrow CO_2 + 4\,H_2O$$

The chain of chalking events is cyclic with respect to TiO_2 and can be disrupted by exclusion of either UV, water, or oxygen.

Durability Control—The TiO_2 industry inhibits the catalytic activity of the TiO_2 surface and improves the weathering resistance of its products by encapsulation in amorphous silica. The shell is a true silica glass precipitated from aqueous solution by technology invented by DuPont in the 1960s [9]. Encapsulation of TiO_2 made it practical to paint cars in white and bright colors. Meanwhile, binders were improved to that less effective deactivation of the TiO_2's catalytic activity suffices for satisfactory performance of automotive finishes in temperate climates.

The SiO_2 glass prevents contact between the catalytic surface of rutile and the organic vehicle and provides a surface for recombination of free radicals. Figure 11 shows particles of a super-durable pigment. Their silica sheaths are barely visible on the transmission electron micrograph. The silica sheaths, themselves, after the TiO_2 was dissolved out, are shown in the transmission electron micrographs of Fig. 12. Even the holes are visible through which the rutile cores were dissolved.

Intermediate levels of weathering resistance are attained by partial encapsulation of the rutile in silica and/or alumina with or without zirconia and by bulky coatings of hydrous aluminum and silicon oxides on rutile.

Alternate approaches to chalking control are less effective or cause performance problems in coating applications. They involve attempts to: (1) recombine holes and electrons at the TiO_2 surface by semiconductor mechanisms whereby the products are slightly yellow; and (2) prevent the hydroxylation of the TiO_2 surface, i.e., interfere with one step of the chalking sequence, causing products to be gritty.

Durability Testing—Durability of coatings can neither be measured nor be predicted quantitatively. The best state-of-the-art technology can do is rank coatings. Cost per sample are exorbitant, precision is poor, and the time lag is prohibitive for many purposes. Years of outdoor or months of accelerated exposure are required for the pigment and binder combinations for which durability is important, that is, for durable pigment in durable binder.

Testing is done by simulation of a "real" world. Paints are made from experimental pigment and usually several pigment standards. Panels are painted. They are exposed where weathering is severe but is not necessarily representative of the intended application. Certain appearance characteristics are measured regularly and often: chalk, color, gloss, etc. Finally, data are reduced, correlated, and compared. Repro-

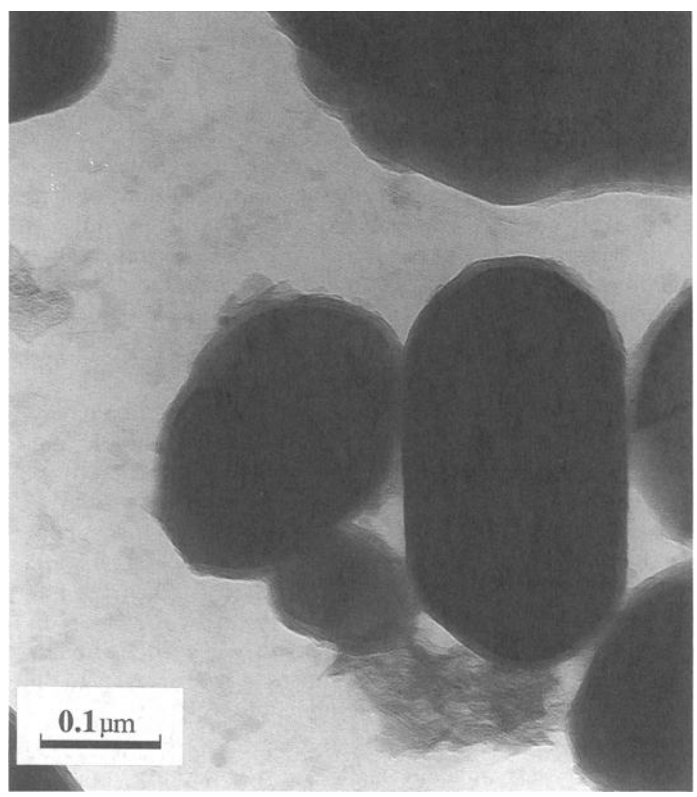

FIG. 11–Encapsulated TiO_2 pigment.

[24]UV-A is the UV wave length region near to visible light, UV-B is the medium UV region, and UV-C is the far (shortest wave length) UV light. Sunlight contains little UV-B and essentially no UV-C.

[25]The band gap is the "forbidden" energy gap between the valence band and the conduction band of a semiconductor. In the language of physics: "UV light induces semiconductor characteristics in TiO_2"; in the language of chemistry: "UV light reduces colorless TiO_2 to black Ti_2O_3."

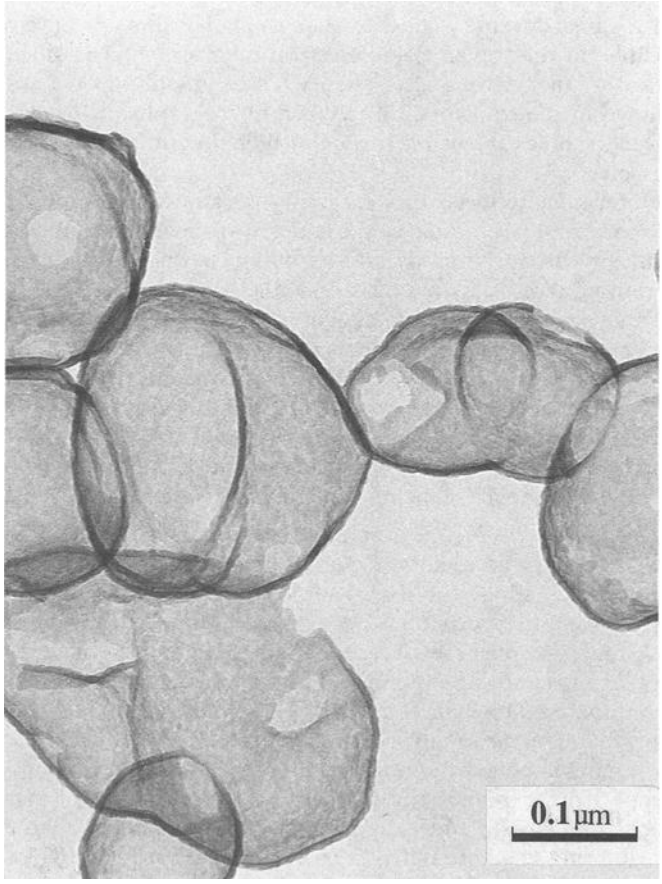

FIG. 12–Silica shells from encapsulated pigment.

ducibility is barely sufficient to tell an interior grade pigment from a durable grade without testing replicates. Experimental durability differences within grades are not generally detectable [*10*].

Results from one binder system cannot be extrapolated quantitatively to binders involving different polymer chemistry, nor can a single acceleration factor predict outdoor performance from accelerated exposures [*11*].

Pigment manufacturers supplement their exposure testing by science-based analyses of the catalytic activity of the pigment.

Pigment Effects on Gloss

Powders do not have a gloss; only surfaces can be glossy. Within surfaces, particulates affect gloss, for example, pigments in paint films. They are detrimental, particularly to the dimension of gloss perceived by the human eye.

Naturally glossy surfaces occur on liquids and amorphous solids.[26] Particulates in paint film, pigments, extenders, and some additives reduce gloss because they roughen the film surface. The more particulate is in the film, the lower its gloss. Clear paint films are glossy if they are thick enough. Thin films can telegraph the roughness of the substrate to the surface of the paint film, reducing its gloss.

Since the volume concentration of white pigments in paint films must be much higher for hiding than the concentration of color pigments and black, the burden of improvement falls on TiO_2 producers. They have increased gloss performance of grades that serve the automotive and industrial markets.

Gloss matters are complicated because a fundamental difference exists between the measured gloss that guides coatings formulation and the perceived gloss that sells cars [*1*]. These two operational definitions of gloss, one based on instrumental measurement of an *intensity of image* and the other on the human perception of a *distinctness of image,* differ profoundly in substance. However, they correlate well enough to guide quality control and pigment development by incremental improvement. The fundamental difference between measured and perceived gloss can, however, misdirect the strategy of product development, for example, a focus on increasing the refractive index.

A mechanism by which pigment causes the surface roughness that degrades gloss explains [*1*] that pigments diminish gloss by an interplay between the surface tension of the wet film with the compressive strength of a particulate bed and a gel structure that develops within the film while it cures. While the film is fluid, surface tension maintains the surface at a molecular smoothness that results in "perfect" intensity-of-image gloss. As the film dries, the structure within the wet film strengthens until it overcomes the surface tension that maintains gloss. Shrinkage of the partially cured film continues, but now shrinkage becomes uneven on a microscopic scale because only the binder/solvent combination, not the pigment, shrinks. Thus, micro-roughness develops and diminished gloss.

Gloss Measurement—Gloss measurement has long been routine: ASTM Test Method for Specular Gloss (D 523). Many conventional gloss meters are on the market. Most perform well for coatings pigmented with white and color pigments.[27] They come with measuring heads for three specular angles, generally 20, 60, and 85°. High-gloss surfaces are best measured at low (20°) specular angle, medium glosses at medium angle, and matte surfaces at grazing angle (85°). The selection of the proper specular angle improves instrumental precision.

The conventional gloss meters measure the intensity of light reflected by a surface, the intensity-of-image component of gloss. The human eye, by contrast, perceives the distinctness-of-image component of gloss. Thus, haze and so-called distinctness-of-image[28] data are used to supplement the conventional gloss measurements.

Compatibility

Usually, TiO_2 is used in combination with other pigments. Interactions between pigments can occur and are detrimental to performance. Often, hiding is decreased, color strength is lost, and chroma is reduced; occasionally, the hue shifts slightly.

Most interaction problems involve surface chemistry. The immediate cause of the problem is flocculation. Either the

[26]Single crystals are an exception, but their surfaces are small. Glass is an amorphous solid. Polished surfaces are not "natural." Incidentally, only liquids, amorphous solids, and single crystals can be transparent.

[27]For coatings that contain flake pigments, the interpretation of angle-dependent reflectance measurements is complicated.

[28]The distinctness-of-image instrument is really an intensity-of-image meter sensitized towards distinctness of image.

white or one of the color pigments has flocculated. Almost inevitably, the color pigment is at fault.

Most color pigments enter the market as toners, lakes, or dispersions, that is, complex composites that can contain more surfactants and modifiers than colorant. These additives are chemically reactive and can interact detrimentally with the surfactants or additives of the paint formula. Dry TiO_2 pigments,[29] by contrast, contain no surfactants and are inert and chemically less complex with far fewer possibilities of adverse interactions.

Chemical interactions between pigments are problems of the past caused by reactive pigments. White lead, for example, was incompatible with TiO_2 because UV exposure could cause gross, though temporary, discoloration. Few modern pigments are susceptible to these problems.

Problems between TiO_2 pigment and resins or additives do, however, occur occasionally because many paint films contain much higher concentrations of TiO_2 than of additives or of color pigments. Components of TiO_2 pigment can thus have significant leverage even if present in relatively small concentrations on the pigment. Problems are usually quite specific to the paint formula. Several such problems have been recognized and are resolved through specialized TiO_2 grades made, for example, for electrocoating primers and for acid-catalyzed paints.

Product Types

ASTM D 476-84 distinguishes four types of TiO_2 pigments (Table 2): one anatase type and three rutiles: interior, exterior, and pigment for paints formulated above the critical pigment volume concentration. The standard was formulated in 1939 with two classes of pigments. In the years since, the design of pigments has progressed to where the coatings industry can now select the most suitable pigment grade for a specific application from far more than two or four TiO_2 types. Granted, a single TiO_2 grade could serve diverse needs but would do so only moderately well. Optimal performance in any application demands specialized pigment grades that satisfy specific requirements of optics, surface chemistry, and dispersion technology. Some of these requirements can be met only through compromise.

The diversity of products can be described in terms of four specific performance dimensions: durability, gloss, dispersibility, and undertone. Then there are products aimed at specific applications: enamel paints, dry hiding paints, pigment slurries, acid-catalyzed coatings, electrocoated primers, etc. Finally, pigment grades are designed for the specific requirements of whole industries: coatings, plastics, paper, and ink.

These are the products designed to specific performance dimensions in coatings:

- *Durability:* Interior—Exterior—Severe Exposure

  Interior grades are unfit for exterior applications except when used underneath top coatings that absorb all light of wavelengths below 400 nm. All-purpose pigments are exterior durable in appropriately durable vehicles at moderate severity of exposure and for moderate appearance requirements. Severe exposure grades are intended for satisfactory performance including high gloss at exceptionally severe conditions, for example, at the horizontal position in the humid subtropics.

  Durability must be manufactured into the pigment surface.

- *Gloss:* Conventional—Flashy

  Conventional pigments satisfy the gloss requirements of most architectural and trade-sales applications and of many industrial coatings. High-gloss pigments are aimed at automotive and some flashy industrial finishes.

  High-gloss application call for pigments of small agglomerate size and low oil absorption.

- *Dispersibility:* Conventional—Low Shear

  Conventional pigments are designed to be dispersed by equipment developing moderate to high shear[30]: media mills, ball mills, roller mills, and high-speed dissolvers at low rates of throughput. Special pigments are available for low-shear, high-rate dispersion by high-speed dissolvers and for stir-in with screening.

  Dispersibility is promoted by surface treatments at some detriment to gloss.

  Unlike many color pigments, TiO_2 pigments are dispersible enough not to require predispersion.

- *Undertone:* Neutral—Blue

  In coatings applications, the undertone of the pigment, blue, neutral, or red, is rarely an issue. Thus, most coating grades have a neutral undertone. Blue undertone pigments are preferred in applications at very low pigment volume concentration. Red undertone pigments do not appear to be in demand.

  Undertone is affected by pigment volume concentration and controlled by the size of the primary TiO_2 particle, small for blue, intermediate for neutral, and large for red.

There are also specific coatings applications addressed by special product designs.

- *Grades intended for coatings below the critical pigment volume concentration.*

  Most TiO_2 pigments, conventional interior and exterior grades, conventional and high-gloss products, conventional and low-shear dispersible pigments, the neutral and blue undertone pigments, are all suitable for applications below the critical pigment volume concentration.

- *Grades intended for applications above the critical pigment volume concentration.*

  Heavily treated, low-gloss products perform better in dry-hiding paints than grades made for high and moderate gloss. In effect, the pigment contains its own, exceptionally effective extender.

- *Slurries intended for waterborne paints.*

  Aqueous slurries are suited only for waterborne applications. The costs of dispersion operations are borne by pigment manufacturers. For medium- and large-scale operations, savings from the elimination of a process step outweigh the costs of slurry-handling facilities.

- *Other specialized grades are made as opportunities are recognized and solutions developed.*

[29]Slurry grades do contain some organic surfactant.

[30]High shear within coatings technology. The plastics industry uses several more powerful mills.

TABLE 2—Excerpt from ASTM Standard D 476-84: Specification for titanium dioxide pigments.

	Type I	Type II	Type III	Type IV
	Anatase	Rutile		Rutile
	Free chalking	Medium chalk resistant		Highly chalk resistant
Typical Application	White exterior house paints; interior use	Low-medium PVC enamels and lacquers	Medium-high PVC enamels; alkyd and emulsion flat wall paints	Exterior coatings requiring excellent durability and gloss retention
TiO_2, min, %	94	92	80	80

Finally, industries other than coatings are targeted by specific products:

- *Plastics*

  Plastics are pigmented by products most of which are optimized for performance at PVCs of less than 1 vol%. Durability and dry-flow characteristics can be important to the plastics industry. High-gloss and low-shear dispersibility are usually not required.
- *Paper*

  The wet-end stage of paper making uses aqueous slurries. Slurry handling and optics are important; low-shear dispersibility, high gloss, and durability are not important.
- *Ink*

  Inks require pigments that are high in gloss. Compatibility with a wide range of solvents and vehicles is often important.
- *Miscellaneous end uses*

  Pigmentary applications (floor coverings, elastomers, roofing granules, fibers, fabrics, sealants, food additives, etc.) and nonpigmentary applications where pigment is used for its TiO_2 content (ceramics, welding rods, etc.) or as a low-cost, mono-disperse particulate (for example, as catalyst support).

Also, the same products can be packaged in different ways, bag, semi-bulk, or bulk, or analyzed for special purposes, for example, food additive purity. Each such product may enter commerce under its own grade designation.

The wrong grade of TiO_2 pigment for any specific application will still be inert, white, and will hide well. But, the inappropriate pigment will fall short of expectations on secondary performance characteristics such as durability, gloss, or rheology. This is in marked contrast to most color pigments where a grade inappropriate to an application is likely to fail grossly.

Matters of pigment classification are complicated by interactions among requirements:

1. Certain requirements are mutually exclusive. For example, aqueous pigment slurries are obviously suitable only for waterborne applications.
2. Some industry requirements overlap. Paper coatings resemble dry hiding paints and are served by similar products.
3. Optimal performance in one dimension can come at the expense of performance in another dimension. Flashy gloss can be attained only at the expense of pigment characteristics that promote stir-in dispersibility.
4. Premium performance can require additional process steps, increasing the cost of manufacture. Pigments for severe exposure and grades for flashy finishes are sold at a premium because they are more expensive to make.
5. Identical performance objectives can be achieved by different product designs.

Nevertheless, I have attempted classification of state-of-the-art products in terms of six performance parameters and intended applications: concentration, gloss level, exposure, optics, slurry, and dispersion. Permutations of these requirements make for 72 potential product niches for coatings applications alone. Fourteen of the niches are occupied by commercial products. They are shown in Table 3. All major manufacturers sell at least several of these products as specific grades or by equivalent sub-classifications within grades.

About two thirds of the potential product niches appear to serve no practical purpose. For example, aqueous pigment slurries are not suited for solvent-based paints, and high-PVC paint films are not made to have flashy gloss.

Obviously, the multiplicity of grades creates costs and incentives for the development of universal grades. Lately some of these attempts have been partially successful, and a few "universal" products have appeared on the market.

Conspicuously absent from this table are anatase pigments. They and the extended TiO_2 grades that used to dominate TiO_2 markets are no longer used in coatings.

OTHER WHITE PIGMENTS

In coatings, only void hiding competes with TiO_2. The classic white pigments—lithopone, zinc sulfide, zinc oxide, and white lead—are far less cost effective. White lead is also too toxic. Pigmentary zinc oxide is still being used in paint, not as a white pigment but as a mildewstat.

Extenders—colorless ground minerals and precipitated particulates—are sometimes described as pigments[31] and are advocated as supplements for true white pigments. Extenders are formulated into coatings to reduce costs by replacing expensive polymer with cheaper mineral. Below the critical pigment volume concentration, that is, in films with excess polymer, extenders do not scatter light because their refractive indices are too low. In films with excess particulates (films above their critical pigment volume concentration), extenders hide indirectly by creating pores. Only in very porous films do extenders scatter light at the particulate/air interface.

In colonial times, calcium carbonate ($CaCO_3$) was used as a white pigment. The pigment was made in situ by the reaction of atmospheric carbon dioxide with "whitewash," a brushed-on slurry of calcium hydroxide. The pigment was held together by minimal amounts of binder. Light was scattered at

[31]They do not ". . . impart black or white or a color to other materials," thus do not meet Webster's definition of a pigment.

TABLE 3—Commercial TiO_2 pigment grades.

Product Type	Intended PVC[a]	Intended Gloss	Intended Exposure	Pigment Delivery	Intended Dispersion
1	Low[b]	Flashy[c]	Indoors	Dry	High Shear[d]
2	Low[b]	Flashy[c]	Indoors	Slurry[e]	Dispersed
3	Low[b]	Flashy[c]	Outdoors	Dry	High Shear[d]
4	Low[b]	Flashy[c]	Outdoors	Slurry[e]	Dispersed
5	Low[b]	Flashy[c]	Extreme[f]	Dry	High Shear[d]

[a]Pigment volume concentration, pigments plus extenders, in the paint film.
[b]Always below the critical pigment volume concentration.
[c]Applications for which gloss is maximized at direct or indirect expense.
[d]Media mills and the like at moderate or low throughput, optimized mill base.
[e]Aqueous slurries.
[f]Including horizontal exposure to tropical and subtropical levels of UV radiation.
[g]Gloss levels from flat through semigloss to high gloss but excluding extremely high gloss.
[h]High shear dispersion is generally not required for less than extreme levels of gloss.
[i]High-speed dispersers and the like.
[j]The film qualities of low-shear dispersion are generally not satisfactory for flashy finishes.
[k]Above the critical particulate volume concentration.
[l]Coatings above the critical pigment volume concentration are usually not suited for outdoors.

the $CaCO_3$/air interface. Because the service life of the coating was minimal, whitewashing ceased when wages increased with industrialization.

Void Pigments

Air-filled voids in a paint film can either act as if they were pigment particles or enhance the effectiveness of a true pigment. Both mechanisms have been implemented in coatings.

Pigmentary and sub-pigmentary voids contribute to hiding of all dry hiding paints films, that is, films starved of binder. Somewhere above the critical pigment volume concentration voids join into an interconnected network of pores. The pores become stress concentrators that degrade the mechanical qualities of the paint film. The network conducts chemical contaminants into the paint film and to the substrate, diminishing the chemical and protective qualities of the film.

It is through the creation of pores that extenders contribute to light scattering. This scattering comes at the expense of film qualities. Problems can be avoided if the voids are sealed and spherical.

Voids of pigmentary size scatter light like particles, about as effectively as pigmentary zinc sulfide but not nearly as well as TiO_2 pigment. Unlike interconnected pores that degrade paint films, sealed spherical voids are not, per se, detrimental to mechanical and chemical film qualities.

One commerical product, Rhopaque® (Fig. 13), generates sealed, spherical air voids in paint films from plastic beads that have one concentric void. The beads are added to the paint as an aqueous dispersion of water-filled resin balloons that lose their water as the film dries. These voids are protected by the thickness of their own plastic shells from the crowding that diminishes the scattering effectiveness of conventional white pigment. Their direct light-scattering effectiveness is only 12% of scattering by the same volume of rutile. Immunity to crowding increases the effective light scattering of voids.

Another, less successful product, Pittment®, generated pigment-sized air voids in paint films by evaporation of droplets of an organic solvent emulsified in the paint.

If the voids are of sub-pigmentary size, small enough to lose their individual optical identity, they do not scatter much light but collectively decrease the refractive index of the matrix. A composite refractive index of polymer and air takes the place of the index of polymer alone. This decrease of matrix

refractive index has a potent effect on the scattering of any true pigment present in the paint film.

A product composed of vesiculated and pigmented polymer beads makes use of this effect. The product, Spindrift® (Fig. 14), is suitable only for low-sheen paints because the beads act as a flatting agent. They have to be larger than TiO_2 particles because each bead has to accommodate several pigment particles plus voids and some binder.

A third approach to void hiding, the use of stretched foam, is very efficient. Hiding can be achieved without any pigment with less polymer on the substrate than by any conventional paint. But foam coatings are pressure sensitive. They are too sensitive for paint applications but are suitable for opacification of textiles, curtain fabrics in particular.

Acknowledgments

I am indebted to my former colleagues for advice, counsel, and the insights I developed during my career in DuPont's white and color pigments businesses. Special thanks go to A. Baidins and R. E. Marganski, my co-authors in a literature review of TiO_2 technology, and to D. A. Holtzen and R. C. Craft-Tulloch, who helped review and revise the manuscript.

Black Pigments

by Frank R. Spinelli[1]

BLACK PIGMENTS FALL INTO three classes [*1*] (Table 1). The first two classes derive their color characteristics from the element carbon, the third class from ferrous oxide, Fe_3O_4. Class 1 blacks are carbon blacks, which are composed of 90% or more of elemental carbon. Class 2 blacks may be referred to as "carbonaceous pigments," which range from 8 to 88% elemental carbon.

CARBONACEOUS PIGMENTS (CLASS 2)

This class of blacks, perhaps the least important for paints and coatings, is composed of two main types:

Mineral Blacks

Mineral blacks are finely ground derivatives of coal and shale and are mixtures of carbon, aluminum silicates, silica, and iron oxides. They can be characterized as having poor jetness, very low tinting strength, low oil absorption, very brown undertone, and poor dispersibility. Consequently, they are rarely used in the paint industry.

Bone Blacks

Bone blacks are made by destructive distillation of solvent-extracted cattle and sheep bones and contain only from 8 to 17% carbon with the remainder mostly calcium phosphate. During the "calcination" (8 h at 800°C), the organic matter is decomposed and the resulting carbon forms a thin, porous film on the surface of the mineral network, creating a large carbon surface area per unit of weight. Consequently, they have high color and great adsorptive ability, but very weak tinting strength. Oil absorption is quite low, and aqueous dispersibility is excellent. Bone blacks are used only in specialty finishes where high color with low oil absorption is essential.

IRON OXIDE BLACKS (CLASS 3)

Naturally occurring as the mineral magnetite, these blacks are synthesized by reacting ferrous sulfate, $FeSO_4$, with alkali and then oxidizing to ferrous oxide, Fe_3O_4 (black magnetic oxide). Having the highest density as well as excellent light fastness and chemical resistance, they are used in the paint industry chiefly in metal-protective primers. It should be noted that black iron oxide, Fe_3O_4, will oxidize at high temperatures to red or brown ferric oxide, Fe_2O_3. Iron oxide blacks have very poor color and strength properties compared to carbon blacks.

CARBON BLACKS (CLASS 1)

Carbon black is the most important black pigment for paints and coatings. This unique, strictly manmade material offers great versatility in end use performance. Through variation in key properties, by careful control of manufacturing conditions, a broad range of grades is commercially available. To provide a better understanding of carbon black as a pigment in paints and coatings, the effects of carbon black property variations on its optical functioning in dispersed media are herein defined. This involves some discussion of how carbon black is formed as well as identification of its key parameters. Following is an elucidation of the mechanisms of carbon black optical function and how they are influenced by variations in each of the key parameters. Based on this knowledge, certain guidelines for selection of a grade of carbon black are enumerated. As a corollary, the subjects of achieving optimal quality dispersion and its importance to end use performance are addressed. Finally, techniques of measurement of carbon black coating's optical performance properties are outlined with reference to the appropriate ASTM tests where applicable.

Carbon Black Optical Function

General Nature of Carbon Black

1. *Principles of Formation*—The formation of carbon black requires the application of thermal energy to a hydrocarbon, usually by incomplete combustion (limited oxygen supply), which results in the rupture of C—H bonds [*2*]. This first stage is often called "cracking" (Fig. 1*A*). The reaction products are aromatic radicals and dicarbon radicals, highly reactive species, which combine to form hexagonal lattices in a planar configuration. Several "layer planes" then tend to stack to form crystallites (Fig. 1*B*). These crystallites tend to form spherical prime particles that continue to grow, forming *primary aggregates*, the characteristic units of carbon black (Fig. 2). Both prime particle and primary aggregate distributions are typically broad since a great number of layer planes and

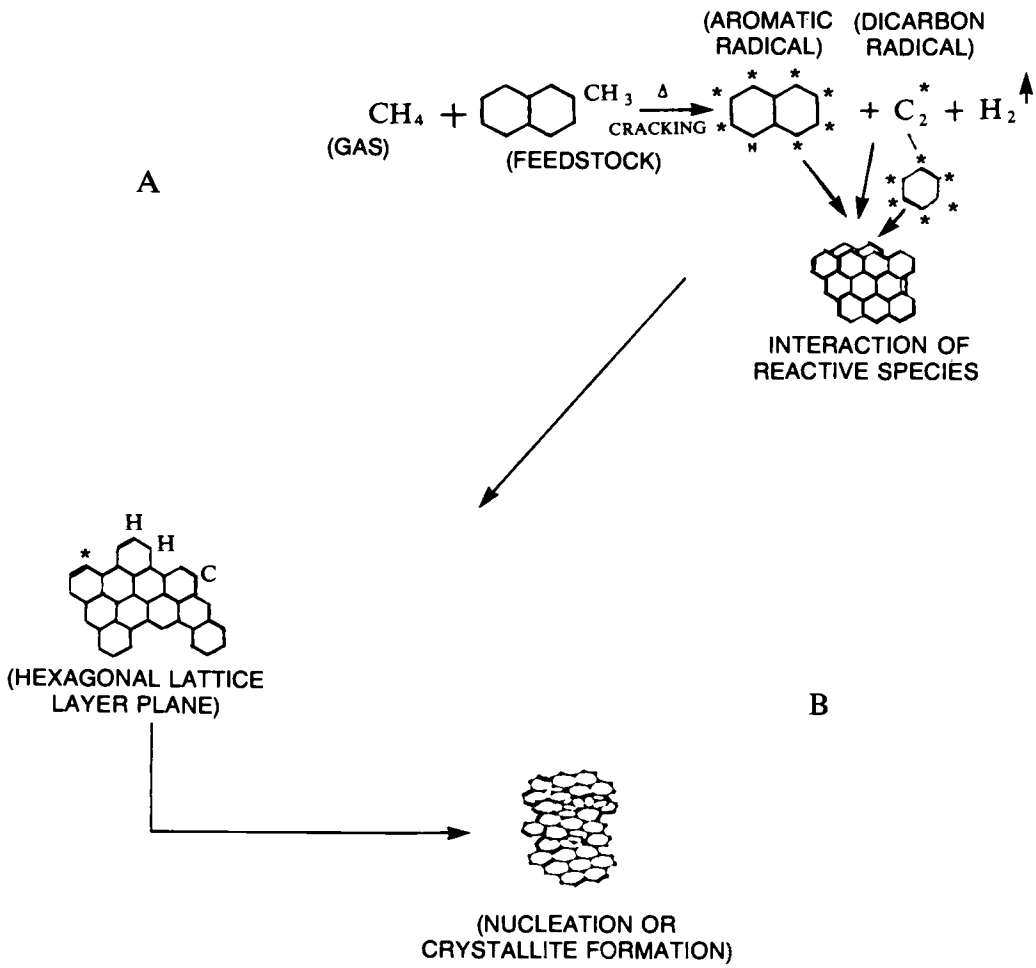

FIG. 1–Formation of carbon black. Asterisks indicate active sites.

crystallites are going through the described processes, but not in phase. Those particles and aggregates which began formation sooner would have longer growth times and would be larger. By choice of hydrocarbon feedstock and careful control of reaction conditions, the key properties of prime particle size, primary aggregate size, porosity, structure, and surface chemistry are varied to create the spectrum of commercial carbon blacks.

2. *Types/Processes* [3]—There are five types of industrial carbons which fall in the general category of carbon black. Included are lampblack, channel black, furnace black, thermal black, and acetylene black. Each of these is made by a different process and, consequently, has some unique properties (Table 2).

Lampblack Process. Oils or resins are burned in shallow pans in an enclosure with restricted air supply, and the smoke

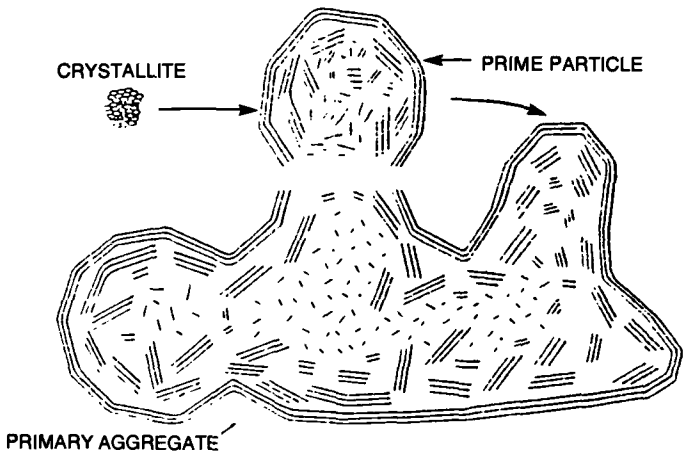

FIG. 2–Growth to particles and aggregates.

is passed through settling chambers prior to venting (Fig. 3). Carbon black deposited on the cool walls of the chambers is subsequently scraped off by motor-driven ploughs. The principal feedstocks are coal tars or petroleum residual oils. Lampblack's major usage in the coatings industry is as a tinting pigment. It exhibits excellent antiflocculation properties and an extremely blue undertone. Though lampblacks have been replaced by furnace blacks to some extent on a tinting strength basis, substantial quantities are still produced for special applications.

Channel Process. Until about 1975, this process was the leading source of carbon blacks for the coatings industry. Its demise was brought about by two principal factors: (1) the escalating cost of natural gas and (2) the increasing stringency of air pollution regulations.

The process (Fig. 4) involves partial burning of natural gas with insufficient air. Small fan-shaped flames from gas burner tips (2000 or more) are housed in sheet metal buildings or "hot houses" and are arranged so that they impinge on channel irons suspended above hoppers. Using scrapers and a reciprocating action of the channel irons, the deposited carbon is collected in the hoppers and passed through the collection system. Yields are characteristically very low, reaching a maximum of about 5% with the coarser grades. This process can produce carbon blacks of particle sizes ranging from about 30 to less than 10 nm. The resultant blacks have typically higher volatile contents (chemisorbed oxygen complexes on the surface) because of the presence of oxygen during formation. Though channel blacks have virtually disappeared from industry, a variant called roller process blacks, made from feedstocks other than natural gas, are still produced in limited quantities in Germany.

Furnace Process Blacks. These are made by partial combustion of a hydrocarbon in a closed reactor (or furnace) under well-defined conditions. The precursors of modern oil furnace blacks were the gas furnace blacks, which are no longer produced.

Oil Furnace Process. A hot flame is first created by burning gas with air inside a closed furnace, and then a liquid hydrocarbon is atomized into the hot flame zone. Furnace designs and reactor configurations vary considerably, but the principle is the same (Figs. 5a and 5b). The feedstock is usually a medium-molecular-weight aromatic oil that must be heated to 200 to 250°C to have sufficient fluidity. Yields are high (30 to 60%), air pollution is virtually nil, and it offers superior process control capability. Blacks ranging in prime particle size from 100 down to about 10 nm, with variations in structure level (degree of aggregation of prime particles), can be produced by varying furnace conditions, feedstock properties, residence times (time in hot zone), and quench distances (how far downstream the cooling sprays are introduced into the furnace).

Oil Furnace Carbon Blacks. These essentially satisfy all requirements of industrial blacks and account for 95% of all the carbon black produced today.

Thermal Cracking or Thermal Decomposition—A final category of carbon black processes uses thermal cracking or thermal decomposition of a gaseous hydrocarbon in the absence of flame. This includes thermal blacks and acetylene blacks, which are not used in the coatings industry.

Mechanisms of Interaction with Light [4]

Since coatings vehicles are usually transparent resin solutions, the function of a pigment in rendering the coating opaque and imparting a desired color is to intercept and modify incident visible light. Carbon black accomplishes this

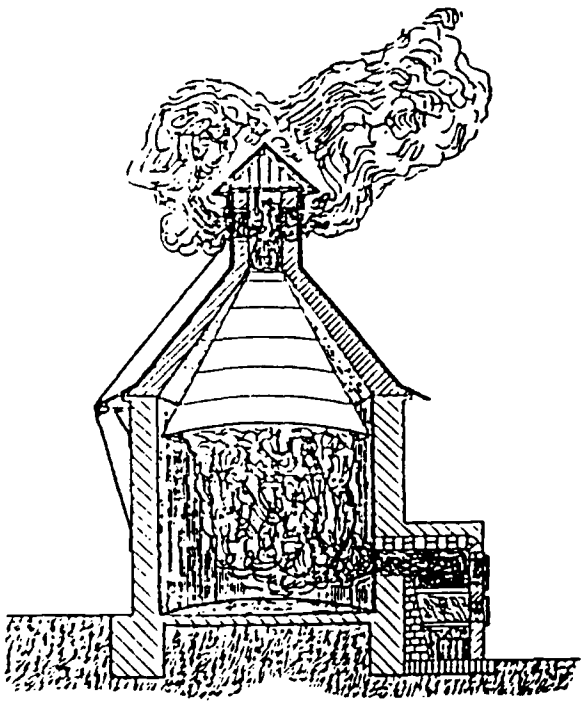

FIG. 3–Old plant for lampblack manufacture.

by means of two mechanisms: light absorption and light scattering.

1. *Light Absorption*—By nature of its quasigraphitic microstructure, carbon black strongly absorbs visible light across the spectrum. In dispersed media, because of its relatively fine particle size and high surface area, it is an extremely efficient light absorber and thus appears black. To achieve opacity, it is necessary to have a sufficient number of carbon black aggregates distributed throughout the resin matrix to intercept virtually all of the incident light (Fig. 6). This condition is often referred to as the opacity loading level and translates to about 2 to 3% carbon black by weight in most vehicle systems. Loadings of carbon black above the opacity loading level will not further enhance the color (blackness).

2. *Light Scattering* [5]—Another factor that contributes to carbon black's appearance is its relatively weak light-scattering ability. When dispersed in a vehicle, individual aggregates of carbon black are much too fine to be efficient scatterers [*6*]. Nevertheless, light scattering plays a significant part in the details of carbon black optical performance.

Carbon Black Parameters Affecting the Optical Function

General Principles

When dispersed in a transparent vehicle, the primary aggregates of carbon black are the optically functional units. Thus, the optical function is affected by variations in the two key carbon black parameters which determine aggregate size: prime particle size and structure.

As primary aggregates decrease in size, the specific surface area increases and incident light must penetrate more carbon, which results in increasing light absorption. Both absorption and scattering efficiencies (per unit weight of carbon black) increase with decreasing aggregate size (Fig. 7) down to a size equal to about one third the wavelength of the incident light, D (about 180 nm for "white light"). Further decreases in aggregate size show a leveling off of absorption efficiency and a decrease in scattering efficiency.

The size of the prime particle determines the size of the primary aggregate at a fixed level of aggregation. The level of aggregation is known in the carbon black industry as structure. It is a parameter that not only indicates the average number of prime particles composing a primary aggregate, but also the degree of anisometry, branching and chaining or shape irregularity (Fig. 8). The higher the structure, the greater the void space within and around a primary aggregate. In fact, the extent to which a carbon black absorbs oil or

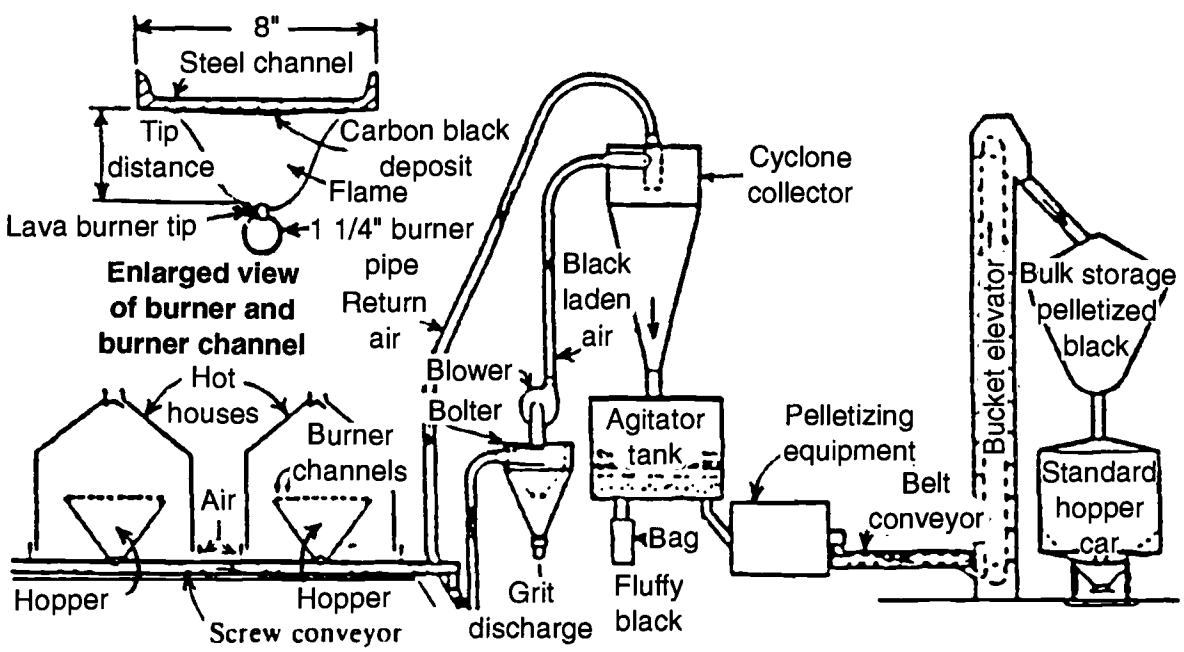

FIG. 4–Channel process for carbon black manufacture.

dibutylphthalate (DBP), which fills the void spaces, is a common industry measure of its structure.

Jetness

The industry term for degree of "blackness" is *"jetness,"* which increases with decreasing aggregate size for two reasons: (1) increasing light absorption efficiency and (2) decreasing light-scattering efficiency. As primary aggregates become smaller, incident light must penetrate more carbon, resulting in more light absorption per unit weight of black. Also, despite the individual variations of absorption and scattering efficiencies per unit weight shown in Fig. 7, the ratio [4] of absorption efficiency to scattering efficiency, *A/S*, essentially increases continuously with decreasing aggregate size. Thus, both mechanisms, absorption and scattering, are synergistic with respect to jetness, and the degree of jetness is controlled by the *A/S* ratio. The smaller the aggregate, the higher the *A/S* ratio and the jetter the black.

Structure can also be a measure of aggregate size for a given prime particle since it reflects the number of prime particles composing a primary aggregate. In this sense it is also an indicator of scattering efficiency. Low-structure blacks have smaller primary aggregates, exhibit less scattering, and have higher *A/S* ratios. High-structure blacks have larger primary aggregates, exhibit more scattering, and have lower *A/S* ratios. Given two carbon blacks of comparable prime particle size, the black of lower structure (smaller, more compact primary aggregates) will show the higher jetness because of a higher *A/S* ratio.

Tinting Strength

Carbon black's primary tinting application is to make gray colors by blending with a white pigment. Addition of a fixed amount of a number of different carbon blacks to a titanium dioxide, TiO_2, dispersion, for example, will result in various depths of gray color. The darkest gray will represent the carbon black highest in tinting strength. Since even a dark gray surface reflects a great amount of light relative to a black surface, the increment of light scattered by the carbon black is insignificant. For this reason, the controlling mechanism in tinting strength is light absorption [7]. Finer primary aggregate size, which favors increased absorption, will enhance tinting strength (Fig. 9). As the primary aggregate size is determined both by prime particle size and structure, higher tinting strength is favored by fine-particle-size, lower structure blacks. However, as shown in Fig. 7, at an aggregate size equal to one third the wavelength of incident light, the absorption efficiency, and consequently tinting strength, levels off and becomes independent of further decreases in size. This phenomenon can be seen in Fig. 9 as well.

Opacity

The extent to which a coating will cover or "hide" a substrate is a function of the nature of the pigment and its loading level. As mentioned earlier, the opacity loading level of carbon black in a coating system is usually 3% by weight or less for normal paint film thicknesses (around 1.0 mil). With much thinner films, higher loadings would be required to achieve opacity. In other words, there must be a sufficient number of primary aggregates dispersed throughout the film to prevent any significant amount of incident light from passing through.

Carbon black creates opacity through the two mechanisms cited earlier, absorption and scattering of visible light. In fact, opacity of carbon black can be considered as being directly proportional to the sum of the absorption coefficient and the scattering coefficient, $(A + S)$. This means simply that light that is either absorbed or scattered is not transmitted through the film. From this relationship, it is also possible to predict that optimum opacity, as a fixed loading, would be rendered by blacks having an aggregate size close to one third the wavelength of incident light (in short, blacks in the regular to medium color categories for white light of 180 nm, as per Fig. 7).

One convenient way to express the opacity of films is to use the parameter called *optical density*. This is a function of the percent of incident light transmitted as follows:

$$\text{Optical Density} = -\text{LOG}_{10} T_\lambda$$

where

T_λ = Transmitted light/incident light, and
λ = Wavelength of incident light.

An optical density of 1.0 would indicate a transmission of 1% (0.01), 2.0 would indicate a transmission of 0.1% (0.001), etc. Since T will vary somewhat with wavelength, it is necessary to use the subnotation to denote the wavelength of the incident light. Further, there is a logarithmic relationship with film thickness (expressed as weight of coating per unit area) for a fixed carbon black loading, i.e.

$$\text{Optical Density} = -\ln(\text{grams/m}^2)$$

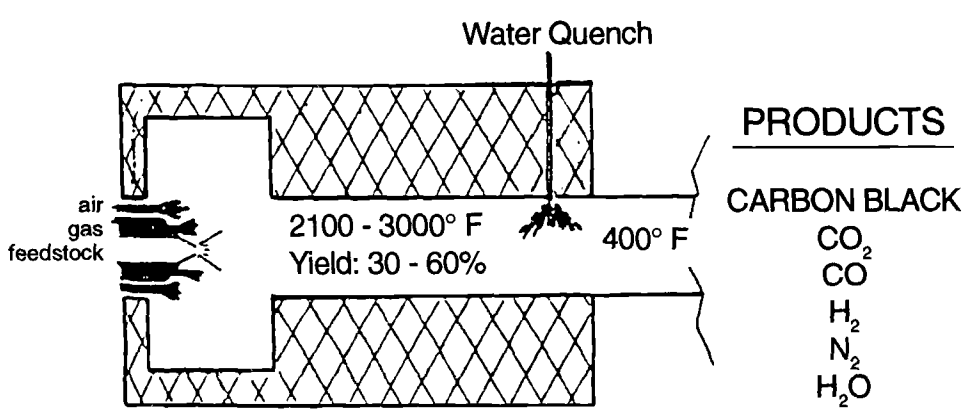

FIG. 5a–Oil furnace reactor.

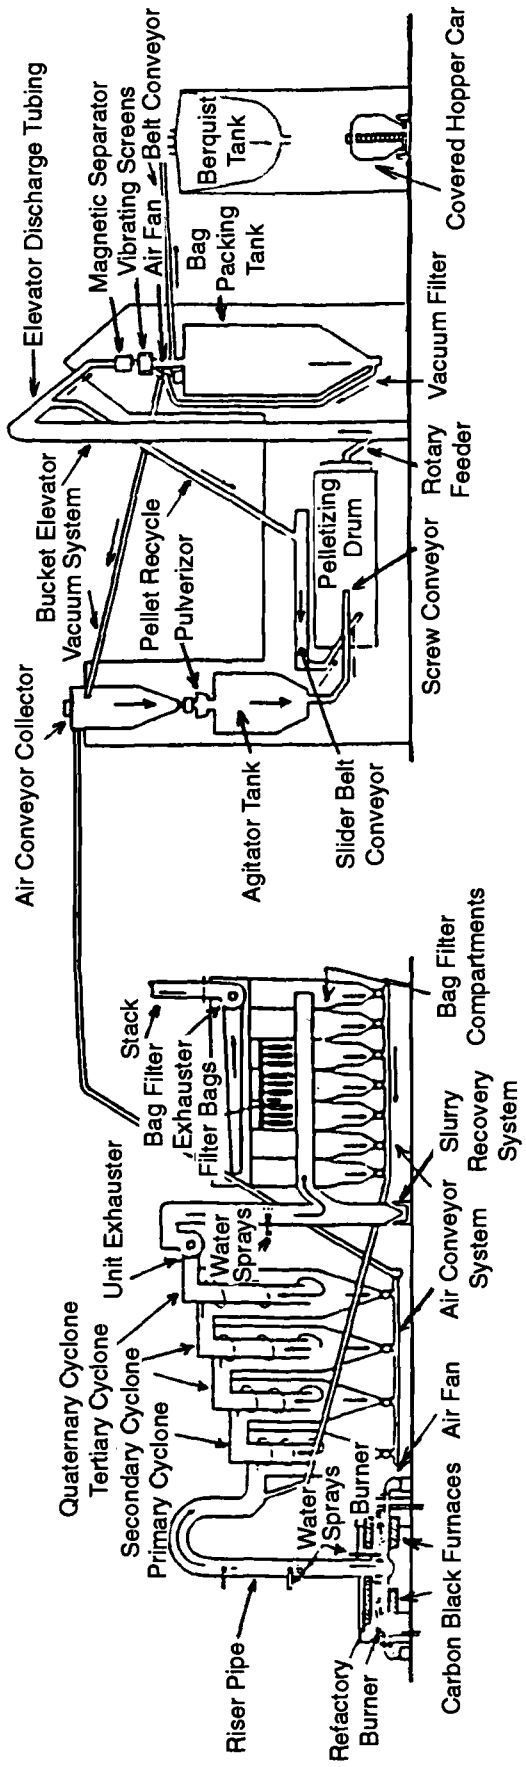

FIG. 5b–Oil furnace plant.

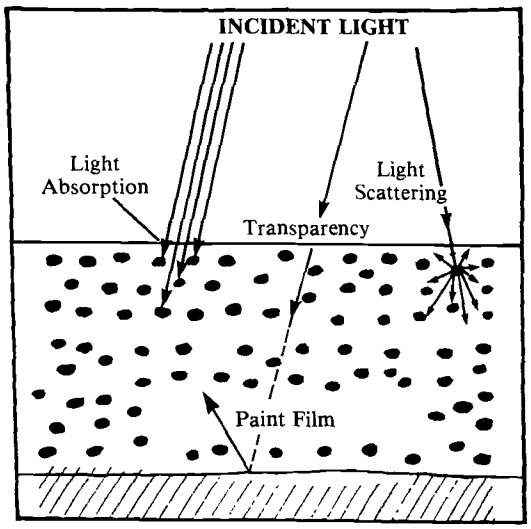

FIG. 6–OPTICAL FUNCTION OF CARBON BLACK. This diagram is an oversimplification of how carbon black functions in that primary aggregates are depicted as spherical and of roughly the same size. In reality, the aggregates are irregular in shape and occur as a distribution of sizes, which complicates the optical functioning considerably. However, the fundamental processes as shown still represent the theoretical basis for more complete treatments of the subject.

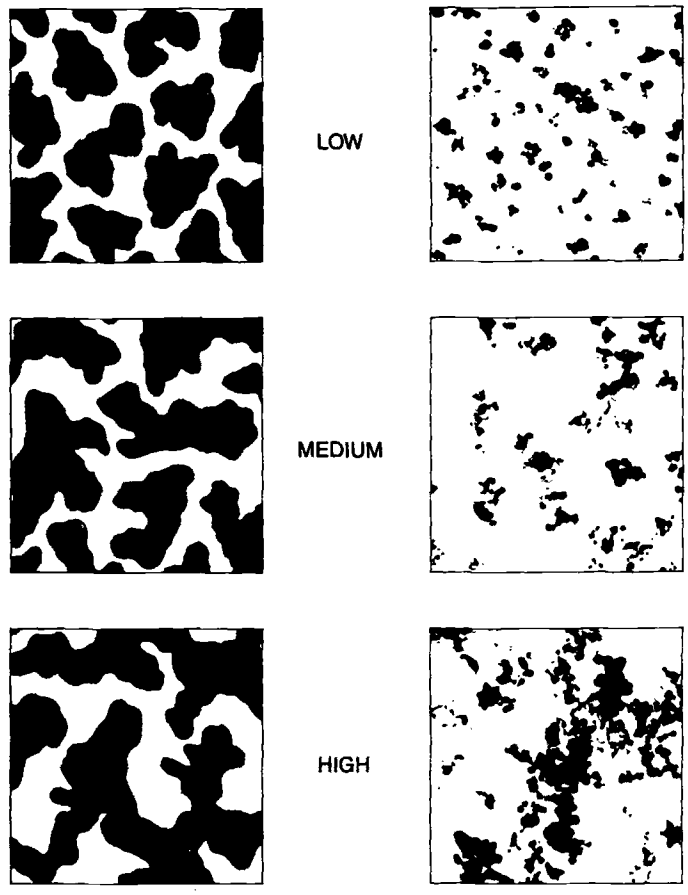

FIG. 8–Structure comparison.

Undertone

In the carbon black industry, blacks are visually characterized as having a blue or brown *undertone* or some gradation in between when dispersed in a coating system. In a black coating it is called mass tone and in a gray it is called tint tone. The phenomenon of undertone results from the fact that both scattering and absorption efficiencies of carbon black vary with wavelength [*8*]. Preferential absorption of blue light tends to make the unabsorbed light reaching the observer favor the red end of the spectrum (browner tone). The degree of preferential absorption/scattering of the blue end of the spectrum increases with decreasing aggregate size. Thus, in a gray finish, where the absorption mechanism is in

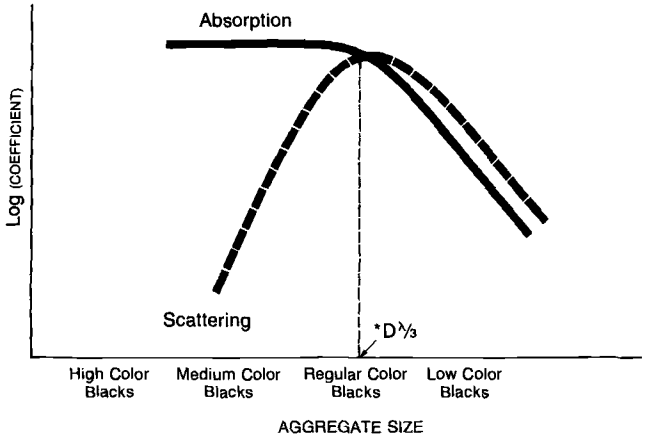

FIG. 7–CARBON BLACK OPTICS. *D λ/3 = An aggregate size equal to one third the wavelength of the incident light.

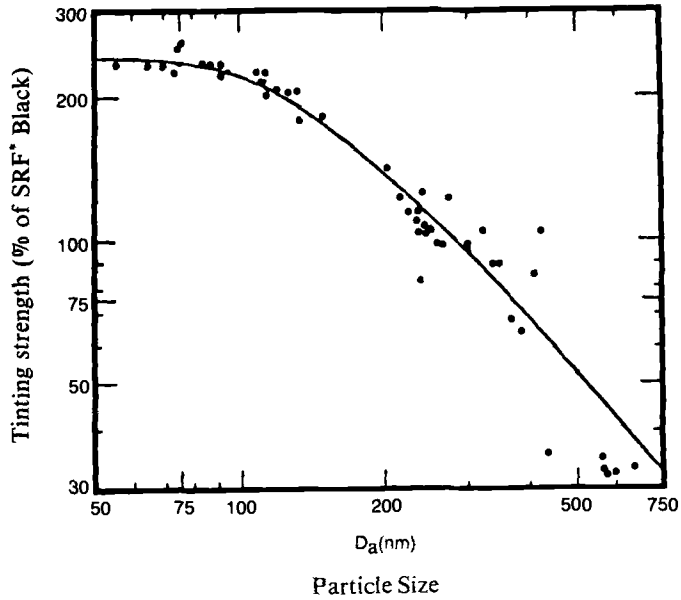

FIG. 9–Tinting strength of a range of carbon blacks.

control, the finer the aggregates the browner the tint tone. In mass tone we have the more complex situation where both preferential scattering and preferential absorption, each with a separate wavelength dependency, contribute to undertone.

Gloss

The term *gloss* is generally taken to mean the specular reflectance of a surface measured at some specific angle (for example, 60°). As with any pigment added to a transparent vehicle, the gloss of the dried film will be influenced by the loading and the properties of the carbon black. Starting with an unpigmented coating having optimal gloss in the dried film and adding a given carbon black incrementally (assuming excellent dispersions), a point will be reached where gloss begins to deteriorate until eventually the finish becomes flat. Since it is the resins in the dry film which create the smooth surface for reflection, the addition of particulate substances such as pigments or fillers in significant concentrations can only interfere with the "smoothness" of the surface.

The properties of carbon black that affect the gloss of a coating are: aggregate size, structure, and surface chemistry. Other factors being constant, the finer the aggregate size the less the effect on surface texture. The finer aggregate blacks tend to give coatings with higher gloss when properly dispersed.

Higher structure, which means more void space and therefore higher oil absorption, tends to work against gloss. This is because more vehicle is "tied up" for a given loading of black in comparing a higher structure with a low structure black. Once again we must emphasize the importance of quality of dispersion. Since higher structure blacks are somewhat easier to disperse, the effect of structure can only be properly observed in cases where optimal dispersion has been achieved.

Surface chemistry generally refers to the amount of volatile content or chemisorbed oxygen complexes on the surface (that is, hydroxylic, carboxylic, quinonic, or lactonic groups). Carbon blacks often are chemically oxidized after formation (aftertreatment) to increase volatile content. While this is usually done to improve rheological properties (for example, flow, viscosity), it normally creates improved gloss as well. The volatile content acts as a built-in dispersing agent, serving to reduce the amount of vehicle needed to completely wet the surface of the black.

The Effect of Dispersion Quality

General Principles

The influence of the key carbon black parameters on dispersibility must first be defined [9]. As the primary aggregates of carbon black become finer, dispersion becomes more difficult for two reasons: (1) higher energy needed to "wet" the higher surface areas and (2) greater attractive forces between aggregates because more particles per unit weight of carbon black means smaller interaggregate distances.

Structure plays a key role as well. Low structure blacks allow closer "packing" (higher density), which results in smaller interaggregate distances and stronger attractive forces or more difficulty in dispersion. Higher structure means more void space (lower density), which reduces interaggregate attractive forces and provides greater accessibility to vehicle penetration or greater ease of dispersion. While lower structure blacks are more difficult to disperse ultimately, they contain less occluded air (lower density) to be displaced so that they incorporate or "wet-out" more readily.

Surface chemistry can be a factor in dispersion both as volatile content or simply as adsorbed moisture. Higher volatile content, acting as a built-in dispersing agent, tends to favor easier dispersion. Adsorbed moisture, present in all carbon blacks in proportion to surface area and ambient conditions in limited amounts, has proven to be beneficial to dispersion in liquid systems.

Density and physical form of carbon black also influence dispersibility. Carbon black as produced is extremely "fluffy" and must be substantially densified (removal of occluded air by agitation), usually to over 10 lb/ft^3 for handling purposes. When the densification is done by rotary agitation in drums, either wet or dry, the result is spherical pellets, which offer ease of handling and reduced dusting. Densification packs agglomerates more closely, increasing interaggregate attraction and making dispersion more difficult. Pelletization adds the dimension of pellet hardness which must be overcome prior to actual dispersion. However, pelleted blacks "wet-out" very quickly and are thereby suitable for certain types of equipment (Table 3).

Optimal dispersion of carbon black can be defined as that condition in which all agglomerates are broken down into their constituent primary aggregates; each aggregate is separated from the others, and the surface of each is completely covered by resin. Primary aggregates are the characteristic units of carbon black and are not broken down under normal dispersion conditions. The steps involved in the dispersion process are:

1. *Incorporation (Wetting)*—This step involves the displacement of occluded air and covering the surface of agglomerates with vehicle, yielding a workable dispersion mix. Sometimes this is referred to in the coatings industry as premixing.
2. *Pellet Breakdown*—When pelleted black is used, Step 1, Incorporation, is easier since initial mixing causes little, if any, pellet fracture. Thus, at the worst, larger pellet fragments need to be "wetted" by vehicle. Pellet breakdown must then be accomplished by the application of additional energy (for example, longer mixing) after Step 1.
3. *De-Agglomeration*—This is the principal step in achieving optimal dispersion and the one that consumes most of the applied energy. Interaggregate attractive forces must be overcome to break down agglomerates into their constituent primary aggregates.

TABLE 3—Preferred form of carbon black.

	Preferred Form	
Equipment	Fluffy	Pellets
Two-roll mill		X
Three-roll mill	X	
Steel ball mill		X
Attritor	X	
Disk disperser	X	
Sand/shot mill	X	X

4. *Stabilization*—At this stage, in order to stabilize the deagglomerated aggregates, each of the aggregates must adsorb sufficient vehicle to completely deactivate its surface. This process can often be facilitated by the use of dispersing agents.

To function efficiently in an optical sense, carbon black must be optimally dispersed. The primary aggregates which characterize carbon black must be separated from one another and distributed fairly uniformly throughout the vehicle matrix to be most efficient at intercepting incident light. Choosing a grade with high surface area for high color applications, for example, must be combined with designing an effective dispersion system to ensure full color development. Mill base formulations, grade selection, physical form of carbon black (fluffy or pellets), and premixing as needed all play a part in ensuring quality dispersion. Perhaps the most important factors in mill base formulation are: (1) providing sufficient vehicle solids to accommodate the carbon black surface (Table 4) and (2) adjusting viscosity to a level suitable for the chosen dispersion equipment.

Dispersion Mechanisms

Available liquid system dispersion equipment utilizes either or both of the two main dispersion mechanisms: (1) shearing force and (2) collision of agglomerates with each other and with dispersion media particles. These mechanisms describe the manner in which energy is applied to carbon black agglomerates during the dispersion process. For example, disk disperses and three roll mills use shearing force while ball mills, sand mills, and attritors rely on collisions.

Dispersion Quality Testing

It is possible to stabilize carbon black dispersions at various levels of deagglomeration. The term *macrodispersion* is applied to very moderate levels of deagglomeration at which only the larger agglomerates are fractured. *Microdispersion*, on the other hand, refers to levels of deagglomeration approaching the ideal of single primary aggregates.

The most accurate way to measure dispersion quality is microscopically. Using X100 optical micrographs, it is possible to set up a classification system. However, it is costly and time consuming and somewhat impractical for production control. More commonly used in the coating industry is the grind gage (Hegman gage, paint club gage, etc.). These devices do not measure microdispersion. Since it is microdispersion that largely determines color performance, it is possible to have two identical mill bases, both "off-scale" on a grind gage, one of which is significantly poorer in dispersion quality. The better dispersed system would be blacker (jetter) and glossier. This leads to the most practical indirect method, that is, using color and/or gloss development, which are extremely sensitive to small variations in degree of microdispersion.

TABLE 4—Suggested vehicle solids to carbon black ratios for mill base compositions.

Type	Nitrogen Surface Area, m^2/g	Suggested Ratio, Vehicle Solids/Carbon Black
High color	230–560	3.5/1 to 4.5/1
Medium color	200–220	2.5/1 to 3.0/1
Regular color	45–140	1.5/1 to 2.0/1
Low color	25–40	1.0/1

Selecting a Grade of Carbon Black for Coloring

Black Coatings

For coloring purposes, a grade of carbon black should be selected that is as low as possible in surface area, but consistent with end use color specifications. This enables the formulator to take advantage of the greater ease of dispersion and lower cost associated with the lower surface area. The desired structure level would be high enough to give acceptable dispersibility, but not so high as to adversely affect gloss or rheology. In some cases the use of aftertreated grades will give an edge in dispersion and gloss as well as protect the rheology at higher loadings. Normally, at opacity level loadings, rheology is only a problem when more concentrated mill bases are used.

Implicit in the selection of a grade of carbon black is the choice of the fluffy or pelleted form. The choice is usually made on the basis of dispersion equipment available or on ease of incorporation or both. Listings of preferred forms for best results with each of the major pieces of equipment are helpful (Table 3). Regarding ease of incorporation, if, for example, a steel ball mill which is a very effective disperser is to be used, the edge in dispersion provided by the fluffy form is not really needed, so it is wise to consider the pelleted form which will "wet in" quickly and which creates less dust on handling.

Candidate grades must be dispersed in the specific formulation in which they are intended to be used. Keeping in mind the sensitivity of color and gloss development to dispersion quality, it is useful to evaluate jetness and gloss both at the end of the prescribed grind cycle and again after an extended cycle. This technique not only identifies which of the candidates will provide the color and gloss levels needed, but also indicates whether or not full color value from a given grade will be achieved under the prescribed dispersion conditions. The factors of carbon black cost and dispersibility must be weighed against desired color and gloss levels in making a final decision. Some commonly used oil furnace grades for the coatings industry are listed in Table 5.

Black Tinted Coatings

While selecting a black for tinting purposes involves the principles mentioned earlier under *General Natures of Carbon Black* on mass tone color, some key points need emphasis. The selection depends upon required tinting strength (see Table 5), tint tone, and relative ease of dispersion.

Tint tone (see under **Carbon Black Parameters Affecting the Optical Function** the section on *Undertone*) refers to the color undertone in tinting. If very blue undertone is needed, grades such as LCF 2 and LCF 3 are suggested. Sometimes it is necessary to sacrifice some tinting strength by going to grades with larger aggregate size in order to maximize blue tint tone (for example, going from LCF 1 to LCF 2). High-tint-strength blacks tend to give browner undertone, which is desirable in some applications.

Finally, where dispersion stability (that is, flocculation resistance) is critical, aftertreated blacks can be helpful. MFF

[a]Based on Nigrometer scale values so lower numbers indicate higher jetness.
NOTE: Above data typical of commercial grades representative of the indicated categories [*11*].

(medium flow furnace) black, for example, exhibits excellent stability and high tinting strength and is often used for tinting in poorer wetting vehicles.

Measuring Appearance Properties of Carbon Black Coatings

A black coating pigmented with carbon black at the opacity level (less than 3% by weight) will probably reflect only about 1% of the light incident upon it. This presents some unique problems in trying to make absolute instrumental measurements since the sensitivity of available instruments is simply not adequate. For this reason, it has been traditional in the carbon black industry and even among end users to depend upon visual judgements of appearance properties in many cases. While no one challenges the incredible sensitivity and versatility of the human eye, it has the drawback of not being able to quantify its observations. Nevertheless, using special techniques, it is possible to obtain quantitative measurements on all appearance properties as outlined below.

Jetness

Jetness or blackness is a function of BET surface area, i.e., inversely proportional to aggregate size (Fig. 10). Traditionally, the industry assigned nigrometer "scale" values, which are a direct function of the amount of light reflected by dispersed samples (coatings, plastics, etc.). Smaller "scale" values indicated jetter carbon blacks. However, the modern approach is to measure the spectral reflectance of a black dispersion, which is made possible by the enhanced sensitivity of current instrumentation. The spectral reflectance curves can then be converted to Hunter L, a, b; or CIE coordinates [*10*] to quantitatively measure jetness and mass tone as well.

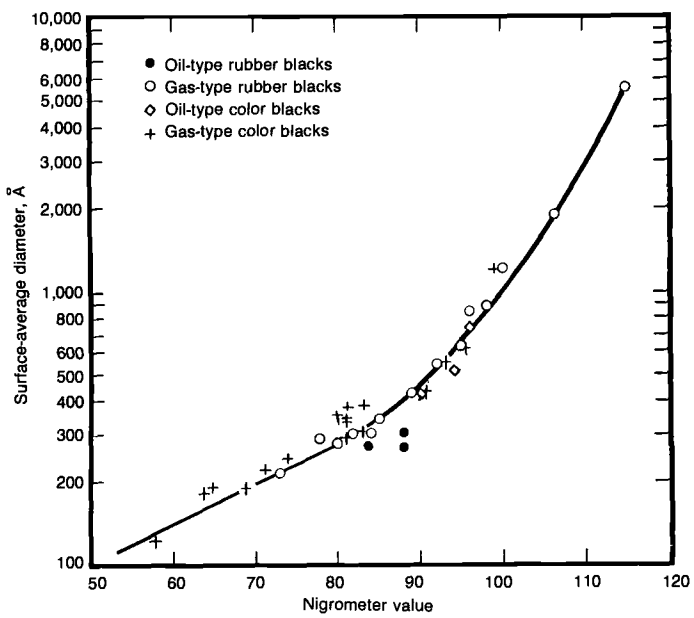

FIG. 10–Nigrometer values versus particle size for a range of carbon blacks.

Undertone

The mass tone is measured as described above in the section on jetness. This is an important tool because visual ratings of jetness are usually influenced by undertone variations among blacks being rated.

Tint tone, on the other hand, can normally be measured directly via absolute reflectance (versus a white standard) using a spectrophotometer or a colorimeter. However, common practice is to measure against a gray standard (ASTM D 3265: Test Method for Carbon Black-Tint Strength).

Tinting Strength

As illustrated in Fig. 9, tinting strength increases with decreasing particle size. The differential measurement technique, described above, is used to assign tinting strength values. The procedure, ASTM Test D 387-86, Test Method for Color and Strength of Color Pigments with a Mechanical Muller, involves dispersing carbon black together with a white pigment in a wetting oil or other suitable vehicle. The refectance of this dispersion versus a standard gray tile or gray vitreous enamel is then a measure of its tinting strength. While it was customary in the carbon black industry for many years to report tinting strength as a percent of a reference black (for example, IRB No. 4), some suppliers are now using an independent tinting strength index, allowing strength comparisons only within their own product lines.

Gloss

Clearly, this property and the manner in which it is measured is not unique for carbon black coatings. Whether the pigmentation is black or any other color, the test (for example, for 60° gloss) is the same.

SUMMARY

Individual key carbon black parameters have been viewed from the standpoint of their influence on the optical function. It is important to emphasize, however, that these parameters do not operate separately. The effect on optical functioning, and therefore on pigmentary properties, is a combined one. Each parameter when varied influences the other parameters, which are also varying. Thus the situation is dynamic and complex.

Dispersion quality and its importance in realizing the full optical potential of a given grade has also been addressed. Therefore, in the grade selection process, the physical form of carbon black as well as key parameters must be considered in light of the chosen dispersion technique.

Colored Organic Pigments

by Peter A. Lewis[1]

DEFINITION OF A PIGMENT

Before entering into any discussion relating to pigments, it is first necessary to clearly define what is meant by a pigment as opposed to a dyestuff. In many earlier texts on color, the terms "pigment" and "dyestuff" are used almost interchangeably.

A definition of a pigment has been proposed by the Dry Color Manufacturers Association (DCMA)[2] in response to a request from the Toxic Substances Interagency Testing Committee. This definition was developed specifically to enable differentiation between a dyestuff and a pigment with the intention of forever ending the confusion surrounding these two terms. As such it is worthwhile reproducing this definition in its entirety:

> "Pigments are colored, black, white or fluorescent particulate organic and inorganic solids which usually are *insoluble* in, and essentially physically and chemically *unaffected* by, the vehicle or substrate in which they are incorporated. They alter appearance by selective absorption and/or by scattering of light.
>
> Pigments are usually *dispersed* in vehicles or substrates for application, as for instance in inks, paints, plastics or other polymeric materials. Pigments *retain* a crystal or particulate structure throughout the coloration process. As a result of the physical and chemical characteristics of pigments, pigments and dyes differ in their application; when a dye is applied, it penetrates the substrate in a *soluble* form after which it may or may not become insoluble. When a pigment is used to color or opacify a substrate, the finely divided *insoluble* solid remains throughout the coloration process."

Additionally, the terms "lake" and "toner" are encountered when dealing with pigments. American terminology, as applied to pigments, defines a toner as an organic pigment that is free of inorganic extender pigments or carriers; as such, the pigment is unadulterated and exhibits maximum tinting capacity for the pigment type. A lake, conversely, is an organic colorant that has been combined with an inorganic substrate or extender such as barium sulfate (Blanc Fixe) or alumina. In European terminology toners are considered to be water-soluble acid or basic dyestuffs that are converted to insoluble pigmentary forms by appropriate precipitation with an inorganic compound. As such, Barium Lithol red (PR 49:1) and the PTMA-based Rhodamine (PV 1) are considered toners. In the coatings industry, the term "toner" may be used to refer to a secondary color that is added to alter the hue of the paint. The term "lake" now has an accepted definition as that used in America.

A most confusing European term, the use of which should be discouraged, is "pigment dyestuff," technically an oxymoron. This term is meant to refer to insoluble organic pigments devoid of salt-forming groups, for example, Benzimidalone Orange (PO 36).

INTERNATIONAL NOMENCLATURE—THE C.I. SYSTEM

In any modern publication discussing pigments of any description, it is likely that the author will make use of the coding system as published as a joint undertaking by the Society of Dyers and Colourists (SDC) in the United Kingdom and the Association of Textile Chemists and Colorists (AATCC) in the United States.

This system is known as the "Colour Index," [*1*] and as such is a recognized trademark, hence the retention of the "u" in "colour" whenever reference is made to a "Colour Index" name or number.

The Colour Index (C.I.) identifies each pigment by giving the compound a unique "Colour Index Name" and a "Colour Index Number." This description is proving to be most valuable to persons within the coatings industry responsible for assembling data on the composition of a coatings formulation for documents such as Material Safety Data Sheets or hazard data sheets. As such the identification of a pigment by mention of its C.I. name and number unequivocally identifies the chemical composition of the pigment in a manner acceptable to most government bodies. For example, DNA Orange has the Colour Index name of Pigment Orange 5 (PO 5) and the Colour Index number of 12075.

The Colour Index Name for a pigment is abbreviated as:

PB— Pigment Blue	PBk— Pigment Black
PBr— Pigment Brown	PG— Pigment Green
PM— Pigment Metal	PO— Pigment Orange
PV— Pigment Violet	PR— Pigment Red
PW— Pigment White	PY— Pigment Yellow

CLASSIFICATION OF PIGMENTS BY CHEMISTRY

Pigments used in paints and coatings may be broadly divided into opaque or hiding whites and colored toners. All the opaque whites are inorganic compounds and as such fall outside the contents of this chapter. For the sake of clarity it should be noted that such compounds include the following:

- Lithopone (co-precipitate of barium sulfate and zinc sulfide)
- Zinc oxide
- White lead (basic lead carbonate)
- Antimony oxide
- Titanium white (mixture of titanium dioxide and blanc fixe)
- Titanium dioxide (rutile form)

The colored pigments as covered in this section are all organic in nature and as such contain a characteristic grouping or arrangement of atoms known as a "chromophore," which imparts color to the molecule. In addition, the molecule is likely to feature a number of modifying groups called "auxochromes" that alter the primary hue of the pigment in a more subtle way such as shifting a red to a more yellow shade or a blue to a more red shade while still maintaining the primary hue of red or blue rather than pushing the hue over to an orange or a violet.

Perhaps the most important of the chromophores is the azo chromophore (—N=N—). The naphthol reds, monoarylide and diarylide yellows, benzimidazolones, pyrazolones, and azo condensation pigments are all examples of organic pigments that feature the azo chromophore. Of equal importance is the phthalocyanine structure based upon the compound tetrabenzotetra-azaporphin; halogenation of this compound results in a major shift in hue from a blue to a green. Pigments are also derived from heterocyclic structures such as translinear quinacridone and carbazole dioxazine violet. Finally there are pigments that result from the vat dyestuffs and miscellaneous metal complexes.

CLASSIFICATION OF PIGMENTS BY COLOR

Reds

Metallized Azo Reds

Many reds used within the coatings industry contain the azo chromophore (—N=N—) and as such are termed "azo reds."

A further subdivision is possible into acid, monoazo metallized pigments such as Manganese Red 2B (PR 48:4) and nonmetallized azo reds such as Toluidine Red (PR 3). Typically, each of the metallized type contains an anionic grouping such as sulfonic (—SO_3H) or carboxylic acid (—COOH), which will ionize and react with a metal cation such as calcium, manganese, or barium to form an insoluble metallized azo pigment.

Conversely nonmetallized azo reds do not contain an anionic group in their structure and therefore cannot complex with a metal cation.

All azo reds contain one or more azo groups by definition and are all produced by a similar reaction sequence involving diazotization and coupling. Diazotization involves reacting the primary amine portion of the molecule with nitrous acid to yield a "diazonium salt," which is then immediately "coupled" to the other half of the molecule to yield the colored pigment.

Figure 1 illustrates the structure of a series of metallized azo reds that are of considerable commercial importance and that find some, albeit limited, use within the coatings industry. Each of these structures features a molecule based on the coupling of a naphthalene ring structure to a benzenoid structure. A brief description of the more common metallized azo reds is as follows:

Lithol Reds—Barium Lithol PR 49:1, C.I. No. 15630:1; Calcium Lithol PR 49:2, C.I. No. 15630:2.

Discovered in 1899, this pigment's major use is in the printing ink industry and finds only limited application within the coatings industry at masstone levels, that is, at a level where the tinting strength of the pigment is not diluted with a white tint base, for such reds as those used on tool boxes, fire extinguishers, and the cheaper lawn mowers where the fastness properties of the pigment are acceptable.

The pigments are bright reds with high tint strengths and good dispersion characteristics; the barium salt is lighter and

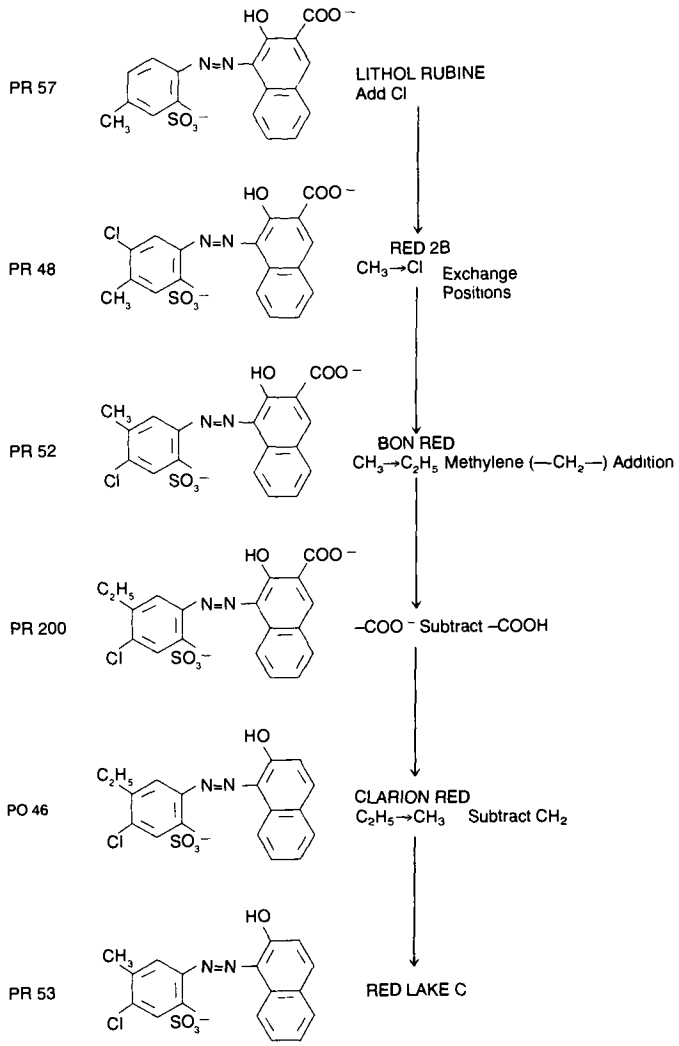

FIG. 1–Structure of metallized azo reds.

yellower in shade than the calcium salt, which may best be described as a medium red. Neither pigment can be recommended for outdoor exposure work since their exterior durability is inadequate for such situations. Additionally, they cannot be used in applications requiring pigments of high acid or alkali fastness since the Lithol Reds will hydrolyze under such conditions to give weaker, yellower shade products.

Permanent Red 2B—Barium Red 2B, PR 48:1, C.I. No. 15865:1; Calcium Red 2B, PR 48:2, C.I. No. 15865:2; Manganese Red 2B, PR 48:4, C.I. No. 15865:4.

Discovered in the 1920s, the Red 2B pigments are azo reds prepared from coupling diazotized 1-amino-3-chloro-4-methyl benzene sulfonic acid (2B acid) onto 3-hydroxy-2-naphthoic acid (BON).

A major outlet for the barium and calcium pigments is in baked industrial enamels, which do not require any appreciable outdoor fastness properties. Use in alkaline systems is again severely restricted due to the tendency of these metal salts to hydrolyze in highly alkaline environments. The barium salt is characterized by a clean, yellow hue as compared to the bluer calcium salt. The barium salt has a poorer lightfastness and weaker tinting strength but a slightly better bake stability as compared to the calcium salt.

The term "lightfastness," used throughout this section, refers to the pigments ability to withstand exposure to light, both direct and indirect, natural and artificial, without suffering any visible change in appearance. The most damaging component of light appears to lie in the ultraviolet region of the spectrum and, as such, a rapid evaluation of a pigment's likely reaction to long-term exposure to light can be assessed using exposure equipment that maximizes exposure to UV light. Many high-performance pigments are exposed under application conditions in specially maintained areas in Florida to more fully evaluate their fastness to outdoor exposure and weatherability.

The Manganese Red 2B has sufficiently improved lightfastness to allow its use in implement finishes and aerosol spray cans for touch-up paints. This salt is bluer, dirtier, and less intense as compared to the calcium salt. Extension of the Manganese pigment with any pigment such as titanium dioxide or Molybdate Orange (PR 104) to an amount greater than 15% is not recommended since its fastness properties will suffer.

Lithol Rubine Red—Calcium Lithol Rubine, PR 57:1, C.I. No. 15850:1.

Made by coupling 3-hydroxy-2-naphthoic acid (BON) onto diazotized 2-amino-5-methyl benzene sulfonic acid (4B acid), this blue shade red was discovered in 1903 and has found widespread use in the printing ink industry ever since as the process "magenta" of the four color printing process.

A clean, blue shade red with high tint strength, its major application in the coatings industry is for interior applications calling for an inexpensive red with both good solvent and heat resistance. Again the pigment must be used at near masstone levels to maximize its fastness properties.

BON Reds—Calcium BON Red, PR 52:1, C.I. No. 15860:1; Manganese BON Red, PR 52:2, C.I. No. 15860:2.

Manufactured by coupling diazotized 1-amino-4-chloro-3-methyl benzene sulfonic acid onto 3-hydroxy-2-naphthoic acid (BON), these reds first were commercialized in 1910. Characterized by outstanding cleanliness, brightness, and color purity, the manganese salt offers a very blue shade with improved lightfastness as compared to the calcium salt. As such, the manganese salt is suitable for outdoor applications and, as with the Manganese Red 2B, can be used in blends with Molybdate Orange (PR 104) to give bright, economical reds.

BON Maroon—PR 63:1, C.I. No. 15880:1.

Illustrated in Fig. 2, BON Maroon was first synthesized in 1906 by Ernst Gulbransson of Farbwerken Meister, Lucius and Bruning. The manganese salt is the only one that finds commercial significance rather than the calcium or barium variation. Its lightfastness is such that the pigment can be used at masstone levels for implement and bicycle finishes. Over 40 years ago, when specifications were not as demanding, BON Maroon actually found application in automotive finishes.

Non-Metallized Azo Reds

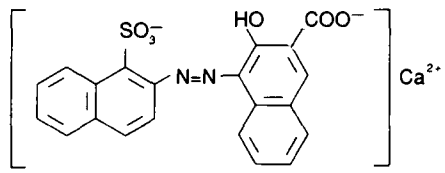
As implied by their classification, the nonmetallized azo reds do not contain a precipitating metal cation and as such offer increased stability to hydrolysis in highly acidic or alkaline environments as compared to the metallized azo reds previously covered.

Toluidine Red—PR 3, C.I. No. 12120.

This pigment, shown in Fig. 3, first synthesized in 1905, is chemically the reaction product from coupling the diazonium salt of 2-nitro-4-toluidine (MNPT) onto 2-naphthol (beta naphthol).

Various shades of Toluidine Red are available commercially described as "extra light, light, medium, dark and extra dark" as are grades offering "haze resistance" and being "easy dispersing" (ED).

Almost the entire U.S. production of Toluidine Red, an amount in excess of 0.75 million kilos, is consumed by the coatings industry. The pigment provides a bright, economical red of acceptable lightfastness when used in full shade coupled with a high degree of color intensity and good hiding power. However, the pigment is not fast to white overstriping since it will bleed through, turning the white to pink, and



2-naphthylamine-1-sulfonic acid ——→ 3-hydroxy-2-naphthoic acid (BON)

FIG. 2–Structure of BON Maroon, PR 63:1.

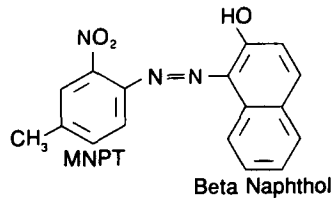


FIG. 3–Structure of Toluidine Red, PR 3.

shows a marked tendency to bleed in high Kauri-Butanol (KB) solvents.

Toluidine Red is used at masstone levels, that is, in full shade without the addition of opaque extenders such as titanium dioxide or zinc oxide, in such coatings as farm implements, lawn and garden equipment, and bulletin paints where a bright, economical red of moderate lightfastness is required to fill the user specification. Because of the pigment's poor durability in tint shades, that is as a reduction with white, it is rarely used at reduced levels.

Para Reds—Para Red, PR 1, C.I. No. 12070; Chlorinated Para Red, PR 4, C.I. No. 12085; Parachlor Red, PR 6, C.I. No. 12090.

Shown in Fig. 4, each of these three pigments is based on the coupling of a primary amine to beta naphthol. The position of the -chloro or -nitro auxochromes on the molecule controls the shade of the pigment. In fact Chlorinated Para Red differs from Parachlor Red only in the position of the -nitro and -chloro groups on the benzene ring. As such these pigments are isomers.

Use of these pigments in the coatings industry has declined rapidly due to the ever increasing and exacting demands placed upon colored finishes by the industry. All of these pigments will bleed in solvents typically used in the coatings industry and as such cannot be used in any finish that requires overstriping.

As a class of insoluble azo reds, they are characterized by intense shades of red through to a scarlet. Their good alkali resistance, lightfastness, and durability when considered as a function of their cost recommends them for use in latex paints and outdoor signs. At temperatures above 250°F (121°C), the pigments will sublime. Lightfastness of tints is significantly inferior to that of the pigments at full shade.

Naphthol Reds—Naphthol Reds are chemically defined as monoazos of 2-hydroxy naphthoic acid N-arylamides without anionic salt forming groups. Their individual properties are dependent upon the specific composition of the pigment in addition to the conditioning steps used in their manufacture. As a class they are a group of pigments that exhibit good tinctorial properties combined with moderate fastness to heat, light, and solvents. The Naphthols are extremely acid, alkali, and soap resistant pigments, properties which lead to their use in masonry paints and latex emulsions.

Naphthol Reds may be described as "medium performance" reds since they exhibit properties that fall somewhere between the Toluidine Reds and Quinacridones, with a cost that corresponds accordingly. Those Naphthol Reds of commercial significance may be briefly covered as:

Pigment Red 7, C.I. No. 12420. Used in architectural paints and some baking enamels. Offering acceptable lightfastness, even in tints, this pigment suffers from poor durability in exterior applications.

Pigment Red 22, C.I. No. 12315. A light, yellow shade Naphthol used in air drying alkyds and aqueous systems that can be satisfied with this pigments marginal lightfastness.

Pigment Red 112, C.I. No. 12370. A newer Naphthol Red that possesses a very clean, yellow hue and that finds use in both industrial and architectural coatings. The tendency of the pigment to bloom at high concentrations and its poor

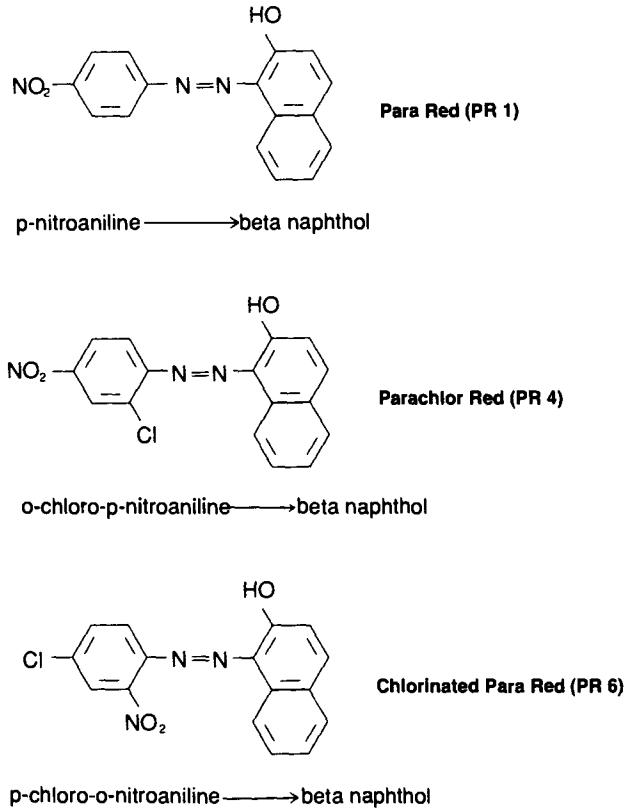

FIG. 4–Structure of the para reds.

overstriping fastness have limited its more widespread use. Lightfastness at both tint and full shade is rated good.

Pigment Orange 38, C.I. No. 12367. A very yellow shade, bright red with good solvent fastness. Can be used in baking enamels at high concentrations without showing any tendency to bloom.

Pigment Red 5, C.I. No. 12490. Showing only marginal fastness to heat and solvents this pigment, nevertheless, finds application in implement coatings. The opaque grade of this pigment can be combined with iron oxide to give an economical red with high hiding.

Pigment Red 146, C.I. No. 12485. A very blue shade red that finds its major use in interior architectural applications. Its poor exterior durability makes the pigment unsuitable for outdoor finishes.

Pigment Red 170, C.I. No. 12475. Increasingly important as a medium performance, moderately priced red, this pigment is available as both a transparent and an opacified grade. Manufacturing techniques are used to produce the pigment in two crystal phases, each exhibiting a unique hue. The opaque grade finds use in farm tractor and implement finishes. Its use with iron oxides allows a practical approach to formulating reds with acceptable lightfastness, hiding, and economics.

Pigment Red 187, C.I. No. 12486. A transparent pigment with excellent heat fastness, moderate durability, and good bleed resistance. Its uses extend to bicycle coatings, coil, and, powder coatings.

Pigment Red 188, C.I. No. 12467. A yellow, clean shade red with acceptable durability at all depths of shade. It is fast to

FIG. 5–Generic structure and key to the naphthol reds.

overstriping at temperatures below 160°C and therefore finds use in the higher quality industrial finishes. Figure 5 illustrates the generic structure of the naphthol molecule and gives the chemistry of several of the types discussed above.

High-Performance Reds

These types of pigments may be broadly defined as products that will meet the exacting demands of the automotive industry with respect particularly to the outdoor exposure requirements demanded by exposure in Florida and Arizona for as little as two and as long as five years.

The high-performance reds considered fall into four basic classes: quinacridone reds and violets, vat dyestuff based reds such as perylenes, benzimidazolone reds, and disazo condensation reds.

Quinacridone Reds—These are heterocyclic in nature since their structure comprises a fused ring in which the ring atoms are dissimilar, being a combination of carbon and nitrogen rather than only carbon as we have seen in the previous pigments discussed, as shown in Fig. 6. Addition of differing auxochromic groups such as methyl (—CH_3) and chlorine (—Cl) gives Pigment Red 122 and Pigment Red 202, respectively, both described as magentas.

The theory behind the superior durability of pigments with the quinacridone structure is that considerable hydrogen bonding occurs between molecules through the carbonyl (=C=O) and imino (=N—H) ring atoms.

As a group of pigments the quinacridones find their primary uses in automotive, industrial, and exterior finishes. A minor use is in the preparation of quality furniture stains and finishes. The pigments combine excellent tinctorial properties with outstanding durability, solvent fastness, lightfastness, heat fastness, and chemical resistance. Table 1 lists those shades currently commercially available.

Vat Reds—Vat Red pigments based upon anthraquinone include such structures as Anthraquinone Red (PR 177), Perinone Red (PR 194), Brominated Pyranthrone Red (PR 216), and Pyranthrone Red (PR 226) as shown in Fig. 7.

The term "vat pigments" originates from the fact that this class of pigments is related to the vat dyestuffs used originally

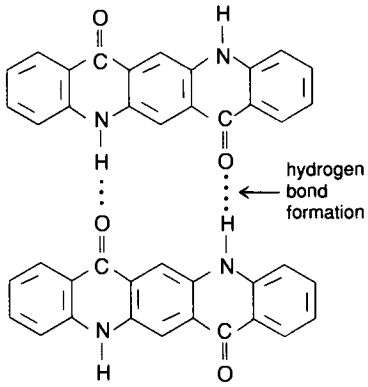

FIG. 6–Trans linear quinacridone showing proposed hydrogen bonding mechanism.

in the dyeing of cotton. Only their high cost limits the more widespread use of these pigments throughout the coatings industry.

Anthraquinone Red, PR 177, C.I. No. 65300. A medium shade red with excellent all round fastness properties. Again finds major use in the automotive industry for the production of clean, bright red coatings.

Brominated Pyranthrone Red, PR 216, C.I. No. 59710. A yellow shade red that also can be classed as an automotive grade pigment because of its excellent fastness properties. Neither light nor dark shades will suffer on prolonged expo-

TABLE 1—Types of quinacridone.

Colour Index Name	Hue	Comments

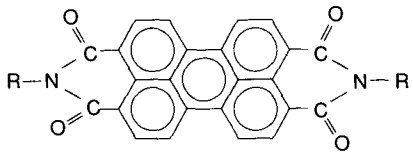
sure in Florida. Transparency is generally not adequate for this pigment to be used in metallic or mica finishes.

Perylene Reds—These pigments provide pure, transparent shades and novel styling effects when used in metallic aluminum and mica finishes. The perylenes offer improved flow characteristics when used in high-solids formulations. Perylenes may also be described as vat pigments and in fact are the only class of Vat pigments that were developed specifically for the pigment marketplace rather than as dyestuffs.

Almost all of the perylenes have a structure as shown by the generic formula given as Fig. 8, that is, they are based upon



R = $-C_6H_3OC_2H_5$	PR 123	Vermillion
R = $-C_6H_3(CH_3)_2$	PR 149	Scarlet
R = $-CH_3$	PR 179	Maroon

R = $-H$	PBr 26	Bordeaux
R = $-C_6H_5Cl$	PR 189	Yellow Shade Red
R = 	PR 178	Red

FIG. 8–Structure of typical perylene.

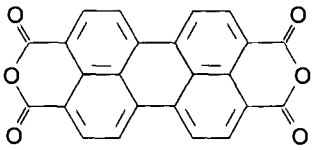

FIG. 9–Structure of Pigment Red 224.

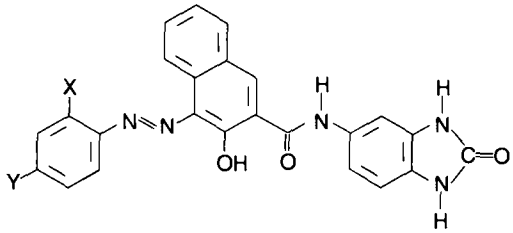
N,N′-substituted perylene-3,4,9,10-tetracarboxylic di-imide. An exception of note is Pigment Red 224, Fig. 9, which is derived from the perylene tetracarboxylic dianhydride.

Benzimidazolone Based Reds—This subdivision of reds includes such pigments as Pigment Reds 171, 175, 176, 185, and 208. Benzimidazolone-based reds are azo reds that contain the benzimidazolone structure as part of their makeup. The reds all possess the generic structure based upon a central naphthol molecule as illustrated in Fig. 10. Such structures exhibit a significantly high molecular weight that greatly influences the pigments fastness properties.

Benzimidazolone reds are used primarily in the coloring of plastics because of their outstanding heat stability, although some uses are found within the coatings marketplace. They show excellent fastness to light at all depths of shade, good weatherability, and excellent fastness to overspraying at elevated temperatures. They all find use in coil coatings, powder coatings, camouflage paints, automotive refinish, and farm



Colour Index Name	X	Y

PR 208	$COOC_4H_9$	H

FIG. 10–Structure of the benzimidazolone reds.

implements where cheaper, less stable pigments would be inadequate.

Pigment Red 175 is a highly transparent red with good lightfastness that finds application in automotive base coat/clear coat systems since it is not sufficiently durable for top coat systems. Pigment Red 171 is also a transparent pigment but with a maroon shade that finds use in industrial systems. Pigment Reds 176, 185, and 208 find considerable use in quality printing ink applications but currently no use in the coatings industry.

Disazo Condensation Reds—These types of pigments have been available commercially in Europe since 1957 and in the United States since 1960. Their outstanding fastness properties have resulted in their use in high-quality industrial finishes.

Figure 11 illustrates three typical structures of the disazo condensation reds. The figure merely serves to show the size and variation of the structures of pigments within this class; no Colour Index names are available at present.

Pigment Red 242, Fig. 12, is a bright yellow shade disazo condensation pigment with excellent fastness properties that is finding increased use in high-quality industrial finishes and as a lead replacement pigment for those high-quality coatings that now must be formulated lead free.

Pigment Red 214, Fig. 13, is another example of a disazo condensation red with properties similar to Pigment Red 242.

Thioindigoid Reds—The thioindigoid chromophore serves as a nucleus for a wide range of red to violet pigments including such as Pigment Reds 86, 87, 88, 181, and 198, Fig. 14. These pigments are all noted for their brightness of shade and generally good fastness properties, resulting in their use in the coatings industry with Pigment Red 88 being the largest volume used followed by Pigment Red 198. Pigment Red 88 is widely used in automotive finishes, but the bleed resistance of Pigment Red 198 limits its use. The commercially availability of these pigments has suffered in recent years with many products having been withdrawn from the marketplace by the almost exclusive supplier, Bayer.

Novel High-Performance Reds

In recent years several novel organic reds have been commercialized and targeted directly at the requirements of the coatings marketplace.

Pigment Red 257, Fig. 15, is a nickel complex with a red-violet masstone and a magenta undertone that exhibits fastness properties similar to that of quinacridone. Pigment Red 257 is particularly useful in the formulation of high-quality industrial and automotive coatings. The pigment also exhibits excellent rheological properties in highly pigmented systems.

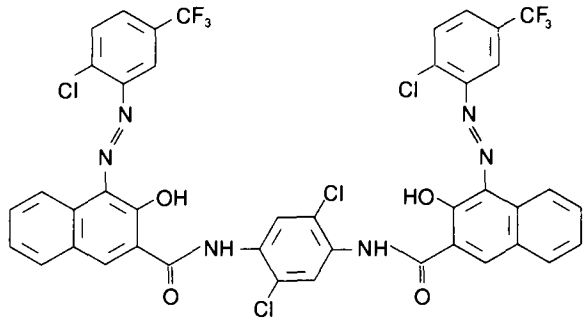

FIG. 12–Structure of Pigment Red 242.

FIG. 14–Structure and key thioindigoid reds.

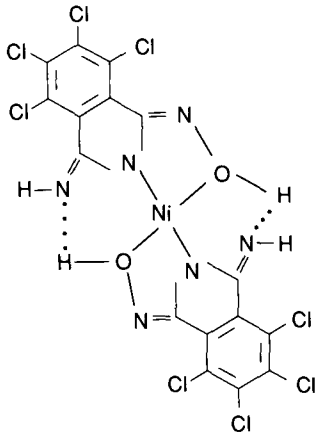

FIG. 15–Structure of Pigment Red 257.

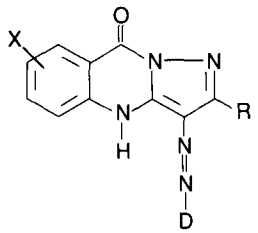

FIG. 16–Generic structure of pyrazoloquinazolone (basis of Pigment Red 251 and 252).

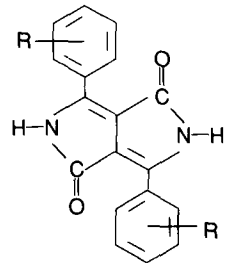

FIG. 17–Generic structure of pyrrolo-pyrrole.

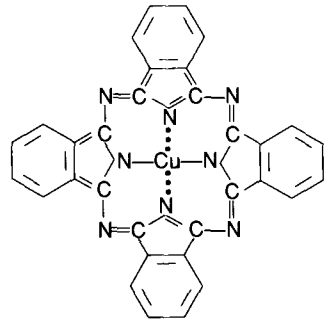

FIG. 18–Copper phthalocyanine, PB 15.

Pigment Reds 251 and 252 are both based on the pyrazoloquinazolone structure as shown in Fig. 16. These pigments are monoazo compounds derived from pyrazolo(5,1-b)quinazolones as the coupling component and substituted anilines or polycyclic amines as diazo component. Each pigment exhibits excellent brightness of hue at full shades, good gloss retention, and high scattering power combined with good light and weather fastness. As such, they are finding increased use in industrial and automotive coatings.

Recently a series of novel reds based upon the pyrrolo-pyrrole structure, Fig. 17, have been marketed into the automotive coatings industry. The first pigment marketed is a bright red with excellent color intensity that will find use alongside quinacridones and perylenes in automotive formulations.

Blues

Copper Phthalocyanine Blue

The most important and most widely used blue throughout all applications of the coatings consuming industry is copper phthalocyanine blue, Pigment Blue 15, Fig. 18.

First described in 1928 by chemists working for the Scottish Dye Works (now part of I.C.I.), this pigment has steadily increased in importance to become a product with worldwide significance. The only metal derivative of significant commercial use is that of copper, derivatives of other metals having been shown by research to have less desirable shade or fastness characteristics. Metal-free phthalocyanine, Pigment Blue 16, once found an outlet as a green shade blue, but its inferior heat stability and its poorer chemical fastness, coupled with a price almost three times that of the copper containing salt, has resulted in a rapid decline in its consumption for all but very special applications.

Copper phthalocyanine is commercially available in two crystal forms, the alpha and the beta form. The alpha crystal is described as Pigment Blue 15, 15:1 and 15:2 and is a clean, bright red shade blue. The beta crystal is described as Pigment Blue 15:3 and 15:4 and is a clean green or peacock shade.

The beta form is the most stable crystal form and readily resists recrystallization. The alpha form, conversely, is the least stable or meta form, which readily converts to the more stable, green shade, beta crystal. As such the crystal requires special proprietary treatments to produce a red shade product that is stable to both crystallization and flocculation.

Copper phthalocyanine gives excellent performance in most coatings applications but there is considerable variation between both the chemical and crystal types available. The coatings formulator should bear this in mind when choosing a grade for a specific application. Use of any of the unstabilized grades in strong solvents or in systems that experience heat during dispersion or application will result in a shift in shade to the greener side and a loss of strength as recrystallization takes place within the unstabilized crystal.

Pigment Blue 15 (C.I. No. 74160) is a red shade, alpha crystal. It is the least stable of the family and as such is referred to as crystallizing red shade (CRS) blue.

Pigment Blue 15:1 is a modified alpha crystal also having a red shade but with modifications to stabilize the structure against phase transformation to the beta crystal. Most commonly the molecule is chlorinated to the extent of one molecule of chlorine per molecule of copper phthalocyanine to give "monochlor" blue (C.I. No. 74250).

Pigment Blue 15:2, described as "non-crystallizing non-flocculating" (NCNF), red shade blue, is an alpha crystal that is stabilized against both flocculation and recrystallization using additive technology. Such additives are introduced during the manufacturing or blending operation and are essentially derivatives of copper phthalocyanine that confer stability by a steric hindrance mechanism.

Pigment Blue 15:3 represents the most stable crystal, green shade, beta copper phthalocyanine. Pigment Blue 15:4 is descriptive of a beta blue that has been modified with phthalocyanine-based derivatives to confer flocculation resistance to the crystal such that it can safely be used in strong solvent systems.

Other specialized, more expensive crystal modifications also exist such as P.B. 15:5, a red shade, gamma crystal and P.B. 15:6, a very red shade, epsilon crystal.

Copper phthalocyanine is a pigment that offers brightness, cleanliness, strength, and economy with all round excellent fastness properties. The only drawback to this pigment is its tendency to change to a coarse, crystalline nonpigmentary form when used in strong solvent systems if the crystal has not been adequately stabilized and has a tendency to flocculate from white pigments such as titanium dioxide when used to tint such paint and lacquer systems. Another negative is the fact that copper phthalocyanine blues exhibit the phenomenon of bronzing when applied at masstone levels, deep tints, and in metallic systems.

Miscellaneous Blues

Indanthrone Blue—Pigment Blue 60, C.I. Number 69800.

Belonging to the class of pigments described as "vat pigments," indanthrone blue is a very red shade, nonbronzing, flocculation-resistant pigment with outstanding fastness properties. This pigment is used in paint systems requiring only small amounts of an intense red shade blue as a shading pigment at low levels where the expense of using indanthrone blue is justified.

Carbazole Violet—Pigment Violet 23, C.I. Number 51319.

A complex polynuclear or heterocyclic, intense red shade blue pigment that possesses excellent fastness properties. Only the pigment's relatively high cost and hard nature limit its more widespread use. The pigment is used at very low levels to produce "brighter whites" by imparting a bluer hue to the undertone of the white.

Yellows

Monoarylide Yellows

Azo pigments whose manufacture is based upon the diazotization and coupling sequence as mentioned when dealing with azo reds. The structures of the major monoarylide yellows are represented in Fig. 19.

Hansa Yellow G—Pigment Yellow 1, C.I. Number 11680.

A bright yellow pigment, made by coupling diazotized 2-nitro-4-methyl aniline onto acetoacetanilide, that has a major use in trade sales, emulsion, and masonry paints. Its major disadvantages are its poor bleed resistance in most popular solvents, poor lightfastness in tint shades, and very inferior bake resistance due to its tendency to sublime.

Hansa Yellow 10G—Pigment Yellow 3, C.I. Number 11710.

A very green shade yellow made by coupling the diazo of 4-chloro-3-nitro aniline onto 2-chloro acetanilide. Greener in shade than Pigment Yellow 1, this pigment is used in the same types of applications and suffers from the same defi-

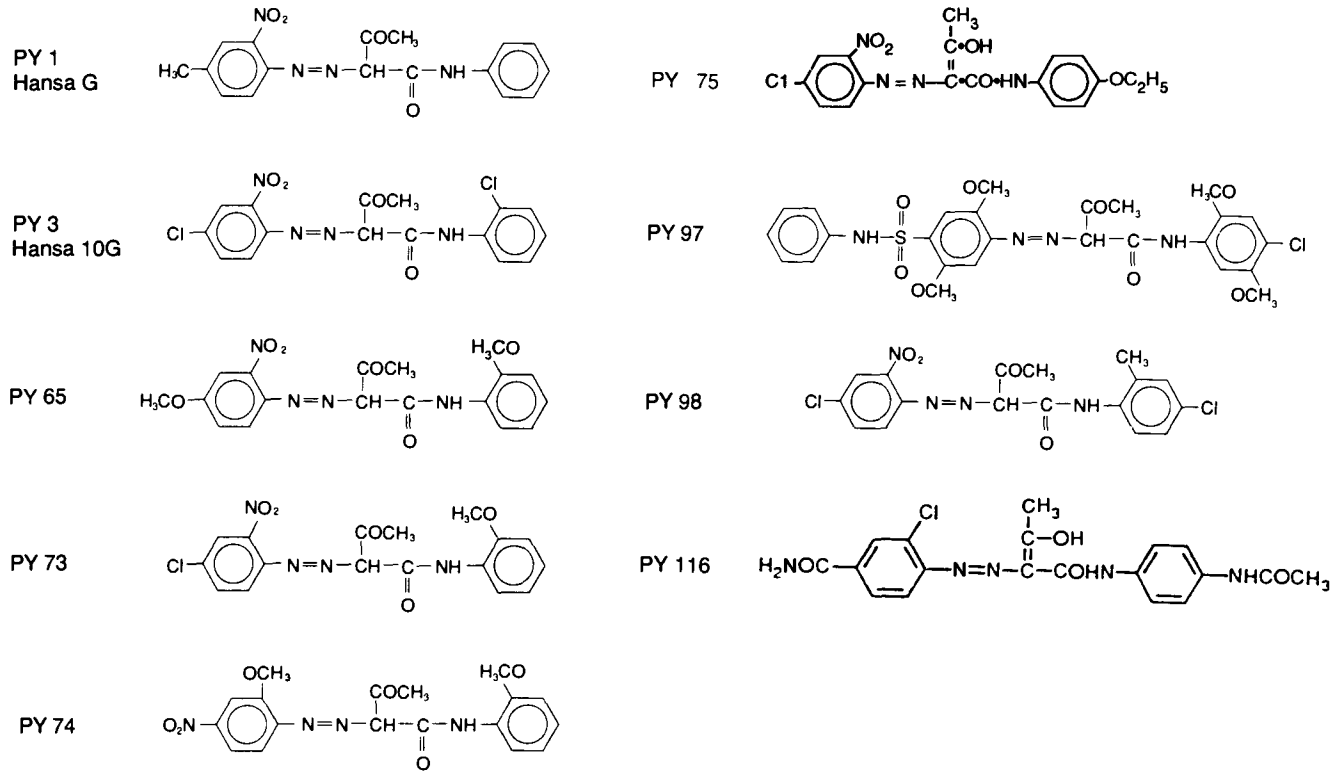

FIG. 19–Structures of the major monoarylide yellows.

ciencies as Pigment Yellow 1 with the exception that Pigment Yellow 3 is suitable for use in exterior applications at high tint levels.

Miscellaneous Monoarylide Yellows—Pigment Yellow 65, C.I. Number 11740: A newer monoarylide pigment produced by coupling diazo 2-nitro-methoxy aniline onto 2-acetacetanisidine. Offering a redder shade than the previous two yellows discussed. Pigment Yellow 65 is used in trade sales, latex, and masonry paints. A more recent application is for road traffic marking paints that are specified as being lead free. The bleed resistance and baking stability are little improved over Pigment Yellows 1 and 3.

Pigment Yellow 73, C.I. Number 11738: Prepared by coupling diazo 3-chlor-2-nitro aniline onto 2-acetoacetanisidine, this is a pigment with a shade close to that of Pigment Yellow 1 that finds use in similar applications. Not considered durable enough for exterior applications, Pigment Yellow 73 nevertheless plays an important role in interior, intermix systems due to its stability against recrystallization in the presence of glycols and wetting agents used in latex systems.

Pigment Yellow 74, C.I. Number 11741: A product from the coupling of diazo 4-nitro-2-anisidine onto 2-acetoacetanisidide which offers the user a pigment suitable for outdoor applications that is considerably stronger and somewhat greener than Pigment Yellow 1. Major outlets, as with all the monoarylide yellows, are in latex, trade sales, and masonry paints. Additionally a specially opacified grade is available that is optimized for its exterior durability although of lower tint strength than the normal more transparent grade.

Pigment Yellow 73 and the opaque grades of Pigment Yellow 74 show the least tendency to crystallize in organic solvent containing systems.

Pigment Yellow 75, C.I. Number 11770: A pigment produced by the coupling of 4-chloro-2-nitroaniline onto acetoacetophenetidide. A red shade yellow that has only recently found considerable application in the coatings industry as a replacement for lead containing medium chrome yellow as used in road traffic marking paints. One of the few diarylide yellows that has been found acceptable from the point of view of economy and durability, being able to withstand nine months exposure on a 100 000 vehicle a day highway. A point worthy of note is that this pigment appears to be inherently "easy dispersing" since the economics of the traffic paint industry demand that any pigment used to replace lead chromes must be dispersed into water or solvent systems with little more than a "Cowles" type disperser.

Pigment Yellow 97, C.I. Number 11767: A yellow derived from the coupling of diazo 4-amino-2,5-dimethoxybenzene sulphoanilide to 4-chloro-2,5-dimethoxy acetoacetanilide. Surpassing the Hansa yellows in solvent bleed and lightfastness, especially in reduced shades, this newer yellow is finding use in high-quality decorating paints.

Pigment Yellow 98, C.I. Number 11727: Similar in shade to Pigment Yellow 3, but considerably stronger and more heat stable, this pigment has only met with limited commercial success in trade sales, masonry and decorative paints. Manufacture by coupling diazo 4-chloro-2-nitro aniline onto 4-chloro-2-methyl acetoacetanilide.

Pigment Yellow 116, C.I. Number 11790: A product from the coupling of diazo 2-chloro-5-carbamoyl aniline onto 4-acetylamino acetoacetanilide, this pigment is similar in shade to light chrome yellow (PY 34) and shows improved light, heat, and solvent fastness as compared to the other monoarylide yellows. As may be expected from its shade, this pigments major use is in lead-free coatings.

Diarylide Yellows

The structures of this commercially important range of organic yellows are shown in Fig. 20. This figure clearly shows the similarity between each of these pigments, which are principally a backbone structure centered on 3,3′-dichlorobenzidine with modifications to the shade and properties by variation of the coupling component used in the diazotization reaction. Table 2 gives a summary of the properties of the major diarylide yellow pigments of commercial significance.

Each of the diarylide yellows offers low-cost, reasonable heat stability, and moderate chemical resistance. The major worldwide market for this class of yellows is the printing ink industry. These yellows are approximately twice as strong as the monoarylide yellows dealt with previously; furthermore, they offer improved bleed resistance and heat fastness. Nevertheless, none of the diarylide yellows have durability properties that would allow for their use in exterior situations and as such should never be considered for an outdoor paint application.

Minor applications in the area of toy enamels and pencil coatings are found for the diarylide yellows, especially if a lead-free formulation is specified.

A range of opacified diarylide yellows is available, having undergone an after treatment that has reduced their surface area and consequently given increased opacity that has resulted in these specific types exhibiting improved fastness properties when compared against their nonopacified counter parts.

Benzimidazolone Yellows

Illustrated in Fig. 21, these yellows take their name from the fact that each features the 5-acetoacetyl-aminobenzimidazolone molecule within its structure. Additionally each is an azo pigment with an acetoacetylarylamide nucleus.

The exceptional fastness to heat, light, and overstriping is attributed directly to the presence of the benzimidazolone group within the pigments structure, first described in 1964 and offered to the marketplace in 1969.

Used initially for the coloring of plastics, these pigments are now finding increased use in the coatings industry where their excellent fastness properties are demanded. Table 3 gives a summary of the properties of this class of pigments.

Heterocyclic Yellows

All these yellow pigments contain a heterocyclic molecule within their structure as shown by the examples presented in Fig. 22. In spite of their apparent complexity, these new high-performance yellows continue to be introduced to satisfy the exacting demands of the coatings industry. Pigments such as Isoindoline Yellow (PY 139) and Quinophthalone Yellow (PY 138) are typical examples of such complex, novel chromophores introduced as recently as 1979 and 1974, respectively.

All of these pigments find application in high-quality coatings where the end use can justify the price of these high-performance products. Table 4 summarizes the properties of

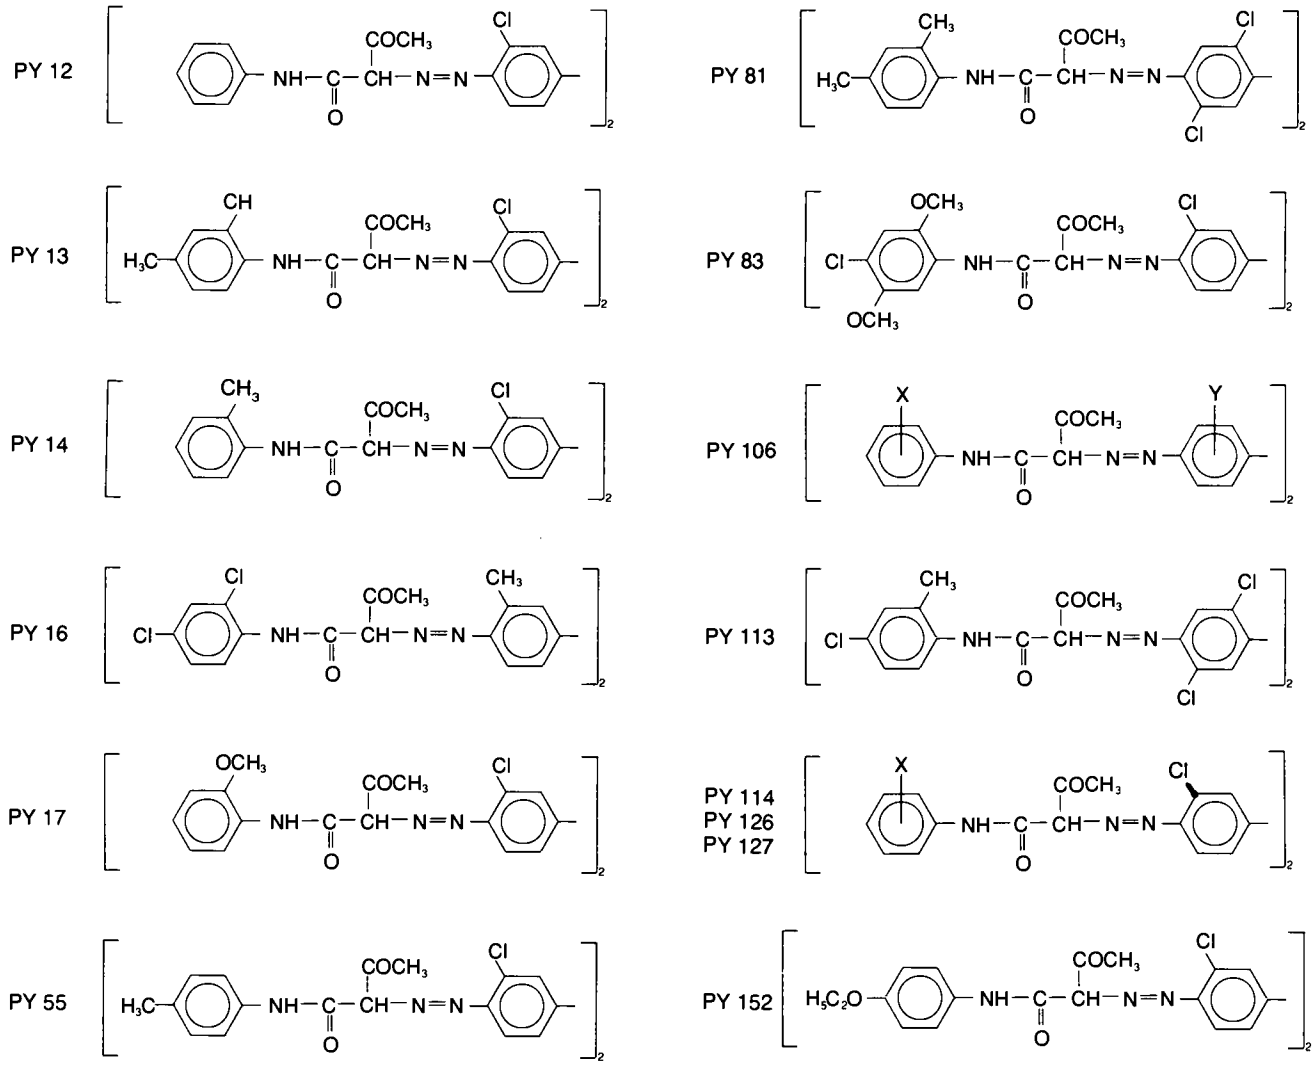

FIG. 20–Structures of the major diarylide yellows.

the heterocyclic yellows currently available that find some use within the coatings industry.

Oranges

Table 5 lists those orange pigments that have significance in todays marketplace.

Azo-Based Oranges

These oranges show considerable variation in structure as can be seen from Fig. 23; all, however, have the azo chromophore (—N=N—) featured within the molecule. The benzimidazolone oranges all feature the azo chromophore in addition to all being produced using 5-acetoacetylaminobenzimidazolone as the coupling agent.

Orthonitroniline Orange—Pigment Orange 2, C.I. Number 12060.

Prepared by the classical diazotization and coupling technique used for all azo pigments, this pigment is the product of coupling diazo orthonitro aniline onto beta naphthol. Its major outlet is in printing inks, and its use is not recommended in coatings due to the pigments poor solvent fastness and lightfastness.

Dinitroaniline Orange—Pigment Orange 5, C.I. Number 12075.

Produced by coupling diazo dinitroaniline onto beta naphthol, this pigment offers good lightfastness in full tone and moderate solvent fastness. As such, Pigment Orange 5 finds outlets in latex paints and air dry architectural and industrial finishes. Its poor baking stability rules out its use in high bake enamels.

Pyrazolone Orange—Pigment Orange 13, C.I. Number 21110.

Synthesized by coupling tetrazotized 3,3′-dichlorobenzidine onto 3-methyl-1-phenyl-pyrazol-5-one, the pigment is a bright, clean yellow shade product that may be used for interior coatings, particularly as a replacement for lead based orange pigments.

Dianisidine Orange—Pigment Orange 16, C.I. Number 21160.

A diarylide orange produced by coupling tetrazotized 3,3′-dimethoxybenzidine onto acetoacetanilide that finds an outlet in baking enamels and interior coatings at full shade.

TABLE 2—Properties of major diarylide yellows.

Colour Index Name	Common Name	Properties
PY 12	AAA Yellow	Poor lightfastness. Poor bleed resistance. Major use in printing inks
PY 13	MX Yellow	Redder shade than PY 12. Improved heat stability and solvent fastness. Major use in printing inks
PY 14	OT Yellow	Green shade. Some use in interior finishes. Poor tint lightfastness
PY 16	Yellow NCG	Bright green shade. Improved heat and solvent fastness. Used in full shade for coatings
PY 17	OA Yellow	Green shade. Some use in interior finishes. Poor lightfastness
PY 55	PT Yellow	Red shade. Some use in interior finishes. Poor lightfastness. Isomer of PY 14
PY 81	Yellow H10G	Bright green shade. Same shade but much stronger than PY 3
PY 83	Yellow HR	Very red shade. Improved transparency, heat stability and lightfastness over PY 12. Some use in interior finishes
PY 106	Yelow GGR	Green shade. Poor tint lightfastness. Major use in packaging inks
PY 113	Yellow H10GL	Very green shade. More transparent than PY 12 and offering better heat and solvent fastness. Some interior finish use
PY 114	Yellow G3R	Red shade. Improved solvent and lightfastness over PY 12. Major use in oil-based inks
PY 126	Yellow DGR	Similar shade to PY 12 but offering improved heat and solvent fastness. Major use in printing inks
PY 127	Yellow GRL	Bright, red shade. Poor lightfastness. Major use in offset inks
PY 152	Yellow YR	Very red, opaque product. Poor lightfastness. Some use in interior finishes as a lead chrome replacement

Tolyl Orange—Pigment Orange 34, C.I. Number 21115.

A diarylide pigment manufactured by coupling tetrazo 3,3′-dichlorobenzidine onto 3-methyl-1-(4′methylphenyl)-pyrazol-5-one. This orange is a bright, reddish shade offering moderate lightfastness and good alkali resistance but poor solvent fastness. As such, the pigment is used in interior coating applications, particularly where a lead-free formulation is specified.

Naphthol Orange—Pigment Orange 38, C.I. Number 12367.

Naphthol Orange is prepared by coupling diazo 3-amino-4-chloro-benzamide onto 4′-acetamido-3-hydroxy-2-naphthanilide to produce a bright red shade orange that exhibits excellent alkali and acid fastness. When used in full shades, this pigment also features acceptable lightfastness. Coatings applications extend to baking enamels, latex, and masonry paints.

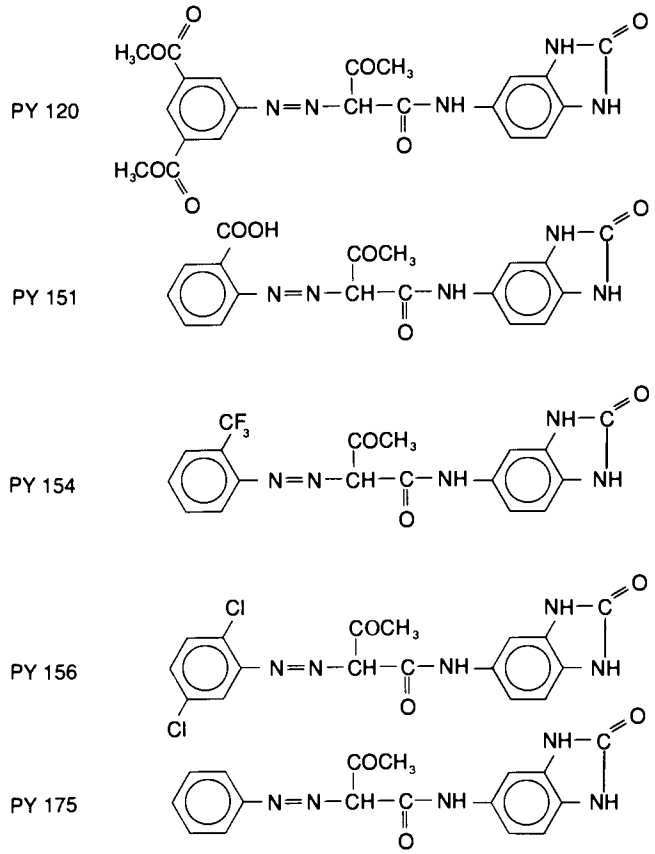

FIG. 21–Structures of the benzimidazolone yellows.

Clarion® Red—Pigment Orange 46, C.I. Number 15602.

TABLE 3—Properties of benzimidazolone yellows.

Colour Index Name	Common Name	Properties
PY 120	Yellow H2G	Medium shade. Good solvent fastness. Excellent lightfastness. Used in industrial finishes
PY 151	Yellow H4G	Greener shade. Good solvent fastness. Excellent lightfastness. Industrial and refinish applications
PY 154	Yellow H3G	Green shade but redder than PY 151. Good solvent fastness. Excellent lightfastness. Industrial and automotive refinish applications
PY 156	Yellow HLR	Redder shade. Transparent. Good exterior durability in full shade and tint. All exterior coatings and refinish applications
PY 175	Yellow H6G	Very green shade. Good solvent fastness. Excellent lightfastness. All exterior coatings and refinish applications

TABLE 4—Properties of the heterocyclic yellows.

Colour Index Name	Properties
PY 60	Arylide Yellow. Very red shade. Moderate light and solvent fastness. Trade sales, latex, and masonry paints. Good acid and alkali fastness.
PY 101	Methine Yellow, bright yellow. Highly transparent and exceptionally brilliant. Industrial finishes and specialty coatings. Only moderate bleed and alkali fastness.
PY 109	Tetrachloroisoindolinone. Green shade. Excellent brightness strength and durability. Automotive finishes.
PY 117	Greenish yellow copper complex of an azomethine. Excellent chemical, light, and heat fastness. Specialty finishes.
PY 129	Azomethine Yellow, very green shade. Excellent chemical, light, and heat fastness. Industrial and specialty coatings.
PY 138	Green shade Quinophthalone. Clean hue and excellent overall fastness properties. High quality industrial and automotive finishes.
PY 139	Red shade isoindoline. Similar in masstone to medium chrome (PY 34). Excellent light and solvent fastness. Industrial and automotive coatings.
PY 150	Pyrimidine Yellow, very green shade. Good heat and lightfastness. Industrial coatings.
PY 153	Red shade nickel dioxine. Excellent fastness properties. Specialty coatings and baking enamels. Poor acid resistance.
PY 155	Azo Condensation Yellow, green shade. Excellent overall fastness properties in full shade. Industrial and specialty coatings.
PY 173	Isoindolone Yellow, very green shade. Excellent fastness properties. Industrial and specialty finishes.
PY 182	Triazinyl Yellow, medium shade. Excellent fastness properties at masstone levels. Industrial finishes.

A metallized azo pigment manufactured by coupling diazotized 2-amino-5-chloro-4-ethyl benzene sulfonic acid onto beta naphthol followed by reacting this product with barium to yield the barium salt of the pigment. Not recommended for coatings due to its poor lightfastness, inferior alkali resistance, and inadequate solvent fastness, this pigment finds its major outlet in the printing ink marketplace.

Benzimidazolone Orange—Pigment Orange 36, C.I. Number 11780.

The product from the coupling of diazo 4-chloro-2-nitroaniline to 5-acetoacetylamino-benzimidazolone, this is a bright red shade orange of high tint strength. In its opacified form, this pigment offers excellent fastness to both heat and solvents and a hue similar to Molybdate Orange (PR 104). As such, the pigment is used in automotive and high-quality industrial formulations which must be lead free and which were formerly made used the lead-based pigment, Molybdate Orange.

Pigment Orange 60—C.I. Number 11782.

A transparent, yellow shade orange that also exhibits excellent heat and solvent fastness with an exterior durability that allows the pigment to be used in automotive and high performance industrial finishes. Manufactured by coupling benzimidazolone to 4-nitro-aniline.

Pigment Orange 62—The newest of the benzimidazolone oranges, the structure of this pigment has yet to be made public. Again a yellow shade pigment that has shares the lightfastness properties of PO 36 and PO 60 but offers inferior solvent fastness and exhibits slight bleed in alkaline systems. Currently the pigment is being used in oil-based inks and artists colors; its use in the coatings industry has still to be fully explored.

Miscellaneous Oranges

Figure 24 illustrates the structures of those oranges that fall into a "miscellaneous" category as far as such structures have been declared. Table 6 summarizes the properties of this series of pigments, each of which is finding increased use within the coatings industry.

Greens

Copper Phthalocyanine Green

When a self shade green is required, rather than a green produced by mixing blue and yellow, then copper phthalocyanine is the green of choice. This pigment is based upon halogenated copper phthalocyanine using either chlorine or a mixture of chlorine and bromine, the former product being Pigment Green 7 and the later, Pigment Green 36.

Pigment Green 7 is a blue shade green made by introducing 13–15 chlorine atoms into the copper phthalocyanine molecule, whereas Pigment Green 36 is a yellow shade green based upon a structure that involves progressive replacement of chlorine in the phthalocyanine structure with bromine. Fig-

TABLE 5—Orange pigments of significance in the coatings industry.

[a]n/a = Not assigned.

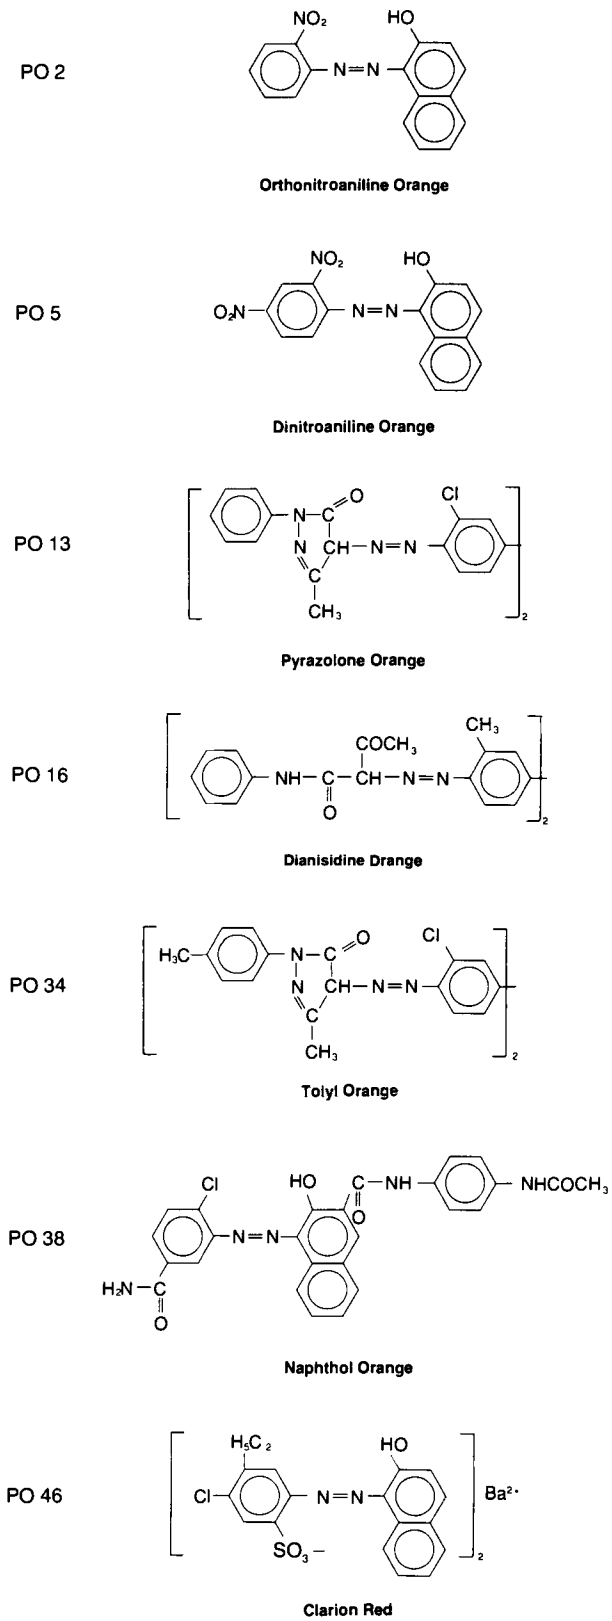

FIG. 23–Structures of the azo-based oranges.

ure 25 illustrates the proposed structures of the phthalocyanine greens. The most highly brominated product, Pigment Green 36, sometimes referred to as "green 6Y" or "green 8G," has an extreme yellow shade and contains 12–13 chlorine atoms.

Both greens exhibit outstanding fastness properties to solvents, heat, light, and outdoor exposure. They can be used equally effectively in both masstone and tints down to the very palest depth of shades. Metallic automotive paints may feature phthalocyanine green at all shade depths. Approximately 50% of the worldwide production of copper phthalocyanine green is consumed by the coatings industry.

Miscellaneous Greens

Table 7 gives a brief summary of the properties of other commercially available organic green pigments that may find some use in the coatings industry. Such inorganic greens as Brunswick Green (PG 15) and Phthalo Chrome Green (PG 13), widely used in industrial coatings, are now being replaced by the more economic organic greens such as phthalocyanine green.

Pigment Greens 1, 2, and 4 are triphenyl-methane-based dyes complexed with phospho tungsto molybdic acid (PTMA) to allow their use as pigments. Their fastness properties are inadequate for most paint applications.

Pigment Green 8, the bisufite complex of 1-nitroso-2-naphthol reacted with ferrous sulfate and then with sodium hydroxide is one of the oldest chelate-based pigments that maintains some minor commercial significance as a colorant for cement. Exhibiting excellent alkali stability this pigment suffers from poor acid fastness.

Pigment Green 10, Nickel Azo Yellow, or Green Gold is the most lightfast azo pigment currently in commercial production, being lightfast at all range of shade from deep tones to pale tints. The pigments does, however, show poor overstripe fastness when used in baking enamels.

Health and Environmental Concerns

The majority of pigments used within the coatings industry are classified as "nuisance dusts" under controlling OSHA standard 29 CFR 1910.1000 with an 8-h time-weighted average exposure tolerance of 15 mg/m^3. Most pigments dealt with in this chapter can be handled in the workplace using normal standard practices of good industrial hygiene as associated with dusty products. However, there are instances which call for specific comment since additional information is available or more specific handling controls are required.

Calcium and Barium Lithol Red, Lithol Rubine, and the BON Reds have each been tested extensively for any toxic properties. The LD_{50} (rat) for each was estimated at greater than 5000 mg/kg. The pigments are classed as nonhazardous as defined by OSHA 29 CFR 1916.25 and not toxic as defined by FHSA 16 CFR 1500.3. BON Maroon has an oral LD_{50} (rat) of 10 g/kg. Additionally, in vitro screening tests for mutagenicity proved negative.

Toxicological results for both Pigment Violet 19 and Pigment Red 122 have been reported. Both pigments exhibited an oral LD_{50} (rat) of 5000 mg/kg or higher. The pigments are thus classified as "non-toxic" under FHSA 16 CFR 1500:3.

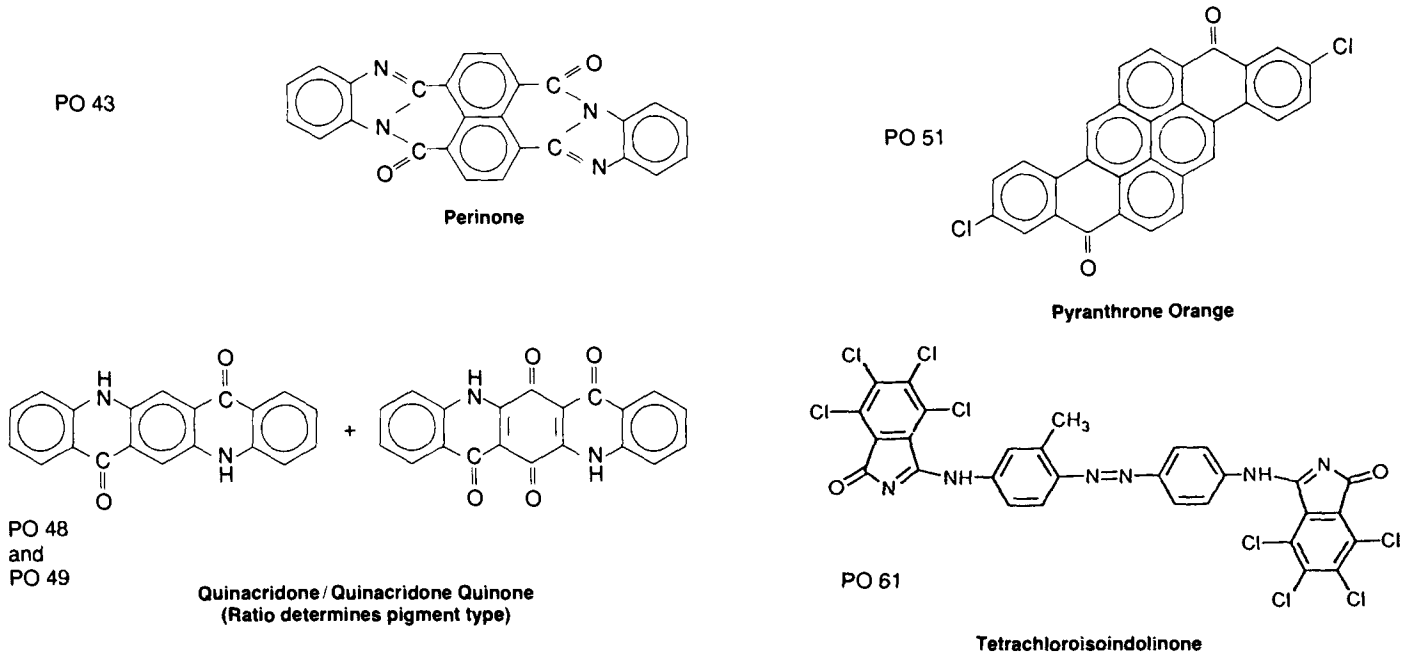

FIG. 24–structures of the miscellaneous oranges.

TABLE 6—Properties of the miscellaneous orange pigments.

Colour Index Name	Properties
PO 43	Perinone. Red shade. Strong clean vat pigment with excellent fastness properties. Used in metallized finishes and high grade paints. Shows slight solvent bleed
PO 48	Quinacridone gold. Yellow shade. Excellent lightfastness. Lacks brightness in masstone. Used in metallic finishes
PO 49	Quinacridone deep gold. Red shade. Dull masstone. Excellent durability. Used in metallics
PO 51	Pyranthrone orange. Medium shade. Excellent solvent, light, and heat fastness. Dull in tint. Exhibits slight solvent bleed. Used in air dry and bake enamels
PO 52	Pyranthrone orange, red shade. Vat pigment with excellent solvent, light, and heat fastness. Dull in tints. Slight solvent bleed. Used in air dry and bake enamels
PO 61	Tetrachloroisoindolinone orange. Medium shade. Exhibits some solvent bleed. Used in metallic automotive finishes
PO 64	Bright red shade. Excellent solvent and lightfastness. Used in industrial coatings
PO 67	Yellow shade. Excellent brilliance in full shade. Good gloss retention. Very good weather and light fastness in full shade. Used in industrial and automotive coatings

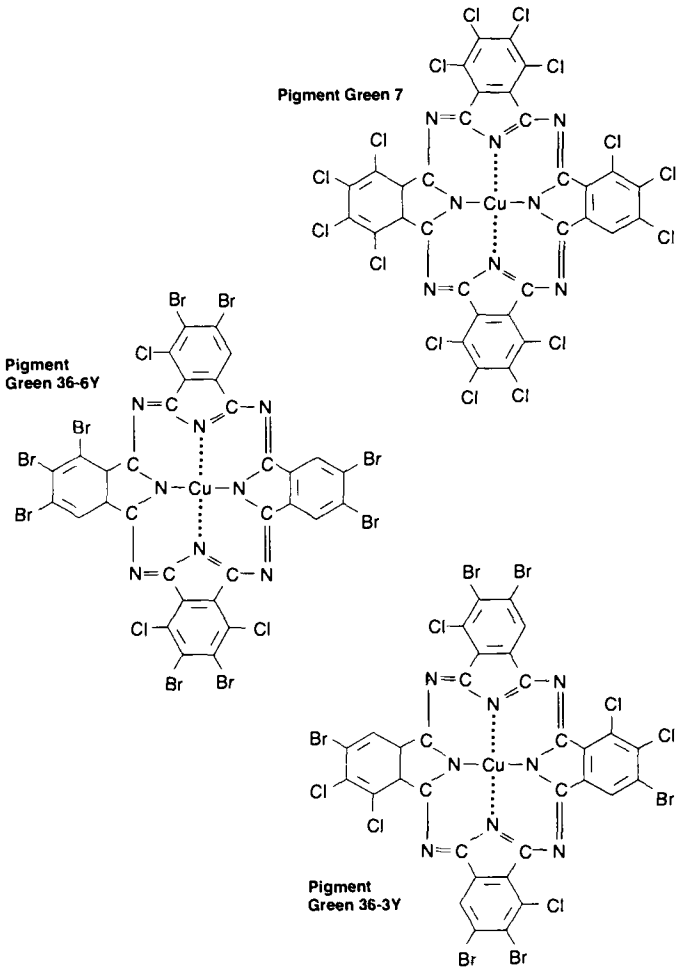

FIG. 25–Proposed structures for phthalocyanine greens (PG 7 and PG 36).

TABLE 7—Properties of the miscellaneous commercial green pigments.

Colour Index Name	Chemical Name	Properties
PG 1	Brilliant Green (Triphenylmethane PTMA)	Brilliant, blue shade. Poor alkali and soap resistance, solvent bleed, and lightfastness. May be used in interior finishes
PG 2	Permanent Green (Triphenylmethane PTMA)	Blend of Pigment Green 1 and Pigment Yellow 18. Bright yellow shade. Poor fastness overall
PG 4	Malachite Green (Triphenylmethane PTMA)	Bright, blue shade. Poor fastness properties overall
PG 8	Pigment Green B (Nitroso)	Yellow shade. Dull hue. Poor fastness properties. May be used in interior emulsions
PG 10	Green Gold (Nickel azo complex)	Yellow shade. Loses metal in strong acid or alkali. Good lightfastness. Moderate solvent fastness. Used in automotive and exterior paints

Additionally, the pigments are classified as being "non-hazardous" as defined by OSHA 29 CFR 1916.25.

Both the disazo condensation pigments and the novel high-performance reds have such low biodegradability that they do not pose any significant risk to either health or to the environment.

In the 1970s it was discovered that the use of trichlorobenzene as a solvent in the manufacture of copper phthalocyanine crude resulted in the formation of poly chlorinated biphenyls (PCBs), principally hexachlorobiphenyl. More modern manufacturing techniques now produce a crude with levels of PCBs significantly below the 25 ppm maximum required by the Environmental Protection Agency (EPA).

The National Toxicological Program examined copper phthalocyanine blue in their long-term bioassay program, and in an almost unprecedented move the pigment was withdrawn from further testing after only 90 days since it failed to exhibit any toxic characteristics during this time period.

Both Pigment Yellow 1 and 74 have been assessed as negative when evaluated in "in vitro" screening tests for mutagenicity.

The industrial handling of diarylide yellows has been the subject of considerable investigation as a result of the relationship of the 3,3′-dichlorobenzidine to the known carcinogen, benzidine. As a result, in the United States, 3,3′-dichlorobenzidine and its salts are classified as an "industrial substance suspected of carcinogenic potential for man" by the ACGIH and as a "cancer suspect agent" by the OSHA (Std. 29 CFR 1910.1007).

In a report of health studies on diarylide yellow pigments, no carcinogenicity was reported from Pigment Yellow 12, 16, or 83 in a two-year feeding study using rats and mice. An oral feeding study using rabbits showed no reduction of the pigments to the parent amine, 3,3′-dichlorobenzidine, during metabolism.

Both Orthonitroaniline Orange and Dinitroaniline Orange are considered to have an oral LD_{50} of greater than 5000 mg/kg (rat) and are therefore classified as "non-toxic" as defined by FHSA 16 CFR 1500.3 and as "not hazardous" under OSHA 29 CFR 1916.3. Both pigments meet the heavy metal content specification under USAST Z66.1-1964 making their use in toy enamels and crayons acceptable.

Pigment Orange 46 contains 15% barium as part of its chemical makeup and as such must be checked for water soluble barium under ANSI Z66.1 prior to it being used in toy enamels and similar coatings.

The LD_{50} for phthalocyanine greens has been shown to be in excess of 2000 mg/kg and the pigments can, therefore, be assumed as not harmful by ingestion. Ninety-day feeding trials with both rats and mice showed no adverse effects nor evidence of adsorption of the pigment. Mutagenicity tests have also proved negative. Concerns about the contamination of phthalocyanine greens with polychlorinated biphenyls (PCBs) have all but disappeared with pigments manufactured within the United States due to today's much improved manufacturing techniques, easily meeting the 25-ppm limit imposed in the United States.

Testing of Pigments for Use in Coatings

Many tests can be applied to a pigment to assess its suitability in a coatings formulation. However, it is of paramount importance that the formulator is satisfied that the tests have a clear relationship to the end use of the coating. It is pointless to evaluate a pigments interior performance only to then use the pigment in an exterior application. For a pigment to be merely the shade and opacity as required by the customer is not an adequate safeguard that the pigment will perform as expected once the product is employed in its intended end use. In today's marketplace, more than any other time in the past, with quality relationships being of such commercial significance, it is vital that the user and supplier have a full understanding of what is expected of any coatings formulation that is in commercial production. The coatings business is under constant change and review and it is in this atmosphere of change that care must be taken to ensure "fitness for use" of any colored organic pigment is fully explored.

Many types of test will be run on a pigment that are not specific to an application but which are a property of the pigment in question and which need to be known in spite of the end use application.

Color and Tint Strength (ASTM D 387-60)

The most obvious property of a pigment is its hue, that is, its color as being distinctly blue, yellow, green, red, etc. and the finer detail that distinguishes a green shade blue from a red shade blue. The other tinctorial properties may be taken as those that are significant when the pigment is used in full tone and those of significance when the pigment is used in reduced shades after diluting the full shade with an opaque white.

Evaluation of any pigment must include a test of full color or masstone that requires inspection of the pigment,

undiluted with white, but fully dispersed in a medium that has relevance to the coatings formulation. Inspection of this full color shows the hue, intensity, transparency, cleanliness, and jetness of the pigment. Comparison of this using side-by-side evaluation with a standard or specification full color will show how close the test pigment comes to the standard. The full color can then be tinted with a white base such as one made from titanium dioxide to enable the pigment's tinting strength to be assessed against a previously approved standard or control. Such a tint is known a bleached, tinted, or reduced drawdown or display.

Oil Absorption (ASTM D 281-31)

A broad definition of oil absorption is the amount of an oil or vehicle which produces a uniform paste when thoroughly incorporated with the test pigment. For standard purposes it is the amount of refined linseed oil, by either weight or volume, necessary to produce a coherent paste from 100 g of dry pigment. Since the transition point of going from a partially wetted powder to an coherent paste is not a clearly defined measure, this test will always be subject to differences between labs and technicians as to when the test's end point is reached. The figure for oil absorption is used by many coatings formulators to give an indication of what effect different pigments will have on the flow properties of the system and to calculate the pigment loading limits. The values are essentially a measure of particle shape, as a pseudospherical particle will have a lower oil absorption than an anisotropic particle.

Bleed Test (ASTM D 279-73)

This test gives an indication of the extent to which the pigment will dissolve, however minutely, in the solvents the pigment is likely to be exposed to during its use. Additionally, an overstripe test can be incorporated where the coating containing the pigment under test is overstriped with a white paint and allowed to dry. The extent of the discoloration of the white is an indication of the pigment's overstripe bleed.

An attempt can be made to quantify this bleed by use of the "Grey Scale for Assessing Change in Color" (B.S. 2662) where the bleed is rated from 5, representing no visible bleed, to 1, representing considerable bleed.

Fastness Tests

The term "fastness" is used in this context to relate to how susceptible or durable a pigment is to the parameter under test. As such, the pigments fastness to light, heat, solvents, etc. can all be measured and quantified using a "Fastness Scale" which rates a pigment from 1 (poor) to 5 (excellent) in all cases except lightfastness which is subdivided into 1 through 8, 1 being total failure to 8 being outstanding.

Among those properties important to the formulator are fastness to solvents, where bleeding is observed by allowing a quantity of the dry pigment to stand for 24 h in contact with a solvent and observing any discoloration of the solvent that occurs, fastness to heat, where the effect of stoving temperatures on the pigment formulated into a finished coating are observed, fastness to acidic or alkaline environments and fastness to light, where several tint levels of a formulation are exposed in such artificial sources as the Xenon or carbon arc fade-ometer (ASTM D 822: Practice for Conducting Tests on Paint and Related Coatings and Materials Using Filtered Open-Flame Carbon-Arc Light and Water Exposure Apparatus) to assess the pigment's behavior in accelerated exposure using the "Blue Wool Scale" to calibrate the measuring equipment (B.S. 1006).

Exposure Testing

It is now generally accepted within the coatings industry on a worldwide basis that the true test of a high-performance pigment is through prolonged outdoor exposure at specifically chosen sites in the state of Florida. To this end, many commercial establishments exist in the state that will provide a controlled service to expose sprayed panels of pigmented coatings angled in a predetermined way towards the sun for periods up to five years with assessments at intervals during this five-year period. Typically many duplicate panels will be exposed per test with a panel being returned to the formulator every six months such that a measure of the system's weatherability as a function of time is maintained on record for each pigment and each system used in outdoor situations.

Specific Gravity (ASTM D 153: Test Methods for Specific Gravity of Pigments)

Defined as the mass of a given volume of a substance as compared to the mass of an equal volume of water at a prespecified temperature, the specific gravity of a pigment is used to arrive at a bulk density or "bulking volume" of the pigment. This is a subjective test that cannot be exactly compared between technicians and between laboratories.

Inorganic Colored Pigments

by Peter A. Lewis[1]

CLASSIFICATION OF INORGANIC PIGMENTS BY CHEMISTRY

BROADLY SPEAKING, the colored inorganic pigments are either lead chromates, metal oxides, sulfides, or sulfoselenides with a few miscellaneous pigments such as cobalt blue, ultramarine blue, iron blue, and bismuth vanadate yellow. This section describes the chemistry, manufacture, and properties of each of these classes of inorganic pigments. Inorganic whites such as zinc oxide, titanium dioxide, lithopone, and zinc sulfide, while pigmentary in nature and most definitely a part of the coatings industry, fall outside of the scope of this chapter.

By chemistry inorganic pigments can be subdivided as shown in Table 1. In addition to the inorganic pigments listed in Table 1, there also exist a series of pigments classed as mixed metal oxides such as, for example, zinc iron chromite brown (PBr 33), cobalt chromite green (PG 26), cobalt titanate green (PG 50), and cobalt aluminate blue (PB 28 and PB 36). These types of inorganic pigments are sometimes also called ceramic colors because of their widespread use in the ceramics industry. Since they are covered in the next chapter of this book, no additional consideration will be given to these colors in this chapter.

CLASSIFICATION OF PIGMENTS BY COLOR

Most likely, when searching for a color to fulfill a particular specification, the coatings formulator is likely to begin the search on the basis of color rather than chemistry. Accordingly, the remainder of this section will concentrate on the classification of inorganic pigments based upon their color rather than their chemistry.

Reds

Iron Oxide Reds

Available as both natural and synthetic products, these pigments also carry such names as haematite, Mars Red, Ferrite Red, Rouge, Turkey Red, and Persian Gulf oxide.

Synthetic iron oxide makes up the largest volume of manufactured iron oxides and is produced by one of four major syntheses:

1. By calcining iron sulfates.

$$12FeSO_4 \cdot H_2O + 3O_2 \longrightarrow 2Fe_2O_3 + Fe(SO_4)_3 + 12H_2O$$

2. From synthetic black oxide by calcining the material in a controlled atmosphere containing oxygen.

$$4FeO \cdot Fe_2O_3 + O_2 \longrightarrow 6Fe_2O_3$$

3. Precipitated red oxide can be prepared in an aqueous medium by growing seed nuclei in the presence of a ferrous salt and scrap steel, the lightness/darkness of the resulting pigment being determined by the crystal size distribution of the precipitate.
4. By calcining synthetic yellow iron oxide to give the dehydrated product, Fe_2O_3.

The wide range of red iron oxide shades available, in addition to their acid and alkali resistance and their economy, accounts for the large volume of these pigments used in today's coatings marketplace.

Molybdate Orange

This pigment is, in fact, Pigment Red 104, a very yellow shade of red that has the common name of molybdate orange, a pigment based upon oxides of lead, chromium, and molybdenum with the empirical formula of $PbCrO_4 \cdot xPbMoO_4 \cdot yPbSO_4$, a solid solution of lead chromate, lead molybdate, and lead sulfate.

Molybdate orange is produced by the addition of a solution of sodium chromate, sodium molybdate, and sodium sulfate under carefully controlled conditions into a solution of lead nitrate at a temperature between zero and 40°C to precipitate the mixed crystal. Control of particle size, particle-size distribution, and crystalline shape combine to determine the actual hue of the pigment, from a red shade of yellow to a red shade of orange with specialty hues such as "chili red."

An opaque pigment with high solvent fastness, moderate heat fastness, and good economy, molybdate orange finds its major outlet in the coatings industry, particularly industrial finishes. On the negative side, the pigment has poor alkali and acid resistance; nontreated grades also tend to darken markedly on prolonged exposure to the environment. Additionally, the pigment is based upon lead, which has been under an "environmental cloud" for some years, a fact which has resulted in molybdate orange being replaced by more expensive, but less toxic, organic reds in decorative paints and almost all original equipment manufacturer (OEM) automotive paints made in the United States.

TABLE 1—Summary of colored inorganic pigments.

LEAD CHROMATES	
Pigment Yellow 34 $PbCrO_4 \cdot xPbSO_4$	Primrose, medium and dark chrome yellow
Pigment Red 104 $PbCrO_4 \cdot xPbSO_4 \cdot yPbMoO_4$	Molybdate orange
Pigment Orange 21 $PbO \cdot xPbCrO_4$	Light and dark chrome orange
Pigment Green 15 $PbCrO_4 \cdot xPbSO_4 \cdot yFeNH_4Fe(CN)_6$	Chrome green (mixture of lead chrome and iron blue)
METAL OXIDES	
Pigment Yellow 42 Pigment Yellow 43 $Fe_2O_3 \cdot xH_2O$	Yellow iron oxide—synthetic Yellow iron oxide—natural
Pigment Red 101 Pigment Red 102 Fe_2O_3	Red iron oxide—synthetic Red iron oxide—natural
Pigment Brown 6 Pigment Brown 7 Fe_2O_3	Brown iron oxide—synthetic Brown iron oxide—natural
Pigment Green 17 Cr_2O_3	Chromium oxide green
Pigment Green 18 $Cr_2O_3 \cdot 2H_2O$	Chromium oxide green, hydrated
SULFIDES AND SULFOSELENIDES	
Pigment Yellow 35 $CdS \cdot xZnS \cdot yBaSO_4$	Lithopone, cadmium yellow
Pigment Yellow 37 CdS	Cadmium yellow
Pigment Orange 20 $CdS \cdot xCdSe \cdot yBaSO_4$	Cadmium lithopone orange
Pigment Red 108 $CdS \cdot xCdSe$	Cadmium red
MISCELLANEOUS TYPES	
Pigment Blue 27 $Fe(NH)_4Fe(CN)_6 \cdot xH_2O$	Iron or milori blue
Pigment Blue 28 $CoAl_2O_4$	Cobalt blue
Pigment Blue 29 $Na_{6-8}Al_6Si_6O_{24}S_{2-4}$	Ultramarine blue
Pigment Violet 16 $MnNH_4P_2O_7$	Manganese violet
Pigment Yellow 184 $4BiVO_4 \cdot 3Bi_2MoO_6$	Bismuth vanadate/molybdate yellow

Cadmium Red

Cadmium sulfoselenide red, Pigment Red 108, is a solid solution of cadmium sulfide and cadmium sulfoselenide produced by calcining co-precipitated cadmium sulfide and sulfoselenide. the pigment's hue is determined by the amount of cadmium sulfoselenide incorporated into the solid solution and, to a lesser extent, the temperature of processing. Pigment Red 108:1 is a co-precipitate with barium sulfate having the empirical formula

$$CdS \cdot xCdSe \cdot yBaSO_4$$

Cadmium red features excellent stability to heat, alkali, solvents, and light when used at high tint and masstone levels. The pigment offers the formulator a clean bright red with high chroma. Use of the pigment in a reduced form as a light tint is not recommended since the durability will suffer at weak tint levels.

Mercury Cadmium Red

Pigment Red 113 is yet another calcined co-precipitate. It is mercuric sulfide co-precipitated with cadmium sulfide to give a pigment with the empirical formula $CdS \cdot xHgS$, offering good hiding properties and good solvent resistance with excellent brightness, but the pigment's inferior heat and acid resistance when compared to Pigment Red 108 has limited its use in coatings applications.

Violets

Technically blue shade reds, the two most important inorganic violet pigments are Pigment Violet 15, ultramarine violet, prepared by the oxidation of ultramarine blue, Pigment Blue 29, and Pigment Violet 16, manganese violet, prepared when manganese dioxide and diammonium phosphate are slurried at high temperatures in phosphoric acid.

Ultramarine violet has good heat and light fastness and a brilliant red shade. The pigment will react with metals to form sulfides and finds use in cosmetic applications and specialty acrylic poster paint and artists colors.

Manganese violet does not possess the same brightness of hue as Pigment Violet 15 and has only moderate opacity and poor alkali resistance. On the plus side, the pigment has high lightfastness and superior fastness to solvents and overstripe bleed. Major uses are in the plastics and cosmetics industry.

Blues

Iron Blue

Also known as Prussian Blue and Milori Blue, this pigment is manufactured by reacting ferrous sulfate and sodium ferrocyanide in the presence of ammonium sulfite to yield a leucoferricyanide called Berlin White, which is then isolated and dissolved in sulfuric acid and oxidized with sodium chlorate to yield iron blue.

$$Na_4Fe(CN)_6 + FeSO_4 + (NH_4)_2SO_4 \longrightarrow Fe(NH_4)_2Fe(CN)_6 + 2Na_2SO_4$$

(Berlin white)

$$6Fe(NH_4)_2Fe(CN)_6 + 3H_2SO_4 + NaClO_3 \longrightarrow 6FeNH_4Fe(CN)_6 + NaCl + 3(NH_4)_2SO_4 + 3H_2O$$

Differing grades of iron blue exist that offer varying masstone, strength, oil absorption, and dispersion characteristics. Chinese Blue, for example, offers a greener undertone, whereas Bronze Blue features a surface bronziness effect that varies dependent upon the viewing angle.

Iron blue offers good resistance to weak acids but markedly poor resistance to even mild alkali; furthermore, the pigment has a tendency to "bleach out" on storage, losing almost all its color when incorporated into a paint formulation that contains oxidizable vehicles such as linseed oil. The pigment has only acceptable lightfastness properties when used at

masstone levels; extension of the paint with a white such as titanium dioxide gives a weak blue tint that will rapidly fade on exposure.

Ultramarine Blue

Going by such varied common names as Laundry Blue, Dolly Blue, and lapis lazuli, this pigment, made by the controlled grinding of a mixture of calcined kaolin, soda ash, sulfur, coal, and sodium sulfate, is Pigment Blue 29. Empirically the product is $Na_6Al_6Si_6O_{24}S_4$, and its major use is as a component of laundry powders and detergent soaps. Less than 5% of the production is used in the coatings industry for interior emulsion paints that require high alkali resistance and lightfastness.

Yellows

Strontium Yellow

Strontium chromate, $SrCrO_4$, prepared by precipitating a suitably soluble chromate with an appropriate strontium salt, is Pigment Yellow 32. Finding a primary use in corrosion-inhibiting coatings, this pigment has poor tint strength, low opacity, and unsatisfactory alkali and acid resistance, which limits its more widespread use in the coatings industry.

Chrome Yellow

A co-precipitate of lead sulfate and lead chromate, Pigment Yellow 34 has the empirical formula $PbCrO_4 \cdot xPbSO_4$. Various types exist that differ in the ratio of the lead sulfate to the lead chromate and as such are described as medium chrome, primrose, and lemon chrome yellows. A typical primrose chrome will contain 23 to 30% lead sulfate in the solid solution of the co-precipitate, whereas a medium chrome will contain 0 to 6% lead sulfate. During manufacture, proprietary techniques are employed such that the orthorhombic crystal form is produced almost exclusively in preference to the unstable monoclinic form.

Many different grades of this type of pigment are available to offer such improvements in properties as better chemical resistance, decreased tendency to darken on exposure, improved weathering, and as a silica-encapsulated product to minimize solubility of the lead contained within the pigment.

Primrose chrome exhibits a very green shade and offers good lightfastness, high opacity, and low rheology coupled with economy of use. The coatings industry, closely followed by the ink and plastics industry, is the largest consumer of primrose chrome. Medium chrome is used widely in road-marking paints in the United States where the law requires a yellow marking line as opposed to white. Grades that have been pre-darkened by the use of antimony during the precipitation stage offer much increased stability to weathering since these grades will not darken further on exposure to sulfur in the atmosphere.

Zinc Chromate

Also called zinc yellow, this pigment is identified as Pigment Yellow 36, as opposed to the lithopone version incorporating barium sulfate which is Pigment Yellow 36:1. It is a bright, green shade of yellow made by the precipitation of hydrated zinc potassium chromate from the reaction of sodium bichromate with zinc oxide and potassium chloride. The lithopone version is merely a co-precipitate of zinc chromate onto barium sulfate to give an extended pigment that carries the Colour Index name of Pigment Yellow 36:1.

Used primarily in corrosion-inhibiting coatings, its poor tinctorial strength and poor resistance to acid and alkali severely limits this pigment's use elsewhere.

Cadmium Zinc Yellow

Yet another solid solution, Pigment Yellow 35 is a cadmium solution co-precipitated with zinc sulfide. Calcination of this product gives pure cadmium zinc sulfide, $CdS \cdot xZnS$. The hue is readily altered by varying the ratio of the two components of this solid solution. Levels of zinc sulfide of 14 to 21% give a green or primrose shade, while 1 to 7% gives a redder shade achieving a golden hue. Incorporation of barium sulfate during manufacture produces a lithopone version, Pigment Yellow 35:1.

Cadmium zinc yellows offer bright, clean, opaque pigments with excellent resistance to heat, light, and strong solvents. Their poor fastness to mineral acids and marked tendency to fade when used at low tint levels limits their use within the coatings industry.

Cadmium Sulfide Yellow

Calcined calcium sulfide, CdS, is identified in the Colour Index as Pigment Yellow 37. This pigment can be produced with hues ranging from a green shade to a very red shade by simply varying the calcination conditions. Offering excellent stability to heat, light, acids, and alkali, this pigment's only major drawback is its tendency to fade in the presence of moisture.

Iron Oxide Yellows

As with most of the commercially available iron oxides, this pigment can be obtained as the natural grade, Pigment Yellow 43, or the synthetic variant, Pigment Yellow 42.

The natural yellow oxides, $FeO \cdot xH_2O$, will also contain clay and various other minor minerals. Available under several names, often related to the country of origin or the pigment's history, the natural yellow oxide is also called Indian Ochre, Ocher, Sienna, and limonite.

The synthetic oxide is produced by direct precipitation using ammonium hydroxide and ferrous sulfate, via the Penniman-Zoph process using scrap steel and a ferrous salt to grow seed particles or by the aniline process where nitrobenzene is reacted with metallic iron to produce iron oxide and aniline. The synthetic product has the empirical formula $Fe_2O_3 \cdot xH_2O$, irrespective of the manufacturing process.

Iron oxide yellows are economical pigments with excellent lightfastness, weatherability, opacity, and flow properties. On the downside, they are dull in masstone and exhibit only fair tinctorial strength and moderate baking stability at best. It is their value in use that has resulted in their widespread acceptance throughout the coatings industry.

Bismuth Vanadate/Molybdate Yellow

The most modern of the inorganic pigments discussed in this section, Pigment Yellow 184, was introduced into the marketplace in 1985. Manufactured by dissolving bismuth nitrate, sodium vanadate, and sodium molybdate in nitric acid followed by the precipitation of a complex mixture of the metals, the precipitate is calcined to give a polycrystalline product, $4BiVO_4 \cdot 3Bi_2MoO_6$. It is a green shade of yellow used

principally for a brilliant solid shade in both automotive and industrial coatings. The pigment has excellent weatherfastness coupled with good hiding power and gloss retention. Earlier grades suffered from the unusual phenomenon where the color under shadows would darken only to lighten again once the shadow was removed. More stable grades introduced recently do not suffer this drawback.

Oranges

Chrome Orange

A basic lead chromate, Pigment Orange 21, is formed under alkaline conditions to give a product of empirical formula $PbCrO_4 \cdot xPbO$, shades varying from a yellow shade to red shade dependant upon the alkalinity maintained during the reaction sequence.

As with all lead-containing pigments, the product will darken on exposure to the atmosphere, the rate dependant upon the sulfur content. The pigment offers low cost and moderate lightfastness and finds use in the protective coatings marketplace with some use as a shading pigment for road traffic paints.

Cadmium Orange

Pigment Orange 20, cadmium sulfoselenide orange, is a solid solution produced by calcining cadmium selenide with cadmium sulfide at approximately 1000°C (1800°F). A change in the ratio of the solid solution components gives pigments that are bright yellow (PY 35) to bright red (PR 108). Barium sulfate added or produced during the processing will form the lithopone grade, Pigment Orange 20:1.

This pigment is used in industrial coatings, for color coding applications, where chemical and heat resistance are principal requirements.

Cadmium Mercury Orange

This pigment is a solid solution of mercury sulfide in cadmium sulfide and is identified as Pigment Orange 23. Again, various hues can be obtained by controlling the formation of the mixed crystal manufactured by precipitating the sulfides of cadmium and mercury from a solution of their soluble salts. Again, the final stage is calcination in an inert atmosphere to give an extremely heat stable pigment with excellent chemical resistance, weatherability, and solvent fastness.

Greens

Chrome Green

These pigments are merely mixtures of a green shade chrome yellow (PY 34) and iron blue (PB 27). As such, Pigment Green 15 offers a range of hues with a light yellow shade to a deep dark shade, providing good hiding, high tint strength, and a moderate chemical resistance at an economical price. It can be used for bake enamels where the bake temperature does not exceed 148°C (300°F), but is restricted to exterior and industrial coatings applications as opposed to decorative finishes because of its lead content.

Chromium Oxide Green

Pigment Green 17 is a pure, calcined chromium oxide, Cr_2O_3, manufactured by reduction of sodium bichromate with carbon or sulfur:

$$Na_2Cr_2O_7 + 2C \longrightarrow CO + Na_2CO_3 + Cr_2O_3$$

This pigment has a unique use in camouflage paints because of its ability to reflect infrared light. Otherwise, the product finds a use where its price can be justified by the resultant excellent light and chemical resistance properties the pigment features.

Hydrated Chromium Oxide Green

Also known as Viridian Green or Guignets green, Pigment Green 18 is a hydrated chromic oxide of formula $Cr_2O_3 \cdot 2H_2O$ from the hydrolysis of the product produced by calcining sodium bichromate with boric acid. The pigment is a bright, blue shade green with high chroma and outstanding fastness properties in both masstone and deep tints.

Browns

Natural Iron Oxides

This is mined from either iron oxide mines operating principally to supply ore as feedstock for blast furnaces with a small offtake directed to the pigment industry or pigment mines which operate solely to supply pigmentary grade ore.

Typically the mined ore is slurried in an aqueous suspension and washed through a series of stages to remove sand and clay after which the slurry passes into a separator tank, then through a Dorr bowl rake where the iron oxide ore is separated and dried as a thin layer on a rotary drum drier. The dried natural ore is then pulverized and classified to produce pigmentary iron oxide. Pigment Brown 7 is an iron oxide brown that is available in shades ranging from light red to deep purple brown. Empirically the product is Fe_2O_3. Metallic brown is produced from calcined hematite (PR 102) and burnt sienna from calcined limonite (PY 43).

Pigment Brown 7:x is a ferrosoferric oxide derived from ores containing 25% manganese dioxide with a distinct composition as $Fe_2O_3 \cdot xMnO$ with varying proportions of clay. Classical names include such as raw umber, burnt umber, and Turkish umber.

Synthetic Brown Oxide

Also known as brown magnetite iron oxide, Pigment Brown 6 is produced by controlled oxidation of Pigment Black 11. Chemically the product may be represented as $Fe_2O_3 \cdot xFeO \cdot yH_2O$.

Pigment Brown 11 is magnesium ferrite from the calcination of a blend of ferric and magnesium oxides, $MgO \cdot Fe_2O_3$.

The volume of all types of brown oxides used in coatings is generally low since most browns are achieved by mixing yellow, red, and black pigments. As a class, these pigments have good chemical resistance and high tint strength and as such find some use in wood stains and furniture finishes.

Ceramic Pigments

by Richard A. Eppler[1]

CERAMIC PIGMENTS ARE COMPLEX MIXTURES of oxygen-containing materials that have been calcined at high temperatures to form specific crystalline phases [*1*]. In most cases, oxide raw materials are carefully mixed and then calcined in either batch kilns or continuous calciners [*2*]. After calcination, they are ground to the necessary fineness in mills. Micronizers and/or jet mills are used to break agglomerates. The final production step involves careful control of the color tone by adjustment with toners.

Because these pigments are formed at high temperatures, they generally offer superb thermal stability and are relatively inert. This results in excellent weathering and light fastness properties. Most of these pigments have superior acid and alkali resistance. They are nonmigrating and nonbleeding in nature and do not interact with polymer systems [*3*].

The principal disadvantage of ceramic pigments is their low tinting strength. In addition, some are relatively high in cost. This is particularly true of cobalt-containing pigments. Some of these pigments are difficult to disperse. However, the recent development of easily dispersed ceramic pigments should eliminate this problem, at least for water-based systems. A final concern is the inherent hardness of these pigments. Their hardness can lead to processing system damage through abrasion. When using ceramic pigments, processing system components designed for use with abrasive materials should be considered.

The major use of ceramic pigments is for applications such as vinyl siding and automotive paints where the product is thermally cured and then placed in an outdoor setting.

CERAMIC PIGMENTS USED IN ORGANIC PAINTS

The major criterion used in selecting ceramic pigments for organic paints is hardness. The pigments listed in Table 1 and discussed below are those that can be used in paint processing equipment without causing excessive wear. Property attributes of the pigments are given in Table 2. All are compatible with most polymer systems, with manganese-doped rutile especially useful when it is necessary to avoid iron.

Nickel-doped rutile, which is often called Sun Yellow, is produced from a mixture of various amounts of titanium (IV) oxide, nickel (II) oxide, and antimony (V) oxide by high-temperature calcination [*1*]. The result is formation of a crystalline matrix of rutile that has the basic chemical formula $(Ti,Ni,Sb)O_2$. The pigment is used for coloring high-performance industrial coatings, wire coatings, vinyl sidings, automotive and other exterior paints, as well as for roofing, granules, porcelain enamels, and ceramic bodies.

Chrome-doped rutile is prepared from a mixture of varying amounts of titanium (IV) oxide, chrome (III) oxide, and antimony (V) oxide by high-temperature calcination [*1*]. The resultant crystalline rutile matrix has the basic chemical formula $(Ti,Cr,Sb)O_2$. The orange-yellow pigment is used for coloring the same systems as nickel-doped rutile.

Manganese-doped rutile is prepared from a mixture of various amounts of titanium (IV) oxide, manganese (II) oxide, and antimony (V) oxide by high-temperature calcination [*1*]. The resulting crystalline rutile matrix has the basic chemical formula $(Ti,Mn,Sb)O_2$. The brown pigment is used for coloring the same systems as nickel-doped rutile.

Spinel brown pigments are an example of the 2-4 inverse spinels [*4*]. The basic pigment is prepared by a high-temperature calcination of titanium (IV) oxide and iron (II) oxide [*1*]. The resulting crystalline matrix of spinel is brown in color and has the basic chemical formula Fe_2TiO_4. The spinel phase permits extensive substitution, within defined limits, with other compounds to provide a variety of shades of brown. Modifiers used for substitution include Al_2O_3, CoO, Cr_2O_3, Fe_2O_3, MnO, and ZnO. The pigments are used for coloring high-performance industrial coatings, wire coatings, vinyl sidings, and automotive and other high-quality exterior paints.

Titanate green and blue-green pigments are also produced by high-temperature calcination of mixtures of titanium (IV) oxide, cobalt (II) oxide, nickel (II) oxide, and zinc (II) oxide to form a crystalline matrix of inverse spinel [*1*]. The pigments have the basic chemical formula $(Co,Ni,Zn)_2TiO_4$. The pigments are used for coloring the same systems as the spinel brown pigments.

Cobalt blue pigments are crystalline spinels formed by high-temperature calcination of cobalt (II) oxide and aluminum (III) oxide in varying amounts [*1*]. The basic cobalt blue pigment (CAS 68186-86-7) has the chemical structure $CoAl_2O_4$. The lighter-colored cobalt blue is prepared by addition of zinc (II) oxide to the ingredients used for the basic pigment. The chemical structure of the resultant material (CAS 68186-87-8) is $(Co,Zn)Al_2O_4$. Blue-green shades are produced by introduction of chromium (III) oxide, partially replacing aluminum (III) oxide in the basic cobalt blue system. It has the chemical formula $Co(Al,Cr)_2O_4$. In addition to being

TABLE 2—Properties of recommended ceramic pigments (see Table 1 for color and pigment reference numbers).

Ceramic Pigment	Heat Stability	Weathering Properties	Light Fastness	Acid/ Alkali Resistance	Hydrolytically Stable	Nonmigrating/ Bleed
Nickel-doped rutile	High	Excellent	Excellent	Excellent	Yes	Yes
Chrome-doped rutile	High	Excellent	Excellent	Excellent	Yes	Yes
Manganese-doped rutile	High	Excellent	Excellent	Excellent	Yes	Yes
Spinel brown	High	Excellent	Excellent	Good	Yes	Yes
Titanate greens and bluegreens	High	Excellent	Excellent	Excellent	Yes	Yes
Cobalt blue—basic	High	Excellent	Excellent	Excellent	Yes	Yes
Cobalt zinc blue	High	Excellent	Excellent	Excellent	Yes	Yes
Cobalt chromite blue	High	Excellent	Excellent	Excellent	Yes	Yes
Cobalt phosphate violet	High	Excellent	Excellent	Excellent	No	Yes
Manganophosphate violet	High	Excellent	Excellent	...[a]	No	Yes
Ceramic Jet black	High	Excellent	Excellent	Excellent	Yes	Yes
Ceramic Jet black—stronger	High	Excellent	Excellent	Excellent	Yes	Yes

[a]Manganophosphate violet has good acid resistance, but poor alkali resistance.

used to color the same systems as the rutiles, the cobalt blues are used in ceramic glazes.

Cobalt phosphate violet is prepared by high-temperature calcination of cobalt (II) oxide and phosphorus (V) oxide to form a crystalline phosphate [*1*]. It has the formula $Co_3(PO_4)_2$. It is used for coloring the same systems as the spinels and in printing inks. Manganophosphate violet is produced by a precipitation process from ammonium salts of manganese (III) and phosphorus (V) [*3*]. This pigment has the chemical formula $NH_4MnP_2O_7$. It is used for inks and other applications where heat stability is of less importance.

One ceramic black is a jet black powder produced by calcination of mixtures of copper (II) oxide and chromium (III) oxide to form a crystalline spinel [*1*]. The basic jet black has the formula $CuCr_2O_4$. A marginally stronger black is produced by a high-temperature calcination of cobalt (II) oxide, iron (III) oxide, and chromium (III) oxide in varying amounts, also to form a spinel. The product has the chemical formula $(Co,Fe)(Fe,Cr)_2O_4$. The ceramic blacks are used in the same systems as the above-described rutiles.

Like most pigments, ceramic pigments are manufactured to have a suitable particle size for incorporation into the coating, but when a paint manufacturer receives them in bags of dry material, the particles generally have absorbed moisture [*5*]. They are stuck together in groups by this layer of water or absorbed air. Hence, in the dispersing process, these layers must be destroyed and the primary particles dispersed in the paint.

There are a number of wetting and dispersing agents which can be added to a paint [*5*]. Discussion of this topic will be found elsewhere in this manual. However, one important additional factor should be noted. Most ceramic pigment manufacturers today offer a line of easily dispersed pigments. These products are formulated with a proprietary dispersant. Adding the dispersant to the pigment itself promotes optimum contact between the dispersant and the pigment. These dispersants are primarily designed for water-based systems.

TESTING OF CERAMIC PIGMENTS

Ceramic pigments are usually tested for two important properties—particle size and tinting strength. Hardness is essentially a property of the pigment crystal produced and is insensitive to production details. Hence, handbook values for the crystal are usually adequate for most purposes.

There are three aspects of particle size to be considered: (1) the particle-size distribution; (2) the concentration of coarse particles; and (3) the particle shape as it affects the formulation of the paint. The measurement and reporting of particle-size distribution of pigments in paints is contained in ASTM Practice for Reporting Particle Size Characteristics of Pigments (D 1366) [*6*]. The practice covers measurements by microscopic techniques, sedimentation methods, turbidimetric methods, absorption, and permeability methods. The recent laser dispersion and electric sensing zone techniques are not yet dealt with in this standard. The procedures described in ASTM Test Method for Particle Size Distribution of Alumina or Quartz by Electric Sensing Zone Techniques (C 690) and ASTM Test Method for Determining Particle Size Distribution of Alumina or Quartz by Laser Light Scattering (C 1070) should be applicable to ceramic pigments [*7*].

Determination of the concentration of coarse particles that may cause defects in a coating is covered by ASTM Test Methods for Coarse Particles in Pigments, Pastes, and Paints (D 185) [*6*].

The amount of pigment which may be added to a paint formulation is a strong function of the shape of the pigment particles. Higher loadings are possible for pseudo-spherical particles than is possible with plate-like particles. This property of a pigment is measured by determining the oil absorption characteristics of the pigment as described in ASTM Test Method for Oil Absorption of Pigments by Spatula Rub-out (D 281) [*6*].

Tinting strength is the other important characteristic that needs to be evaluated. The determination of the color of a pigment requires that it be dispersed into a medium similar to that in which it is to be used. It is never acceptable to imply application color from the color of a dry pigment. The techniques for dispersing a pigment in a suitable vehicle and then measuring the color in both masstone and letdown are detailed in ASTM Test Method for Color and Strength of Color Pigments with a Mechanical Muller (D 387) [*6*].

Extender Pigments

by Henry P. Ralston[1]

COATING FORMULATORS FREQUENTLY USE extender pigments to reduce the raw material cost of a coating formulation and, in some cases, improve coating performance. Extender pigments are relatively inexpensive compared to titanium dioxide or color pigments and are easily incorporated into a coating. Most are white or near-white inorganic minerals, beneficiated to varying degrees, with a coarser particle size and lower oil absorption (binder demand) than primary pigments.

Extender pigments include inexpensive fillers, such as coarse calcium carbonate, which are used to reduce cost by filling coating volume with minimal impact on performance. Other extender pigments such as hydrous and calcined kaolin can actually enhance coating performance plus provide very favorable economics by improving the efficiency of a more expensive pigment such as titanium dioxide.

Some extenders have specific features that improve coating performance, such as better durability, derived from the unique platy particle shape of talc or mica. Pyrogenic, fumed, and diatomaceuos silica are frequently used as functional additives to control rheology and film gloss. While extender pigments can vary in form and use, the added value delivered to the coatings formulator remains [*1–4*].

CALCIUM CARBONATE

Description

Calcium carbonate, also known as calcite, whiting, or limestone, has the chemical formula $CaCO_3$. It is produced by dry or wet grinding of limestone or by precipitation via carbonization of slaked lime. Product from ground limestone is dependent upon both the initial crude mineral and the subsequent degree of processing or beneficiation. Limestone ore is crushed and milled; the dry ground product is air classified to different particle-size fractions. Wet ground product is milled as a slurry, undergoes flotation to remove impurities, and is then filtered and dried. The coarser dry-ground grades of calcium carbonate are used as inexpensive fillers.

Precipitated calcium carbonate is produced by heating natural limestone to form calcium oxide, which is then slaked in water and reacted with carbon dioxide to form a low-solids slurry. The precipitate is vacuum filtered, dried, and ground. Both particle shape and size of precipitated grades can be carefully controlled by altering reaction conditions to yield effective extender pigments. Fine-particle-size precipitated grades and fine-ground limestones are utilized as extender pigments.

Physical Properties

Calcium carbonate products are differentiated further by physical properties such as particle size, brightness, residue, and, for precipitated grades, oil absorption. Fine-particle-size products have an average particle size of from less than 1 to about 4 μm with coarse-particle-size grades ranging up to about 15 μm. Most are high in brightness, ranging from 90 to 98, with a pH of 9 to 10. Ground carbonates have low oil absorption which correlates with low resin demand in coatings.

Coatings Performance

Calcium carbonate is widely used in water-based trade sales architectural coatings since it is less expensive than titanium dioxide, a primary pigment in paints and coatings, and significantly lowers raw material cost. Fine-particle-size calcium carbonate functions as an extender by spacing titanium dioxide and maintaining or improving optical properties of the dry coating film at lower titanium dioxide levels. Higher-oil-absorption (binder demand) precipitated grades may contribute to opacity. Finer-particle-size grades tend to develop high gloss; high brightness can have a positive effect on the color of the coating.

Coarser grades of calcium carbonate are primarily used as fillers to reduce cost but also contribute to flatting and enhance low sheen control. Some grades may cause frosting and chalking in exterior applications.

KAOLIN

Description

Kaolin, also known as china clay, is an aluminum silicate with the chemical formula $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$, which is commercially available in both hydrous and calcined (anhydrous) forms. Domestic deposits occur primarily in South Carolina and Georgia. It has a platy particle shape with finer particles present as individual platelets and coarse particles present as stacks of platelets or booklets.

[1]Technical Service Engineer, Engelhard Corporation, 101 Wood Avenue South, Iselin, NJ 08830.

Copyright© 1995 by ASTM International

The hydrous form is produced by air flotation or water washing. Air-floated grades are crushed and ground to a specific particle size and air classified. This process is very dependent on the initial ore deposit.

Water washing involves processing the mineral in an aqueous slurry and separating particles of different size, which can then be recombined to yield products with controlled particle-size distribution. These products can also be further beneficiated by bleaching, ozonation, high-intensity magnetic separation (HIMS), or chemical flotation to remove impurities and improve color. Some grades are subjected to a delaminating process that physically separates coarse platelets from one another.

Water washing offers a more carefully controlled product available in either slurry or dried form. Predispersed spray-dried beads offer ease of handling and are suitable for water-based coating systems. Pulverized, acid grades are recommended for solvent-based coatings.

Calcined (anhydrous) forms are produced by subjecting hydrous kaolin to thermal dehydroxylation, which removes the water of crystallization and alters the crystal shape.

Physical Properties

Kaolins are also differentiated by properties such as particle size, brightness, residue, and oil absorption. Hydrous kaolins have an average particle size ranging from an extremely fine 0.2 up to 5 μm depending on the product. Dry brightness ranges from 85 to 90%, and most water-washed grades are very low in residue. Acid grades have a pH of 4 to 5, while predispersed grades are 6 to 7. Kaolins are chemically inert. Water-washed grades are lower in impurities such as soluble salts than are air-float grades.

Calcined grades range from below 1 to 2.5 μm in average particle size and are usually higher in brightness than all except premium hydrous grades. These grades have a more irregular particle shape and higher oil absorption than the hydrous grades.

Coatings Performance

Fine particle-size hydrous kaolins are commonly used in latex and alkyd trade sales paint. Finer particle size improves opacity and allows for cost reduction by extending/reducing the amount of titanium dioxide. Finer particle-size products also develop higher gloss and are particularly useful in enamels and semigloss formulations. Chemically modified hydrous kaolins are effective in high-solids and water-reducible industrial coatings.

Delaminated grades also develop good opacity, and the platy particle shape improves barrier resistance and film integrity. Delaminated grades or coarser hydrous grades are more suitable for exterior trade sales formulations and exhibit more controlled chalking and better overall durability. Air-floated grades are not used significantly in coatings because the higher water-soluble salt content can cause viscosity instability.

Calcined kaolins are widely used in interior latex and alkyd trade sales flats to develop dry hiding and reduce cost at lower titanium dioxide levels. Dry hiding is due to the higher oil absorption (binder demand) of the calcined grades, resulting in more air/pigment and air/binder interfaces in the dry paint film. These grades develop good flatting, and the harder calcined particles also improve scrub resistance in interior latex coatings [*5,6*].

TALC

Description

Talc is a hydrated magnesium aluminum silicate with the chemical formula $3MgO{\cdot}4SiO_2{\cdot}H_2O$. Deposits are found domestically in New York, Vermont, Montana, Texas, and California. Talc varies widely in purity depending on its source and may also contain dolomite, limestone, and silica, among others. Western talcs are highly platy, while eastern talcs have an acicular particle shape. Both dry and wet grinding techniques are used in its beneficiation. Ore flotation processes are used to produce high-quality products. Dry processing includes use of jaw crushers, Raymond mills, and cyclones. Advanced milling technologies eliminate oversized particles.

Physical Properties

Key properties for talc include composition, color, particle size, water solubility, and oil absorption. Some grades are available with an average particle size of 1 to 3 μm, but most are around 5 to 15 μm. Brightness ranges from 70 to 85 for inexpensive grades and 87 to 92 for premium grades. Oil absorption depends on particle shape and size but in general fits in between calcium carbonate and kaolin. Slurry pH is basic at 9 to 10. Talcs are hydrophobic and organophilic [7].

Coatings Performance

Talcs are used in many different types of coatings including interior and exterior trade sales paints, primers, traffic paints, and industrial coatings. Western platy talcs develop good flatting and provide good chemical and water resistance due to high-purity and low-soluble calcium. These are best for sanding primers because of softness and good sealing properties, while coarse grades help develop surface roughness ("tooth"). Platy talcs have good flow properties and improve barrier resistance and durability in exterior trade sales paints and enamel hold-out in interior applications. Talcs also enhance durability of traffic paints. Eastern acicular talcs have better color and develop lower viscosity at high loadings due to lower oil absorption.

SILICA

Description

Silica is a general term describing products with the chemical formula SiO_2 of which both natural and synthetic types are available. Those most widely used in paint and coatings are crystalline, microcrystalline, diatomaceous, precipitated, and fumed. They differ in method of production, physical properties, and function.

Crystalline silica is produced by crushing, grinding, and classifying quartz. Microcrystalline differs from crystalline in that its deposits, found principally in Arkansas, have a higher concentration of fine particles. It is produced in a similar manner as crystalline, but the ore is finer in particle size. Both are decreasing in usage because of reported health and safety issues related to crystalline silica.

Diatomaceous silica, also known as diatomaceous earth or simply diatomite, consists of the skeletal remains of single-celled aquatic plants called diatoms. Domestic deposits are located in California, Nevada, and Washington. The ore is crushed, milled, dried, and air-classified. Calcined grades are processed in high-temperature rotary kilns and separated into selected particle size ranges by air classification. These products have superior color and are preferred for coatings applications.

Synthetic silicas are produced by a number of differing chemical and thermal processes. Precipitated silica is produced by acidification of sodium silicate to form aggregates of ultra-fine particles. Aggregate size and degree of structuring are controlled by reaction conditions. Fumed silica, produced via high temperature hydrolysis of silicon tetrachloride with hydrogen, also exists in aggregates of ultra-fine particles, and particle size and surface area are also dependent on reaction conditions.

Physical Properties

Since processing of crystalline silica is essentially a size reduction operation, particle size and particle-size distribution are the primary means of differentiating products. Crystalline silicas range from 2 to 10-μm average particle size. Microcrystalline grades are easier to disperse and are less abrasive than crystalline grades. Brightness is from 85 to 90% and pH from 6 to 7. Oil absorption is intermediate between calcium carbonate and hydrous kaolins. These extenders ae translucent and don't contribute to hiding as do some calcium carbonates and kaolin. Diatomaceous silica is a very high oil absorption material found in aggregates ranging in mean particle size of 2 to 20 μm. Calcined grades have a brightness of 87 to 90%.

The synthetic silicas are differentiated by surface area and particle size. Surface area of precipitated types is about 60 to 300 m^2/g, while fumed silica ranges from 50 to 400 m^2/g. Ultimate particle size of the individual particles are less than 0.1 μm for both; however, precipitated may develop larger aggregates. Fumed silica has a pH of 3 to 4, and precipitated is 6 to 8. These grades are often made hydrophobic by reaction with organofunctional silanes to improve performance in coatings.

Coatings Performance

Crystalline silica is used in trade sales, industrial coatings, and primers. It is an inexpensive extender which contributes to low sheen control, burnish resistance, and durability with minimal impact on rheology in latex trade sales paints. It is also used in powder coatings where its low binder demand does not affect flow properties.

Diatomaceous silica is primarily used as an inexpensive flatting agent in latex trade sales paints because of its high binder demand [*8*]. Precipitated silicas are used as flatting agents in solvent-based industrial coatings. Fumed grades, more expensive than precipitated because of high-energy requirements during production, are used as rheology modifiers and flatting agents in industrial coatings.

MICA

Description

Mica is a family of hydrous aluminum potassium silicates of which one, muscovite, has the chemical formula $K_2O{\cdot}3Al_2O_3{\cdot}6SiO_2{\cdot}2H_2O$. Micas are best known for a very platy particle shape and high aspect ratio. These are coarser in particle size than most extenders. Higher-aspect-ratio micas are produced by frictional wet grinding. Dry processing in high-pressure air jets to both delaminate and reduce the particles results in lower-aspect-ratio mica.

Physical Properties

Most coating grades of mica have an average particle size of 5 to 50 μm. Residue of 325 mesh varies from less than 1 to as high as 50%, depending on the particle size of the product. Brightness ranges from 65 to 80%, low compared to other extenders, while pH is 7 to 8. Oil absorption is higher than other hydrous minerals and is closer to coarse calcined kaolins.

Coatings Performance

Mica is best known for its very platy particle shape, which forms layers parallel to the paint film. Mica reinforcement increases durability and resistance to moisture penetration, corrosion, checking, heat, and chemicals. It helps prevent cracking in exterior architectural coatings and traffic paint. It prevents cracking and sagging in textured coatings. Mica provides good barrier resistance in primers and roof coatings [*9*]. Its platy particle shape, however, limits loading levels due to rheology constraints.

BARIUM SULFATE

Description

Barium sulfate ($BaSO_4$) is available as barytes, its naturally occurring form, or as blanc fixe, a synthetic precipitate. Barytes has a nodular particle shape with deposits found predominantly in Nevada, Georgia, Missouri, Montana, Tennessee, Illinois, and Washington. The ore is beneficiated by flotation techniques and then wet ground to obtain the required particle size and bleached to improve color. Some higher quality ores are dry ground and air classified. Blanc fixe is a very white, fine-particle-size extender not as widely used in paints and coatings as barytes. It is precipitated to a specific particle size from solutions of barium salts and sodium sulfate. Blanc fixe is also used to make lithopone (extended) grades of pigments. Multistage washing and filtration removes soluble impurities, and the products are then dried and ground.

Physical Properties

Barytes is best known for its high density and very low oil absorption relative to other extenders. Particle size ranges from about 1 to more than 10 μm depending on the grade. Brightness also varies from below 70 to greater than 90% depending on the source and degree of beneficiation. Slurry pH runs from 4 to 10. Blanc fixe is a more uniform product with a 1 to 2-μm average particle size and high brightness (95 to 98%).

Coatings Performance

Barytes is used in industrial and automotive primers and undercoats. Its low oil absorption allows for high loadings with less impact on rheology compared to higher binder demand extenders. It helps develop a smooth surface with minimal impact on the gloss of subsequent coats. Because extenders are sold by weight, its high density can be a disadvantage in trade sales coatings where more weight is needed to fill a given volume. Higher density relative to other pigments can increase settling and cause stability problems. Blanc fixe has been used to develop dry hiding as a partial replacement for titanium dioxide in trade sales and industrial coatings [*10*].

OTHER

Wollastonite

Wollastonite is a calcium metasilicate with the chemical formula $CaO{\cdot}SiO_2$ of which the primary domestic sources are New York and California. It has an acicular particle shape and is brown to white in color. It is principally produced by dry processing. Typical coating grades range from 2 to 10 μm in mean particle size. Brightness ranges from 80 to 95%, and pH is 9 to 10. Its acicular particle shape provides some reinforcement in coatings, and high pH is effective in buffering latex systems. Surface-modified grades improve performance in industrial coatings by both reducing resin demand and improving bonding between the mineral and resin [*11*].

Nepheline Syenite

Nepheline Syenite is an anhydrous sodium potassium aluminum silicate with the chemical formula $K_2O{\cdot}3Na_2O{\cdot}4.5Al_2O_3{\cdot}20SiO_2$ and is mined and beneficiated in Canada. It has high brightness (95 to 98%) and is relatively coarse in particle size (2 to 16 μm). Its low binder demand makes it particularly effective in exterior trade sales architectural coatings. Nepheline syenite provides good tint retention and prevents checking and cracking in exterior paints and also develops good scrub resistance in interior latex paints.

Sodium Aluminosilicates

Synthetic sodium aluminosilicates are produced by reacting aluminum sulfate with sodium silicate to produce a structured extender. These have high brightness (92 to 98%) and relatively coarse particle size of 5 to 6 μm. Sodium aluminosilicates are used as partial replacements for titanium dioxide in latex trade sales paints similar to calcined kaolin but at higher cost; some of the highly structured grades are used as flatting agents in latex paint.

Alumina Trihydrate

Alumina trihydrate (ATH) has the chemical structure $Al(OH)_3$ and is produced from bauxite ore as an intermediate in aluminum production. It is most commonly used as a flame retardant and smoke suppressant in thermoplastic and thermoset polymer applications. ATH has a brightness ranging from 85 to 98% depending on the grade. Some very fine particle size grades, less than 1 μm, may be effective in spacing titanium dioxide in trade sales paints.

COMPARISON OF DIFFERENT EXTENDER PIGMENTS

Physical Properties

Physical properties of the pigment extenders described above are compared in Tables 1 and 2. Calcium carbonates are available in different particle size grades and are very white in color and high in brightness. Low oil absorption enables high loading levels with minimal influence on rheology. High pH makes these products appropriate for latex paints. Surface-treated grades are available for solvent-based systems. Precipitated forms are higher in brightness, finer in particle size, and have higher oil absorption approaching that of calcined kaolins.

D 4139-82	Determining Volatile and Non-volatile Content of Pigments (Guide)

Hydrous kaolins are the finest particle size naturally occurring extenders. Neutral predispersed grades are available for latex systems, and acid grades are available for solvent-based systems. These products have very low residue, which improves gloss development. The calcined grades have slightly better color, and higher oil absorption contributes to opacity.

Talcs are available in a wide variety of grades depending on the source. These are more similar to calcium carbonate in particle size, although brightness is somewhat deficient. Platy particle shape is a key parameter. Crystalline silica has lower binder demand than kaolin or talc. Coarser grades are effective flatting agents. Mica is much coarser in particle size than most extenders. It also has lower brightness and high residue, which limit the levels at which it may be used.

The high oil absorption of diatomaceous earth makes it an effective flatting agent. Precipitated and fumed silica, as more carefully controlled reaction products, are more appropriate for industrial coatings applications. Barytes, wollastonite, and nepheline syenite are coarser particle-size products which are less broadly used than finer particle-size extenders.

Comparative Performance in Coatings

Performance characteristics of the extenders previously discussed are compared in Table 3. Coarse calcium carbonate filler does not provide significant improvement in coatings performance and is primarily used to reduce cost. Fine-particle-size hydrous kaolin helps develop hiding power and gloss. These extenders develop good film properties, help maintain stability, and aid in coating application. Calcined kaolin also contributes to opacity development and is fairly good in maintaining film properties, rheology, and application properties. Talc develops good film properties but may have an deleterious effect on rheology, particularly at higher loadings. Coarse amorphous silica is an adequate filler.

PERTINENT ASTM TEST STANDARDS

ASTM standards useful in evaluating extender pigments are shown in Table 4. Standard specifications are useful for categorizing extenders by mineral type and provide some general test guidelines. Analytical standards are useful for chemical analysis of extenders for identification purposes.

Standards for measurement of physical properties are very useful in categorizing extenders and for predicting suitability for a particular coatings application. Particle size, oil absorption, fineness of dispersion, pH, and water-soluble salt content are important parameters in determining the suitability of an extender for a particular coatings application. Actual product specifications should always be mutually agreed upon by supplier and user.

Metallic Pigments

by Russell L. Ferguson[1]

METALLIC PIGMENTS, INCLUDING ALUMINUM, zinc, gold, bronze, nickel, and stainless steel, provide the paint and coatings industry with a variety of aesthetic and functional properties. These pigments, either in flake or powder form, contribute to the metallic effects associated with automotive topcoats; general industrial finishes; silver, gold, and copper finishes; metallic ink systems; and many of the high-performance primers for coatings systems. In addition to providing metallic and polychromatic effects, they provide functional, anticorrosive benefits.

History and Manufacturing Methods

The origin of metallic coatings can be traced back to early civilizations, who utilized thin, gold sheets to overlay wood, bone, or other materials. As the artisans molded these foil sheets, the thin edges would break off into flakes. It was soon discovered that by mixing these flakes in a resinous polymeric material, a similar effect could be achieved. This process was later continued, and by shredding the foil into flakes, artisans were able to produce gold and later silver and bronze metallic effects on ornamental objects. In the middle of the 19th century, a mechanical stamping process, along with newly developed smelting processes, made gold and silver substitutes more readily available. Aluminum, gold, bronze, and later stainless steel and nickel became readily accepted substitutes.

Today, with the exception of zinc powder, most metallic pigments utilize the Hall Wet-Ball Milling Method [*1*]. This process carries out the particle-size reduction in the presence of a suitable lubricant and solvent, offering a safer production method. Eliminating the explosive hazards associated with mechanical stamping processes has allowed the production of finer metallic flakes that find widespread use today. Stamping and dry-ball milling are still utilized in the manufacture of gold bronze flakes.

The post-milling manufacture processes for metallic flakes generally include a screening operation to remove undesirable particles, along with tight controls on aesthetic properties. Color adjustments, along with polishing and blending operations, are utilized in the final stages of the manufacturing process. The metallic flake pigments are available as a dry flake or in a wide range of solvents, including aliphatic and aromatic solvents, alcohols, plasticizers, water, and coalescing solvents.

Zinc powders have a similar, but divergent, history. Not being sought after for aesthetic properties, they were first used in the mid-1800s for anticorrosive functionality and were referred to as "blue powder." Zinc-gray coatings were used extensively for industrial and marine environments by the early 1900s. However, it was not until the late 1930s and 1940s that the industry gained a firm foothold. The manufacture of zinc dust is carried out by melting and vaporizing zinc metal followed by a controlled condensation of the vapor in an inert atmosphere. The product is collected, screened, classified, and packaged [*2*].

Properties

Metallic pigments share similar properties; however, each is distinct enough to be considered separately.

Aluminum

Aluminum pigments are manufactured from aluminum metal with a purity ranging from 99.3 to 99.97%, depending on the grade being manufactured. Although amphoteric in nature, the pigment exhibits a high degree of chemical resistance. Aluminum pigments owe their aesthetic and functional properties to the geometry of the particle, particle-size, and particle distribution. The pigment is a flake-like particle (lamellar) and has either a round or irregular perimeter. Once formulated into a coating, they orient parallel to the substrate and film surface. This orientation provides for exceptional barrier properties in the appropriate coating system. Metallic or polychromatic coatings containing aluminum flake pigments, either by themselves or in combination with transparent colors, offer a two-tone quality often sought after. The two-tone, or flop, feature is an important characteristic in many automotive top coats.

There are two general types of aluminum pigment: leafing and nonleafing. Leafing grades are manufactured using a saturated fatty acid as the lubricant (typically stearic acid), which allows the flakes to float at, or near, the surface of a paint film. This continuous layer of flakes provides a solid silver color, unable to be tinted with other pigments. The nonleafing grades utilize an unsaturated fatty acid as the lubricant (typically oleic acid) which allows the flakes to orient throughout the paint film. Nonleafing pigmented coatings can be tinted with organic pigments to offer a polychromatic appearance.

Aluminum flakes range in size from 0.1 to 2.0 μm in thickness, and 0.5 to 200 μm in diameter. Generally, aluminum flakes are supplied in a paste form with a typical composition

[1]Vice President of Technical Functions, Silberline Manufacturing Co., Inc., R.D. 2, P.O. Box B, Tamaqua, PA 18252.

Copyright© 1995 by ASTM International

of 64% aluminum metal, 1% lubricant, and 35% hydrocarbon solvent [3].

Gold Bronze

Gold bronze pigments are neither gold nor bronze, but are typically manufactured from a composition of copper and zinc alloy. By altering the copper-zinc ratios, four standard gold bronze colors can be produced. The standard alloy subdivisions are: (1) copper—100% copper, 0% zinc; (2) pale gold—90% copper, 10% zinc; (3) rich pale gold—85% copper, 15% zinc; and (4) rich gold—70% copper, 30% zinc. Further oxidative treatments can be utilized to produce special colored bronzes, varying from brown-golds to oranges and reds. Additionally, blending of any of the above-mentioned bronze powders will result in an almost unlimited pallet of gold-bronze colors.

Gold-bronze pigments are flake-like particles (lamellar) with an irregular perimeter. In a coating or ink application, they orient parallel to the substrate and film surface [4].

Zinc Pigment

Zinc dust is the only metallic pigment that is not found in a lamellar form. Produced through the condensation of zinc vapor in an inert atmosphere, the zinc dust is a spherical particle averaging about 8 μm in diameter. Zinc dust is predominantly zinc metal (96 to 97%), with some zinc oxide (3 to 4%), and traces of lead, cadmium, iron, and other elements.

Stainless Steel Flake

Stainless steel is a composition of iron, chromium, nickel, manganese, and molybdenum. There are three groups of stainless steel alloys available: (1) martensitic, (2) ferritic, and (3) austenitic, differentiated according to alloy composition. Of the three groups, austenitic is the most corrosion resistant and typically used to manufacture stainless steel flake. Austenitic alloys owe their corrosion resistance to higher levels of nickel and molybdenum. Stainless steel pigment has a lamellar geometry and will orient itself parallel in a coating system. Stainless steel flake has a high degree of durability and will resist tarnishing, abrasion, and chemical attack. Additionally, stainless steel flake is able to maintain stability in water-based systems.

Nickel

Nickel pigments can be found in either powder or flake-like form. They are typically composed of nickel metal, with traces of carbon, oxygen, sulfur, and iron. Nickel flake powders are available dry, as a paste in mineral spirits, or as a paste in mineral oil. Nickel powders have good electrical conductivity [5].

METALLIC PIGMENT GRADE CLASSIFICATION

Aluminum Pigments

Aluminum pigments are more widely used than any other metallic pigment and can be divided into a number of different categories. The grade classification is, in general, determined by the intended use. Most of the following categories contain a wide range of grades from very coarse, large flakes to very fine, small flakes.

Leafing Grades

The standard grade category is composed of a series of grades from very coarse flakes (having water coverage from 6000 to 9000 cm^2/g) to very fine flakes (having water coverage in the area of 35 000 cm^2/g). These grades are used, primarily, in trade sales and maintenance coatings. Their leafing values are traditionally 50% minimum.

The ultra-leafing grades are characterized by very high leafing values (in the area of 90 + %) and exceptional brightness. Their uses include aerosol coatings and ink applications.

Nonleafing Grades

The standard grades are represented by a full range of products from very coarse, low-opacity to very fine, high-opacity grades. They are used in diverse applications from maintenance coatings to general industrial applications and automotive refinish.

The automotive grades are distinguished from standard grades by possessing improved aesthetics, including brighter, more sparkling appearances, with tighter control on particle-size distribution. Many subcategories exist under this heading, including specialized grades for base coat/clear coat systems, circulation resistance, etc.

Plasticized and polymer-modified grades are represented by a full range of products designed for end-use systems that cannot tolerate solvents (mineral spirits). The primary end use is plastic and ink applications.

The dedusted grade category comprises dry aluminum flakes held loosely together by Teflon bonds, resulting in a nondusting product. These grades are used in some general industrial coatings; however, the primary application is to act as a sensitizer for slurry explosives.

The surface-treated grades include aluminum flakes whose surface chemistry has been altered to allow for improved aluminum flake performance. These grades are used in powder coatings and some solvent-borne coatings where improvements in flake orientation and performance are desired.

The aqueous grade category consists of aluminum pigments treated with various chemical components to stabilize the flake for use in waterborne systems. Various levels of inhibition and performance are available.

Gold Bronze Pigments

These pigments are primarily used for coating and ink applications. They can be divided into four categories, based on alloy composition:

1. *Copper*—coppery-red color (100% copper).
2. *Pale Gold*—reddish gold color (90% copper; 10% zinc).
3. *Rich Pale Gold*—gold color (85% copper; 15% zinc).
4. *Rich Gold*—greenish gold color (70% copper; 30% zinc).

Zinc Pigment

The zinc pigment, dust and flake, is used in coatings, primarily for corrosion-resistant properties. The categories available are:

1. *Regular Zinc Dust*—7 to 8-μm particle-size diameter.
2. *Fine Zinc Dust*—5 to 6-μm particle-size diameter.

3. *Ultra-Fine Zinc Dust*—3 to 4-μm particle-size diameter.
4. *Zinc Flake*—Available in several grades, based on particle-size.

Stainless Steel Flakes

These flakes are used in specialized coatings that require good resistance to severe environmental conditions.

Nickel Powder and Flake

The powder and flake are used in coating and plastic systems to provide electrical conductivity and corrosion-resistance characteristics.

FORMULATION AND APPLICATION GUIDELINES

Formulation Considerations

Metallic flake pigments, by the nature of their geometry and composition, are malleable and therefore somewhat fragile. The dispersion of these flakes into a coating system is critical in maintaining optimum aesthetic and functional performance. The preferred dispersion process involves the addition of vehicle or solvent to the metallic pigments, with slow-speed mixing, to gently separate the flakes. Once a thick, uniform slurry of metallic flakes, solvent, and vehicle is achieved, the formulator can continue to let down to final product composition. Severe dispersion techniques such as Cowles high-speed mixers, sand mills, etc. will destroy the flake integrity, resulting in loss of aesthetic and perhaps functional properties. Zinc pigment, which is not a flake, can be dispersed using conventional paint dispersion techniques.

Appropriate selection of vehicle, solvents, and additives must also be considered when formulating with metallic pigments. The leafing properties of aluminum and bronze flakes can be detrimentally affected by such properties as acid value of the resin; polar solvents, or solvents with low-surface tension; moisture in the system; and additives, including driers that are good wetting agents. Since most metallic pigments contain mineral spirits, coating system compatibility must be considered.

The current trend toward waterborne coatings also poses problems in formulation. Dispersion of metallic pigments can be accomplished through the correct selection of an appropriate coalescing solvent. However, even good dispersion will not guarantee good coating performance. Metallic waterborne coatings have the potential for hydrogen gas generation. This potential has been addressed by many manufacturers through various inhibiting processes. While many inhibited grades are available on the market today, performance may vary in different aqueous systems. In addition to the potential for hydrogen gas generation, tarnishing and printability have been addressed by manufacturers of gold bronze flakes. Stainless steel flakes, because of the very nature of their composition, can be used in waterborne coating formulations without the possibility of gas generation.

Another solution to the VOC (volatile organic compound) problem is the use of powder coating systems. Specialized grades of aluminum pigments have been developed to meet the needs of these 100% solids systems. These grades have been surface-treated to allow for improved flake orientation, along with modified electrical conductivity. Applied electrostatically, the surface-treated aluminum flake will perform in a similar fashion to the powder coating resin.

The application of metallic pigmented coatings and inks will depend on the system being used. Traditional ink application methods will apply to both leafing and nonleafing metallic pigments. In the case of coating systems, leafing metallic pigments can be applied by brush, roller, or spray application. Nonleafing grades, however, must be applied using appropriate spray application techniques. Improper application techniques can lead to poor flake orientation which will result in reduced aesthetic and functional properties.

Market Applications

Metallic pigments are widely used in the coating, ink, plastic, and explosive markets. In the coating industry, metallic pigments offer both functional and aesthetic properties. Those pigments that are lamellar (aluminum, gold bronze, stainless steel, and nickel) are opaque and orient parallel to substrate and coating film surface. Thus, they provide a barrier to ultraviolet (UV) and infrared (IR) light, along with moisture and oxygen penetration. Zinc pigment, while not a flake, possesses superior corrosion protective properties for steel or iron substrates. Because zinc is higher in the electromotive series, it acts as the anode of a corrosion cell. The iron or steel substrate is protected by the zinc because of the formation of insoluble compounds with lower oxidation states.

The aesthetic benefits of metallic pigments are widely known in the coatings industry. In the area of trade sales and maintenance coatings, aluminum pigments provide very bright, silvery finishes typically found in many roof coatings, aerosol applications, and bridges. In general industrial and automotive coatings, various polychromatic and metallescent appearances are produced utilizing nonleafing grades.

In the ink and plastic industries, the primary benefits derived are from aesthetic properties. Gold bronze flakes, along with aluminum flakes, provide attractive polychromatic finishes.

The explosives industry utilizes aluminum flake pigment as a sensitizer in slurry explosives.

Economics of Use

The extensive markets for metallic pigments has mandated their use in a wide range of systems for many years. Their properties, both functional and aesthetic, along with the traditional economic values associated with their properties, have established them as an important raw material in the coating, ink, and plastic markets. The economics of these pigments are dependent on a number of factors, including cost of the raw material, degree of sophistication of the pigment, and the end product for which it is intended.

TESTING

ASTM Test Methods

ASTM covers various specifications and test procedures for metallic pigments. Included are:

- D 962-81—Specification for Aluminum Pigments, Powder and Paste, for Paints
- D 480-88—Test Method for Sampling and Testing of Flaked Aluminum Powders and Pastes (includes tests for volatile analysis; coarse particles; leafing properties; brushing, smoothness, lustre properties; and easily extracted fatty materials)
- D 95-83—Test Method for Water in Petroleum Products and Bituminous Materials by Distillation
- D 185-84—Test Methods for Coarse Particles in Pigments, Pastes, and Paints
- D 235-87—Specifications for Mineral Spirits (Petroleum Spirits) (Hydrocarbon Drycleaning Solvent)
- D 267-82—Specifications for Gold Bronze Powder
- D 520-84—Specification for Zinc Dust Pigment
- D 521-81—Test Methods for Chemical Analysis of Zinc Dust (Metallic Zinc Powder)
- D 4017-88—Test Method for Water in Paints and Paint Materials by Karl Fischer Method

Test Methods Not Covered by ASTM Specifications

ASTM test methods cover many of the properties of metallic pigments; however, there are additional tests which further serve to characterize these pigments. Included are:

Acid Spot Test

This test is designed to determine the acid resistance of aluminum pigments in coating systems. A metallic pigmented coating is tested by placing drops of a 10% solution of hydrochloric acid on the panel. Three rows of three drops are placed on the panel and each row is removed after 1-h intervals (Fig. 1). If the aluminum pigment is acid resistant, no spotting will be apparent after the first or second hour, with only slight spotting after 3 h. A nonacid-resistant aluminum will show definite spotting from the acid solution after the first hour.

Particle-Size Analysis

One of the key elements in any metallic pigment is the particle-size distribution. Instruments are available on the market today to characterize, or fingerprint, metallic pigments. Unfortunately, most of these instruments are incapable of characterizing lamellar-shaped pigments; however, their increased sophistication has allowed for a very close approximation. In addition to providing a distribution of the particles in a pigment, also provided are surface area, average particle size, and percentages at various levels.

Water Coverage

This test can be used to determine the particle-size thickness and surface area of leafing and nonleafing metallic flake pigments. This test has been fully described by Edwards and Ray [*6*]. A dry, metallic pigment is dusted onto a surface of clean, distilled water, which is contained in a shallow, rectangular pan. The accurately weighed flake metallic pigment is dusted onto the surface of the water and separated until it is one flake thick. The coverage of metallic flake on the water

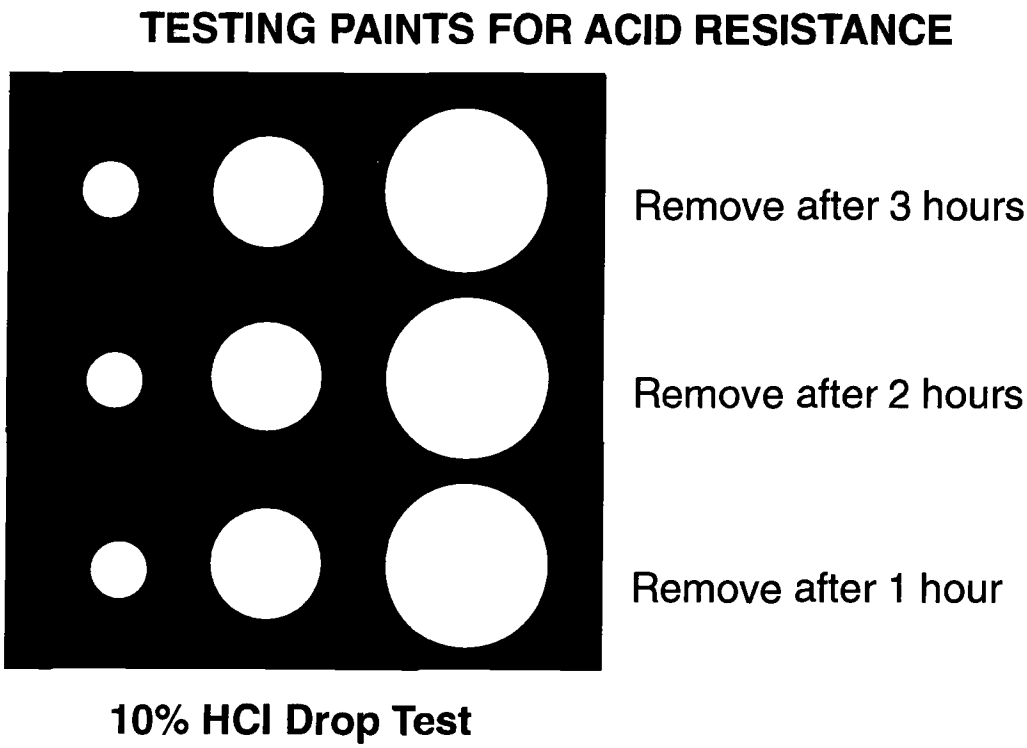

FIG. 1—Testing paints for acid resistance.

can then be measured, and total surface area can be calculated based on the weight of the metallic flake pigment used. The thickness of the metallic flake pigment can also be calculated using simple density and volume calculations.

Degradation Test

This test is designed to determine the level of flake deterioration in a coating system when subjected to severe stress. Automotive coating systems are often circulated through pumps, regulators, and long piping and tank systems to keep all the components of the coating in suspension. Circulation may have detrimental effects on the metallic flake integrity, causing bending, curling, and even breakage of the metallic flake. The loss in aesthetic properties due to flake deformation results in a darkening of the coating, along with a change in the flop characteristic. This test is designed to evaluate the capability of the metallic flake to resist deformation under these stress conditions.

A metallic pigmented coating is placed into a water-jacketed Waring blender. Using a standard cutting blade, the blender is operated at high speeds for 5 to 15 min. The metallic coating is a sprayed pre- and post-blender operation, and visual and instrumental comparisons are made. The degree of flake deformation can be translated into numerical data based on the brightness of the metallic coating (face and flop).

Gassing Test

Aluminum and other metallic pigments, by their very nature, will react with water to generate hydrogen gas. Today, due to VOC regulations, more and more coating and ink systems are moving toward waterborne technologies. Metallic pigment manufacturers have developed technologies to inhibit the aluminum flake pigments, and this test is designed to determine the gas generation potential and stability characteristics of metallic flake pigmented aqueous coating systems. Approximately 200 mL/s of a metallic pigmented coating is charged into an Erlenmeyer flask. Attached to the flask is a glass condenser with Tygon tubing coming out of the top and extending into an inverted buret filled with water. The Erlenmeyer flask is suspended in a hot oil bath, which accelerates the potential for hydrogen gas evolution. This test is operated for seven days (168 h) at a temperature of 52°C. The acceleration of the environmental conditions will allow for hydrogen gas generation, which will pass out of the Erlenmeyer flask, through the Tygon tubing, and into the inverted buret. The water in the inverted buret is displaced by the hydrogen gas and generation can be easily read through this displacement (Fig. 2). The specifications for gas generation should be designed around the metallic flake pigment and coating system tested. The specification for gas generation should not exceed the volume of the buret (typically, 100 mL/s).

Electrical Resistivity/Conductivity

In waterborne coating systems it is often useful to know the conductivity or resistivity of the components of the system. In order to measure metallic pigments, it is necessary to disperse the metallic pigment in an isopropyl alcohol/deionized water mixture. This mixture should be agitated using an air mixer for at least 5 min, after which the metallic pigment should be filtered out. The resultant filtrate can be tested for resistivity/conductivity using a conductivity meter (i.e., Jenway Conductivity Meter, Model 4010).

pH Measurement

In waterborne coatings and ink systems, it is often necessary to know the pH of the components of the system. The pH

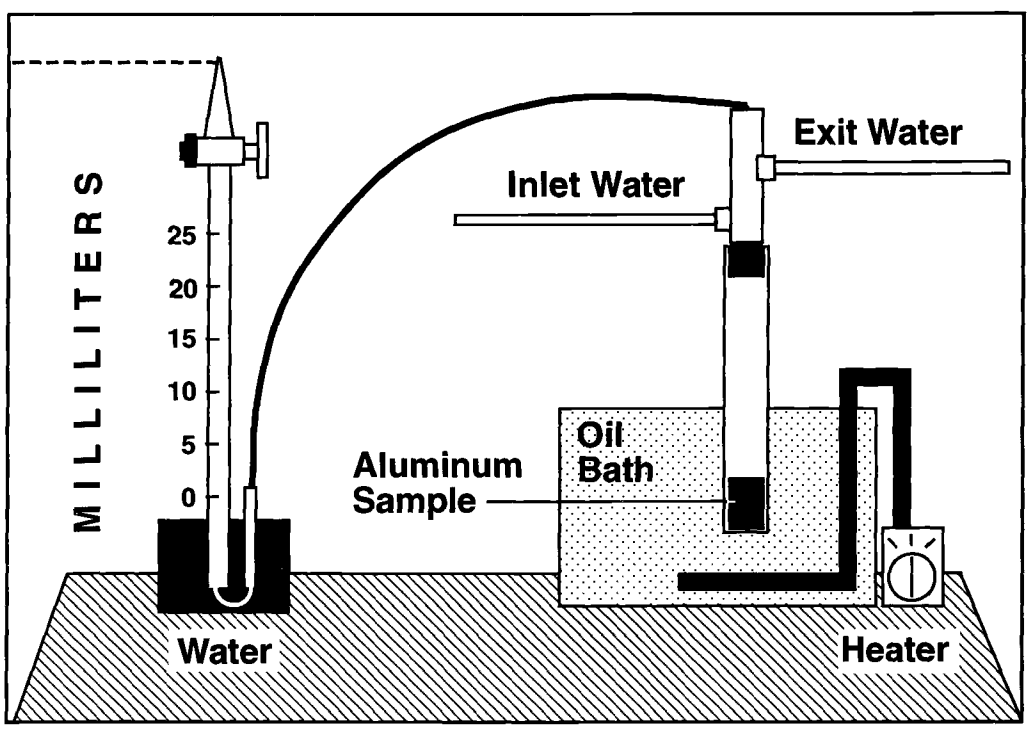

FIG. 2–Gas evolution test for metallic coatings.

of metallic pigments can be evaluated by adding the metallic pigment to a mixture of isopropyl alcohol/deionized water. The slurry should be mixed using an air mixer for at least 5 min. The metallic pigment should then be filtered out, and the pH of the resultant filtrate can then be evaluated.

Aesthetic Properties

Metallic pigments are used for the aesthetic properties they lend to coating systems. Each metallic pigment grade offers a slightly different appearance property to these coatings, and it is necessary to be able to assess these differences. Visual and quantitative data can be generated based on a number of these properties. Four of the most important properties are:

- The *face-color*, or *head-on-brightness*, attribute generally refers to the amount of reflected light from a metallic pigmented coating when viewed at approximately 20 to 25° off of specular.
- The *flop, flip/flop,* or *metallic travel angle* refers to the amount of reflected light when viewing a metallic pigmented coating at an angle that is 70 to 110° off of specular. Metallic travel is often referred to as the degree in change of brightness going from the face angle to the flop angle.
- *Seed level* refers to the degree of protrusion of the metallic flake through a coating film surface.
- *DOI (distinctness of image)*, closely related to gloss, refers to the reflection of an image from a metallic pigmented coating back to the observer. The clearer, or more distinct, the reflected image, the higher the DOI value. Typically, the finer the pigment, the higher the level of DOI.
- *Patina* is the packing appearance of the metallic flakes in coating systems. A good patina is often described as having a smooth, velvety appearance, lacking individual flake identity in the coating. If an observer sees only a continuous metallic film without breaks, protrusion, or individual flake identity, the metallic coating is considered to have a good patina. Many coating systems and pigment parameters affect the patina of a coating system. Typically, higher solids coatings, poor application methods, coarse pigments, and poor flake orientation contribute to poorer patina properties.
- The *color* attributes from the face and flop angles can be numerically measured. There are a number of instruments available today that are capable of measuring reflected light at different angles. All of them are goniospectrophotometers and are capable of measuring reflected light on metallic pigmented coatings at angles from 10° off specular to 110° off specular. ASTM Task Force Committee E-12.03.02 is currently working on a standard test method to evaluate metallic pigmented coatings utilizing specified goniospectrophotometric angles.

Pearlescent Pigments

by Carl J. Rieger[1]

PEARLESCENT PIGMENTS, SOMETIMES REFERRED TO as nacreous pigments, are attempts to create the natural pearl luster effects seen in pearls or sea shells [*1*]. These pigments are high-refractive-index coatings on thin transparent flakes. The high-refractive-index material reflects incident light, and the transparent flakes allow some light to be transmitted through the flakes. Many different grades and types of pearlescent pigments are available. These grades range from materials for soft, satin-like effects from small-particle-size pigments to materials with sparkle metallic effects from larger-size pigments. A special type of pearlescent pigment that produces an iridescent color effect is termed an "interference pigment." These are very thin films with a high refractive index that exhibit color through an optical effect called light interference. This is similar to the "rainbow effect" seen in soap bubbles or in oil and gasoline slicks [*2*].

Because of these optical effects, pearlescent pigments can exhibit color without conventional light-absorbing pigments present. The colors arise from light interference effects that will be described in more detail later. Other types of pearlescent pigments have conventional absorption colors added by either depositing these colorants onto the pearlescent-pigment surfaces or by mixing colorants with pearlescent pigments.

HISTORY

The earliest use of pearlescent pigments is credited to French rosary makers in the 17th and 18th centuries. They used the scales of fish to impart pearl effects to the glass beads used in making rosaries. The modern era of pearlescent pigments began in the late 1920s when scales of fish, namely herring, were used to make simulated pearls for costume jewelry. Because "natural pearl essence," as the material extracted from the fish scales came to be called, was so expensive, synthetic pearl pigments were developed in the 1930s. These early synthetic pearl pigments were mainly lead salts. They possessed both the high refractive index and thin platelet shapes required for pearlescent pigments.

The modern commercial forms of pearlescent pigments consist of:

1. Titanium dioxide and ferric oxide coatings on mica.
2. Bismuth oxychloride crystals grown from a solution of bismuth salts.
3. Natural pearl essence, guanine, and hypoxanthane purines from fish scales.

Mainly because of its high cost, natural pearl essence is used in cosmetic applications such as fingernail polish, lotions, and creams.

Titanium-coated mica types of pigments evolved in the early 1960s through the work of Linton and others [*3–6*]. Coated mica of both the titanium dioxide and ferric oxide types have the dominant share of the pearlescent pigment market. This market involves uses in plastics, coatings, and inks in addition to cosmetic applications.

MANUFACTURING AND COMPOSITION

The type mica used in pearlescent pigments is called "wet-ground mica." This is ground as a water paste in Muller mills to give a delamination effect in the grinding process. As the mill rollers go over the mica, it becomes thinner and smaller in particle-size reducing aspect ratio. These mica flakes are then dried, sieved, and classified into the desired particle-size distribution.

Various particle sizes are available. The coarse particle-size distributions impart a sparkling, wet-look effect. The fine particle-size distributions impart a satin, soft appearance. The particle size for use in exterior grade pigments intended for automotive paints is very carefully controlled so that they contain no particles greater than 50 μm. This prevents clogging of paint filters in recirculation systems of automotive assembly plants and is vital for good application characteristics.

When titanium dioxide-coated types of pearlescent pigments are made, classified mica is suspended in water. Then, under controlled conditions of temperature and pH, titanium sulfate or titanium tetrachloride solutions are added slowly to yield uniform deposition of the hydrous titanium dioxide on the mica flakes or platelets. This suspension is filtered, dried, and calcined at temperatures above 800°C to convert the hydrous oxide into the crystalline form of titanium dioxide (TiO_2) and to increase its refractive index. The normal crystal form for these pigments is the anatase form of TiO_2, but conversion to the rutile form may be made by addition of small amounts of stannic chloride prior to the calcination operation. For the ferric oxide coated mica pigments, a similar procedure is followed except that ferric chloride solutions are added to the mica-water suspension instead of the titanium salts. By varying the thickness of the titanium dioxide

[1]Vice president, The Mearl Corporation, Applications and Development Laboratory, 3 Greentown Rd., Buchanan, NY 10511.

Copyright© 1995 by ASTM International

or ferric oxide layer on the mica, the various interference colors can be obtained.

Bismuth oxychloride crystals are made by a precipitation process under controlled crystallization conditions. In this procedure, a bismuth nitrate solution in hydrochloric acid is added simultaneously with sodium hydroxide at a constant pH and temperature to grow flat, hexagonal-shaped platelets in the particle-size range of 11 to 15 μm. These are very high quality pearlescent pigments because of the narrow particle-size range, high refractive index, and flat shape of the bismuth oxychloride platelets. Bismuth oxychloride has about twice the reflectance of the best titanium dioxide-on-mica types of pearlescent pigments.

A lower quality and smaller size, 5 to 10 μm, type of bismuth oxychloride is made by a "dump" procedure in which a bismuth nitrate solution is added to a sodium chloride solution or vice versa. Because of the small size and irregular-shaped platelets obtained with this process, this type of bismuth oxychloride gives less luster on reflection than the 11 to 15-μm types.

Several patented post treatments [*7,8*] are available to modify commercial preparations and to give these pearlescent pigments the weathering resistance needed for exterior applications such as automotive paints, outdoor signs, and plastics.

OPTICAL PROPERTIES

Pearlescent luster is developed by the specular reflection of light as it strikes the broad surfaces of the platelets. These platelets are dispersed throughout the depth of the paint or ink film or plastic article. This reflection of light from pearlescent pigment particles dispersed throughout the thickness of the coating reinforces the luster and differentiates it from a strictly surface reflection as featured by leafing aluminum flake.

The requirements for a good pearlescent pigment are:

1. A high refractive index preferably greater than 2.
2. An optical thickness, i.e., the geometrical thickness of the layer multiplied by the refractive index, of approximately 100 to 140 nm for pearl (white) pigments. As interference pigments are produced by increasing the geometrical thickness, this optical thickness increases to 200 nm for gold, 250 nm for reds, 300 nm for blues, and 370 nm for green interference colors.
3. A high aspect ratio primarily derived from the mica. the larger the diameter-to-thickness ratio (the aspect ratio), the better the pearl effect. Another way of describing this would be to term it a "platey" structure. The mica itself plays no role in the optics and functions merely as a substrate upon which the high-refractive-index material is deposited.
4. Proper particle-size distributions are needed. Optimum luster occurs when the size distribution, measured by laser diffraction methods, falls between about 10 to 40 μm. Smaller particles, 5 to 10 μm, act as light scatterers and detract from luster. Particles larger than 40 μm give a grainy effect and reduce opacity. Pearlescent pigments are essentially transparent pigments and, as such, do not have good opacity or hiding.
5. Smooth surfaces that give high luster in comparison to rough surfaces that can cause light scattering. Uniformly dense surfaces also give low surface areas, as measured by the Brunauer-Emmett-Teller (BET) method,[2] that can improve weatherability.

APPLICATIONS

Industrial Coatings

Pearlescent pigments have been used in many industrial coating applications. One such use is coil coatings. Polymers often used in these applications, such as fluoropolymers, require high baking temperatures. Since they have been calcined at over 800°C during their manufacturing process, pearlescent pigments can tolerate high bake temperatures of 500 to 600°F (260 to 315°C) without any damage to pigment mechanical integrity or optical properties. Not all organic pigments can be used in such coil coating applications because of temperature limitations.

Pearlescent pigments find application in ink formulations such as gravure, silk screen, flexographic, and, to a lesser extent, offset printing inks. The particle size of some pearlescent pigments is too large for most offset applications.

Bismuth oxychloride pigments have been used for many years as coatings on wood furniture to sharply bring out the "grain" of the wood. Also, bismuth pigments have been utilized in the costume jewelry industry for coating and dipping beads and pearls.

Other applications for these pigments include roller and knife coating of leather and paper as well as coating of various types of toys and balls. The pigments are also used in the popular craft industry.

Automotive Coatings

Pearlescent pigments were first used in original-equipment-manufacture (OEM) automotive paint in the early 1980s, and they became a major styling tool about 1985 [*9,10*]. Since pearlescent pigments, chiefly the coated mica types, are transparent in nature, they do not "gray out" or "muddy up" the expensive transparent organic coating colorants used in automotive coatings. These pigments add to the chromatic effect of organic pigments and contribute to the "flop" or polychromatic effect desired in these coatings. Flop is defined as a change of color as viewing angle changes.

For the 1991 model year, it is estimated that nearly 40% of all U.S. automotive OEM coatings contained pearlescent pigments. European and Japanese paint companies are also using pearlescent pigments in their OEM paint formulations.

Pearlescent pigments have been stabilized by various methods to give the durability required for automotive end uses. Panels have been weathered outdoors in Florida and Arizona for five or six years with little or no change in color or gloss. The use of the color base coat and clear top coat now favored in the automotive industry has also added to the gloss and weathering stability of coatings formulated with pearlescent

[2]Brunauer, S., Emmett, P. H., and Teller, E., *Journal of the American Chemical Society*, Vol. 60, 1938, p. 309.

pigments because the clear top coat affords additional protection for the pigmented coat underneath.

Another interesting property that pearlescent pigments optically display is referred to as "geometric metamerism," or "goniochromaticity." These terms mean that the color of the pigments changes as the viewing angle changes. While this is a very desirable attribute from a styling standpoint, it complicates color measurement of coatings that contain pearlescent pigments [*11–14*].

Powder Coatings

Pearlescent pigments have been successfully used in powder coatings for a number of years [*15*]. Since they are nonmetallic in nature, these pigments are free of some of the arcing and flashing problems that occur in electrostatic spray application of powder coatings.

One limiting factor found with the use of pearlescent pigments in powder coatings is their inability to be used in the "melt mix" method of incorporation. This calls for the extrusion of pigments and the powdered polymer to encapsulate the pigment. The use of an extruder is not the problem since pearlescent pigments are extruded in the plastics industry. The problem arises through the use of hammer-mill type mill used to reduce the size of the polymer mass into a powder that will spray through an electrostatic spray gun. Pearlescent pigments must retain their platey or flake-like shape to properly reflect light and produce luster. If these pigments are broken or smashed by milling, the pearlescent effect is greatly reduced. This leaves only dry mixing of the pearlescent pigment and the powdered polymer as an alternative method of incorporation. Such a technique has certain drawbacks such as separation due to different specific gravities, different particle sizes, and so on that can take place due to vibration during shipping, handling, and application.

A new method called the "bonding" method has recently been used with pearlescent pigments and metallic flakes in powder coatings. This technique involves "bonding" of the pigments to the powder by various proprietary methods.

Pearlescent pigments have been used to powder coat automotive wheel covers, bicycles, and outdoor furniture.

Water-Based Coatings

Since pearlescent pigments are chemically very inert and not sensitive to pH, they make ideal pigments for use in water-based coatings. Because of their inert nature, they do not evolve hydrogen gas or react with water-borne systems. Pearlescent pigments are hydrophilic in nature and as such disperse very well in most water-based systems.

Pearlescent pigments have been successfully used in Canada in water-based truck-paint finishes for several years. Currently they are being used as the automotive industry switches from high-solids to water-based coatings with lower volatile organic compound content.

Ink formulations based on water-borne systems have also been developed for both the coated mica and bismuth oxychloride pigments. These are being used in Europe to replace the metallic ink formulation that may be an environmental problem.

Water-based coatings containing exterior grade pearlescent pigments have been tested in outdoor exposure in Florida for three years. These show good weatherability with optimum gloss and color retention.

COLOR MEASUREMENT

Visual

Instrumental color analysis of coatings pigmented with pearlescent pigments is rather difficult. As mentioned earlier, the phenomenon known as goniochromaticity complicates instrumental measurements. As a result, much color observation has been done visually using both draw down cards with nitrocellulose lacquers and coated panels. Comparing a sample and a standard on a black-and-white draw-down card is an effective way of making color comparisons since both the interference color and the absorption color can be seen. Due to the transparency of pearlescent pigments, the color appears different over the black and the white portions of the card.

The interference color can be best seen and visually compared to the standard by looking at the black portion of the draw-down card. The absorption color can be best evaluated and compared by viewing the white portion of the card. Color appears more intense over the black portion because the incident light is reflected and the complementary color is absorbed. On the white portion of the card, the reflected light and the complementary color are both reflected back to the viewer with only a slight diminishing of the specular effect.

Side-by-side draw downs of samples against a standard batch are so effective that they can be used in process control with samples taken at various intermediate stages of the manufacturing process. Also, final quality control judgments can be made using visual assessment of side-by-side draw downs.

Colorimeters and Spectrophotometers

The use of colorimeters and spectrophotometers to measure the color of pearlescent pigmented coatings results in only limited information. Most of these instruments measure at fixed angles of illumination and fixed reflectance angles, such as 0°/45° or 45°/0°. This results in only a portion of the pearlescent color being measured through diffuse reflection. These instruments are not capable of measuring at specular or slight off-specular reflection angles. It is at these near-specular angles that pearlescent pigmented coatings exhibit most of their color through specular reflection.

Colorimeters can be used to measure the bulk color of pearlescent pigments. Highly concentrated draw downs can be made, and the colorimeter readings may be used to determine the bulk color of white and pearl pigments. Colorimeters and spectrophotometers may also be used to measure color on draw-down cards. These data are useful in comparing various batches to each other for quality control and SPC. Color loss from test panels used in accelerated weathering devices and from actual outdoor exposure may be followed using colorimeters and spectrophotometers. Loss of gloss may be followed in weathering test panels with the use of gloss meters at the 20° gloss angle.

Goniospectrophotometers

When the color of coatings with pearlescent pigments or metallic flake is measured, it is necessary to measure at more than one angle. The reason for this is that the color of these types of coatings changes with viewing angle. An instrument capable of making multi-angle color measurements is called a goniospectrophotometer. These instruments are usually capable of changing the angle of incident light (illumination), changing the angle of viewing (reception), or tilting the specimen under investigation. For most of the commercial quality control instruments, only the angle of viewing is changed and the other variables are held constant with the incident-light angle usually fixed at 45°.

Figure 1 shows the viewing angles used in some of these commercial instruments. The optics used are called normalized reflective angles, which means all viewing angles are referred to the specular angle that is sometimes called the gloss angle. Incident light strikes the ample at 45°, and thus the specular angle is also 45°. The near specular angles are usually 15 to 20° off the specular angle to exclude any gloss from affecting the color readings. To completely characterize pearlescent pigmented finishes, it is necessary to measure at least three angles. This is usually near specular, i.e., about 15 to 20° off specular, at 45° off specular, and at several far diffuse angles, usually 70 to 115° off specular. All commercially available goniospectrophotometers will measure reflected light at a minimum of three angles, and several instruments measure at more angles, with one measuring at twelve angles. Research goniospectrophotometers that allow angle variation of about 5° off specular to 110° in five-degree intervals are also commercially available.

The importance of measuring at more than one angle is apparent from Figs. 2 and 3. In Fig. 2 the reflection curves taken at near specular angle are nearly identical, whereas in Fig. 3, when this same set of panels was measured at a diffuse angle, markedly different reflection curves are obtained. These data were obtained using one gold interference pearlescent pigment to which a small amount of phthalocyanine blue had been added and another gold interference pearlescent pigment to which a small amount of phthalocyanine green had been added. At the near specular angle, the gold interference color is apparent, and, since both coatings used the same gold pigment, the two curves are nearly identical. However, at the diffuse angle, the colors of the organic pigment added to the pearl finish are now apparent, with one curve typical of a blue and one curve typical of a green colorant. If this same pair of panels were presented to a conventional 0°/45° colorimeter, the readings would be of a blue and a green colorant with no information obtained about the color due to the gold pearlescent pigment.

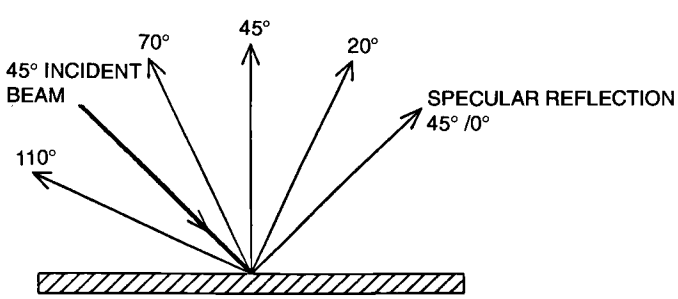

FIG. 1—Normalized reflection angle schematic for a commercial goniospectrophotometer.

Figures 4, 5, and 6 are reflection data for the color of panels coated with solid color, metallic flake, and pearlescent pigment, respectively, as a function of viewing angle. These curves were obtained at 14 viewing angles from 10 to 110° off specular with a research-type goniospectrophotometer. From Fig. 4, it is apparent that the solid color, i.e., nonmetallic or pearlescent, does not change appreciably with viewing angle, so conventional colorimeters and spectrophotometers measuring at 0°/45° can be used to obtain information about coating color. Figure 5, which contains reflection data for the metallic-flake (aluminum) pigmented coating, has a change in the lightness (L) value with angle, but has very little change in the chroma values (a and b). Adding organic colorants to metallic flake will increase the chroma change. The reflection data in Fig. 6 demonstrates the change in color as a function of viewing angle of a blue interference color pearlescent pigment. Changes in the chroma values are readily evident. In Figs. 4, 5, and 6, L^*, a^*, and b^* are the CIE 1976, International Commission on Illumination 1976, apparent-color scales, ASTM Standard Terminology on Appearance (E 284).

ASTM has a task group under E-12.03.02 developing a specification for visually and instrumentally measuring the color of metallic and pearlescent pigments. In addition to development of an instrumental method for measuring the color of such pigments, the task group is also involved in having a visual method approved. Recently one of the instrument companies has developed a color-matching booth especially designed for color matching these types of pigments. This booth contains a combination of three differently positioned light sources, and rotation of the sample panels through five different angles will provide 15 viewing geometries ranges from 10 to 110° off specular. This visual color matching booth should provide color matchers with a new tool for studying metallic and pearlescent pigmented finishes.

TESTING

Weatherability Testing

Weatherability tests with pearlescent pigments take the form of both accelerated and outdoor testing. Accelerated testing includes use of such devices as QUV exposure chambers, condensation testers, and water-bath soaking. Outdoor testing may include exposure in Florida and/or Arizona at 5° South or Black Box. Specimens consist of painted metal test panels, pieces of pearlized plastic film, or injection-molded, pigmented parts.

Color and gloss readings are made on the original test panels before exposure, and panels are exposed in replicates. Panels are removed from the test fences at various times and tested for changes in color and gloss. Testing with the stabilized exterior grades of pearlescent pigments usually goes on for at least five years, and the panels are viewed and examined every six to twelve months. Such testing has shown that exterior-grade pearlescent pigments have the capability of standing up to the weathering stresses found in modern automotive coatings along with other exterior uses. Accelerated

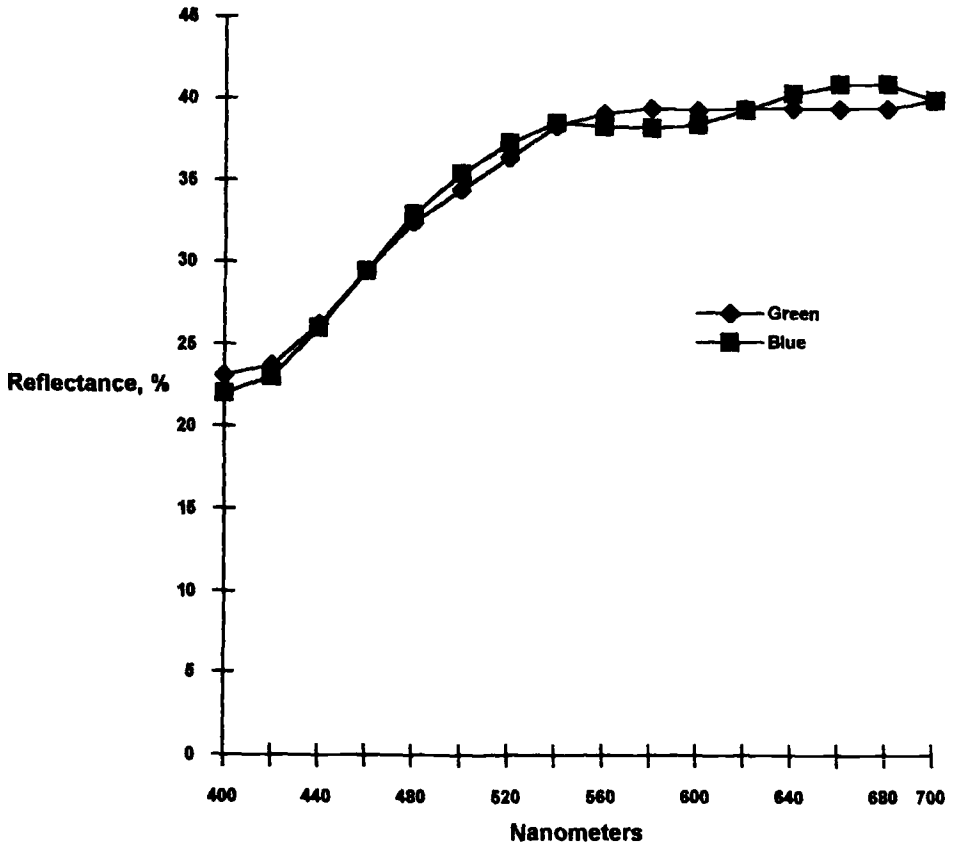

FIG. 2–Reflection as a function of wavelength at near the specular angle for a gold pearlescent pigment containing a blue or a green colorant.

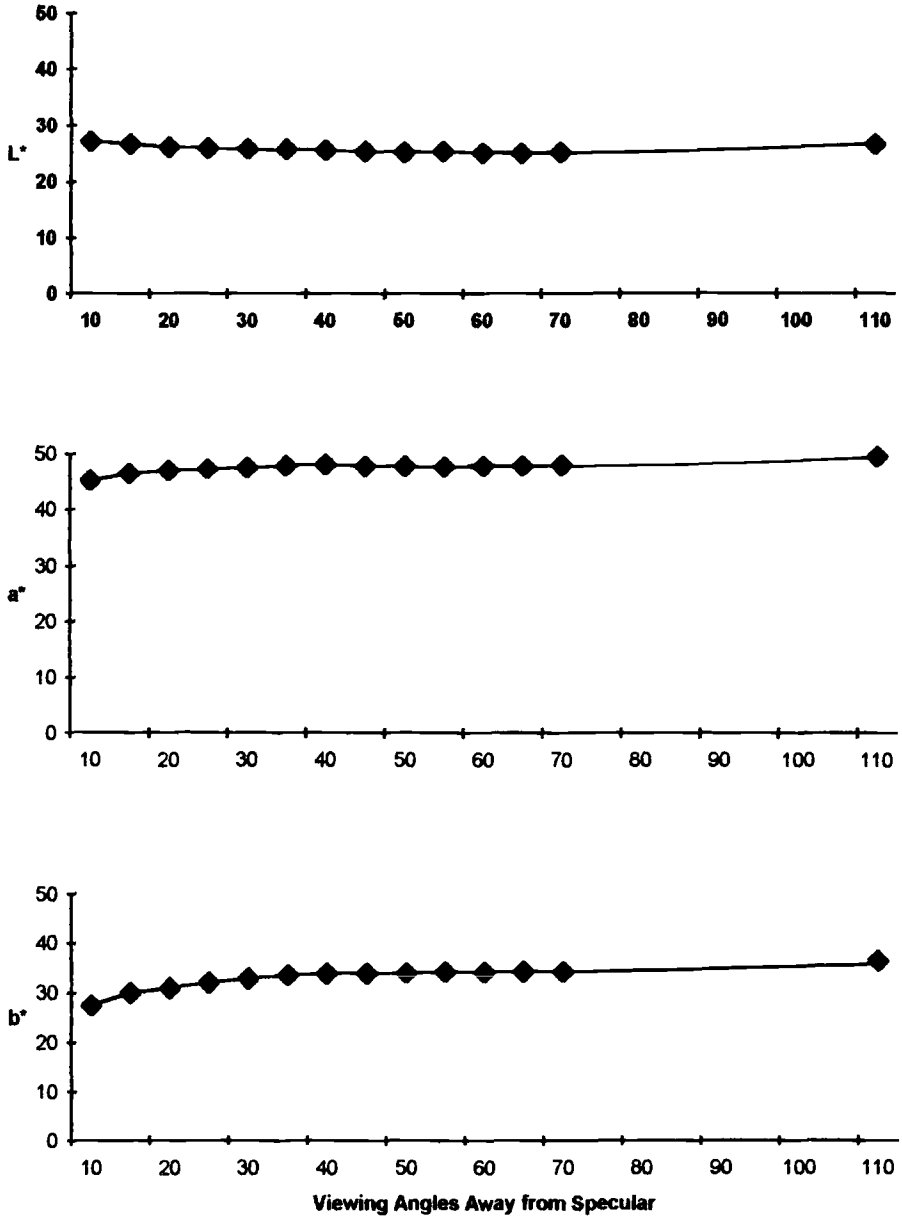

FIG. 4—Variation of color in a solid color-coated panel as a function of viewing angle.

weathering has proven to be reliable and capable of differentiating between the stabilized exterior grades and the untreated types generally used in plastics or inks.

Particle Size

Early methods for determining the particle-size distribution of pearlescent pigments involved manually counting particles viewed under a microscope. The microscopist usually counted about 1000 particles, grouped them in 5-μm intervals, and then created a distribution curve. The technique was tedious and time consuming, plus it did not give enough statistical data about the large particles.

More modern methods that have been tried include the Coulter Counter, automated sedimenters, and sieving. Most had difficulties because of the shape of pearlescent pigments, i.e., they are flakes with very thin thickness and very broad surfaces. These pigments are roughly the same size as metallic flake pigments, but they are much larger in size than organic colorants and most inorganic pigments. The most successful instruments found thus far for measuring particle size of these pigments are the laser diffraction types. These give good relative measurements. The numbers obtained, however, are not absolute values since the theory for these devices is based on spherical particles and not platelets. Calibration of these laser diffraction instruments with standardized glass spheres have shown them to be reliable and reproducible with pearlescent pigments.

As mentioned above, pearlescent pigments are classified into particle-size distributions for various end uses. Automotive coating sizes are carefully controlled by sieving to remove any particles over 50 μm. Such large particles can lead to

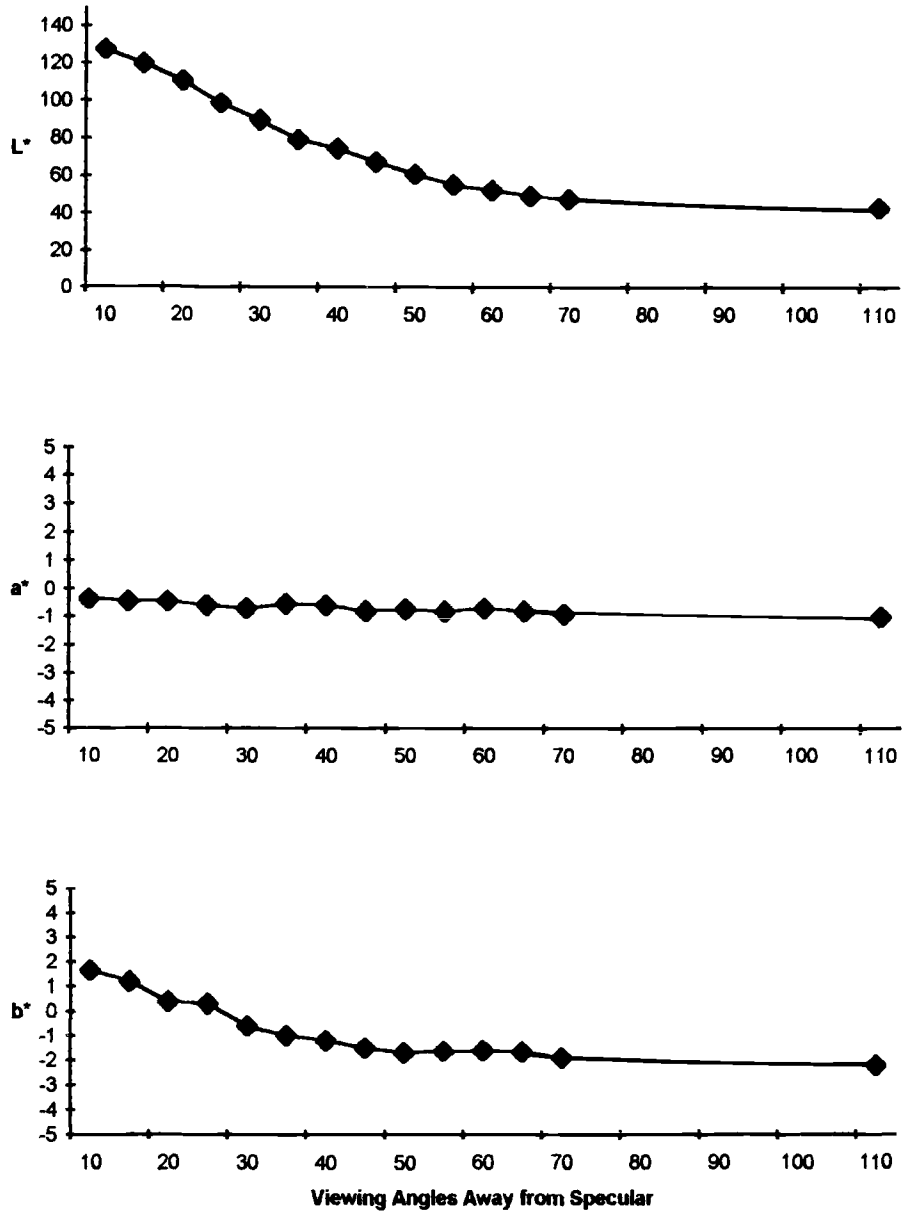

FIG. 5–Variation of color in a metallic flake-coated panel as a function of viewing angle.

clogging of filters in automotive painting operations. Very fine particle sizes are required for some applications such as offset ink formulations and some low solids, water-based coating systems. Particle sizes of pearlescent pigments range from about 5 to 20 μm for fine grades and up to 100 to 150 μm for the coarse grades.

Chemical Testing

Chemical testing of pearlescent pigments consists of analyses of the chemical composition, i.e., percentage of TiO_2 or ferric oxide (Fe_2O_3), of mica, and of other ingredients. Also, trace analyses for heavy metals such as lead, arsenic, Cr^{+6}, are done by atomic absorption, ICP instrumentation, and X-ray fluorescence. Both extractions in 0.5 *N* HCl and total dissolution methods are used in these analyses. Extraction methods usually give less than 20 ppm lead and 3 ppm arsenic in pearlescent pigments. Other tests performed include conductivity, pH in aqueous solution, specific gravity, bulk density, and, when a solvent is present, flash point.

HEALTH AND ENVIRONMENTAL CONSIDERATIONS

Pearlescent pigments are nontoxic and nonmetallic materials that do not exhibit the arcing and conductivity usually associated with metals. Lead and arsenic contents are less than 20 and 3 ppm, respectively. All ingredients are Toxic Substances Control Act (TSCA) listed. The health hazard rating for dry pearlescent pigments are:

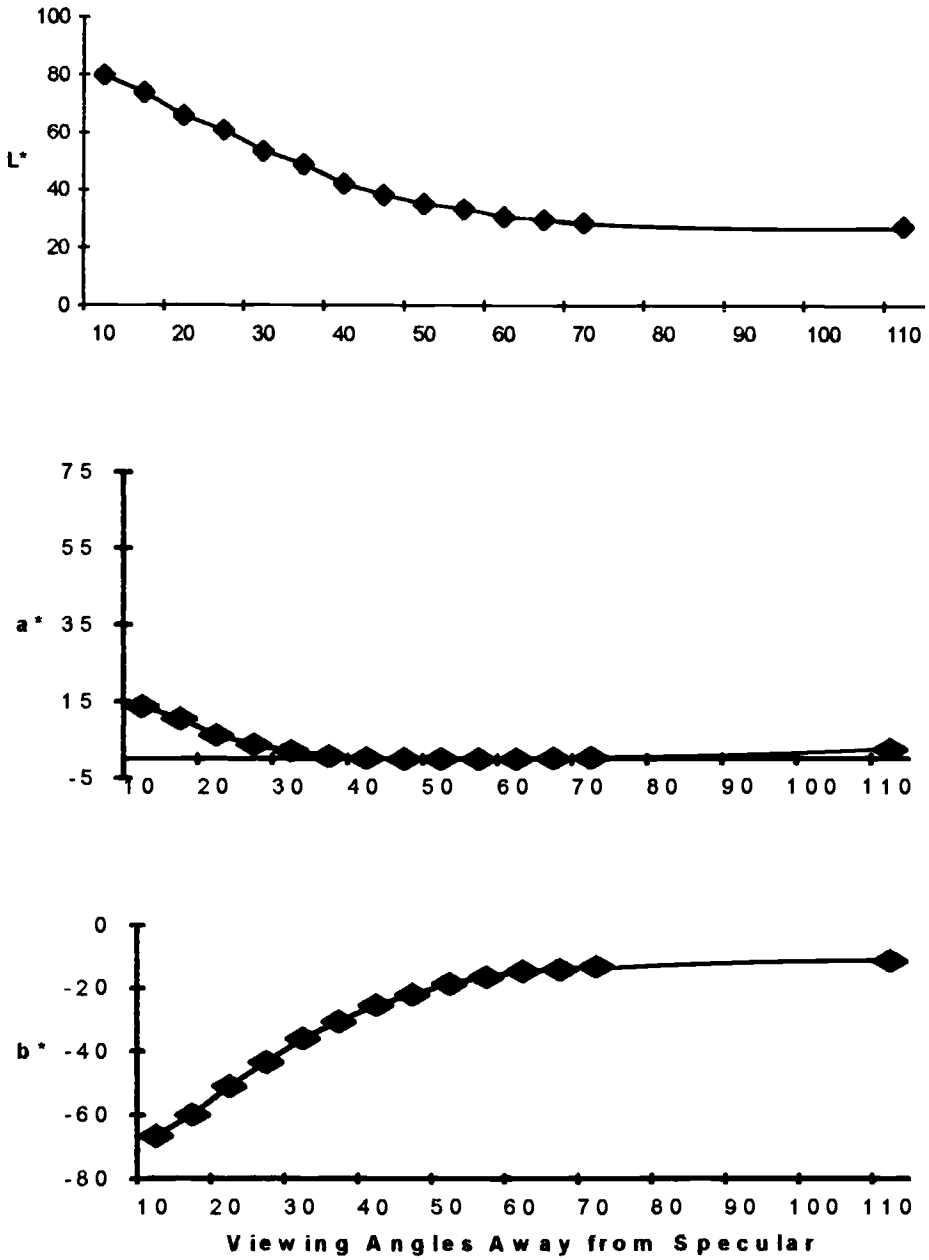

FIG. 6–Variation of color in a pearlescent pigment-coated panel as a function of viewing angle.

Health—O
Flammability—O
Reactivity—O
Personal Protection—E

If dusting occurs when handling the dry products, a dust mask should be worn. Several grades are also available in a "wetted out" form to produce nondusting products. Many pearlescent pigments have been used for years in cosmetic applications. These cosmetic grade pearlescent pigments have FDA approval for use as cosmetic ingredients and color additives.

Inorganic Anti-Corrosive Pigments

by M. Jay Austin[1]

WHAT IS CORROSION?

CORROSION IS AN ELECTROCHEMICAL PROCESS that takes place on the surface of metals, deteriorating them and—if not halted—destroying them. The process usually occurs in a liquid or gaseous environment and may take the form of a direct chemical attack, electrochemical reaction, electrolysis, or oxidation. During deterioration, the metal may form compounds or be taken into solution. The following factors must be present for corrosion to take place:

- A thermodynamically unstable metal.
- An electrolytic conductor of ions.
- An electrolyte (an electrical conductor such as a moist path).
- An electron acceptor.

If corrosion is extreme, the metal will, in essence, return to the more stable composition of its original ore, disintegrating into oxides, carbonates, and sulfates. For instance, the rusting of iron metal occurs naturally under atmospheric conditions, since rust, a hydrated form of the common iron ore, ferric oxide, is more stable than iron metal [*1*]. In this example, the unstable iron metal is also an electrical conductor. Salt water is usually the electrolytic conductor of ions, and dissolved oxygen is the electron acceptor [*2*].

Rates of corrosion vary, often depending on the electrolyte. Normally, metallic surfaces in contact with acidic solutions (such as salt water [*3*]) will exhibit the most rapid rate of corrosion; neutral solutions will be somewhat less corrosive and alkaline solutions the least corrosive. Metal may also corrode in the presence of soil or a dissimilar metal [*4*]. While many types of corrosion exist, this discussion is limited to the degradation which occurs when a metal's natural protective oxidative film is attacked and worn away.

Common examples of this sort of corrosion include the progressive red rusting of iron, the white rusting of zinc, and the tarnishing of copper.

THE USE OF COATINGS TO PROTECT METALS AGAINST CORROSION

Before the beginning of recorded time and ever afterward, mankind has battled corrosion with a multitude of methods and mechanisms. For our purposes, we will limit our discussion to examination of the following five mechanisms of protecting metals by using coatings:

- Barrier effect of film or vehicle.
- Barrier pigment effect.
- Sacrificial pigments.
- Vehicle enhancement (film formulation and development).
- Active inorganic inhibitive pigmentation.

Barrier Effect

Among the oldest inhibitive methods known, barrier coatings provide a protective, physical shield between a metal and air, moisture, or chemicals. While the composition and thickness of barrier coatings vary widely, they generally have a low permeability or moisture vapor transmission rate. As a rule, the lower the transmission rate, the less likelihood that oxygen and moisture will reach the substrate. Some common barrier coatings include organic paints and lacquers, metallic coatings (hot dip), and heavy mastics.

Barrier Pigment Effect

Pigments not only add color to coatings but can also protect metal from corrosion by reinforcing the film and limiting permeability. "Lamellar" pigments, for example, such as mica and micaceous iron oxide, form a wall of flat, thin particles within a paint film. These resist penetration, forcing water to wend a long, tortuous path toward the substrate (Fig. 1). Metallic flakes of aluminum, bronze, or steel produce similar effects.

Since not all pigments are compatible with all resin systems, care must be taken when adding pigments to a coating. In highly acid or alkaline environments, inert or chemically resistant pigments should be used.

Sacrificial Pigments

Zinc is a "natural" for use in protective coatings since zinc-rich coatings offer cathodic protection when applied to ferrous substrates, that is, the zinc acts as a cathode during the corrosion process, receiving the attack normally suffered by the ferrous metal [*5*]. To some degree, the duration of the pigment's efficacy is dependent on the thickness of the sacrificial coating.

Vehicle Enhancement

The formulation of a coating itself can add greatly to corrosion protection. The addition of pigments, for example, can

[1]Vice President and technical director, HALOX Pigments, a division of Hammond Lead Products, 1326 Summer Street, Hammond, IN 46320-2240.

Copyright© 1995 by ASTM International

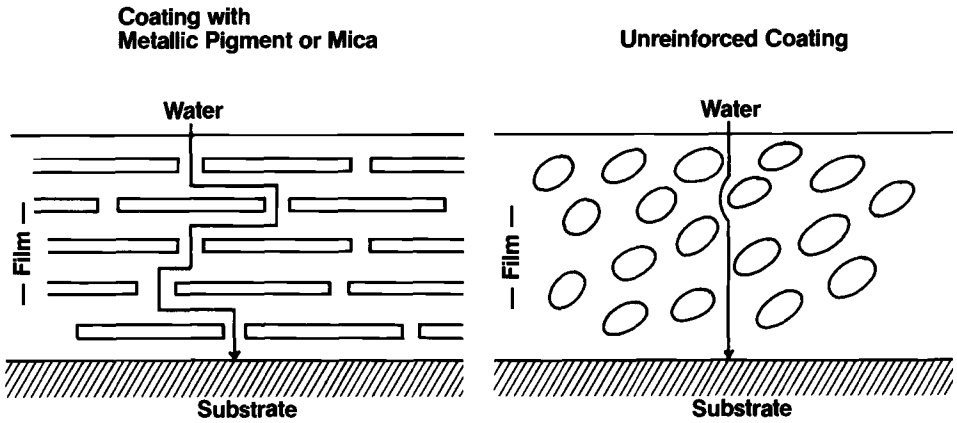

FIG. 1–Barrier pigment effect. Water takes a straight path through an unreinforced film, but is forced to take an extended path through lamellar particles of a metallic flake or mica-reinforced film (after Alan Smith, *Inorganic Primer Pigments* [*2*]).

help reinforce film structure and reduce permeability (as mentioned earlier). Some pigments, such as red lead, react with components in linseed oil/alkyd primers to produce lead soaps which increase the corrosion resistance of the paint film [*6*]. Other additives are used to enhance other coating or film characteristics, such as drying time, flow, adhesion, and mildew resistance. Binder selection and manufacturing methods may also be adjusted to offer maximum corrosion prevention.

Inorganic Inhibitive Pigments

The majority of this chapter will focus on the following active inorganic inhibitors: borates, chromates, leads, molybdates, phosphates, phosphites, and silicates. These pigments help prevent corrosion by increasing the likelihood of a chemical reaction which can produce a protective coating on the surface of a metal or otherwise foiling the chemical reaction between metal and corrosive solution. The ability to render a metal surface passive is called *passivation* and is covered here in two forms: (1) cathodic/anodic and (2) oxidative.

Cathodic and Anodic Passivation—Inhibitive inorganic pigments minimize corrosion in neutral solutions by acting as polarizing agents to retard the three elements of the corrosion process: cathodic reactions, anodic reactions, and ionic currents in the solution and the metal itself [*7*].

Since the cathodic and anodic processes are the basis for the corrosion process, control of these processes can play an important role in corrosion inhibition. The cathodic process consists of electrons passing from the metal to an electron acceptor, such as oxygen or hydrogen ions at the negative terminal, or cathode. In the anodic process, metal ions pass into the solution at the positive terminal, or anode (Fig. 2).

As polarizing agents, inhibitive pigments work in a variety of ways. Some slow the electrolytic process by retarding the reactions through *resistance polarization*, that is, by increasing a film's electrical resistance on the surface of the anode or cathode [*8*]. Some inhibitors, such as zinc, magnesium, and manganese, form insoluble deposits with hydroxyl ions in neutral solutions at the cathode. These deposits create a visible film on metal surfaces and help increase cathodic resistance polarization. Some inhibitors work in acid solutions, enhancing polarization by raising the concentration of positively charged hydrogen ions at the cathode.

Inhibitive pigments such as zinc chromate, phosphate, silicate, and borate suppress corrosion by enhancing anodic passivation in acid solutions. In neutral solution, the pigments are adsorbed onto the metal surface, reducing anodic activity.

Oxidative passivation—Though oxidation is usually thought to contribute to the deterioration of a metal, oxidation sometimes creates a protective layer on a metallic surface. Passivation can occur if a metal is oxidized to a stable compound that is part of the electrolyte [*9*]. Consider, for example, the protective layer of aluminum oxide on aluminum metal. The oxide minimizes atmospheric corrosion despite the reactive nature of the metal.

Strong oxidizing conditions are normally required for passivation to occur. Take the case of iron and nitric acid. Exposed to concentrated nitric acid, iron will develop a very thin inhibitive passive film; dilute nitric acid, however, will attack the metal [*10*].

Neutralization—Another mechanism of inhibitive pigments is neutralization of corrosive substances as sulfates, acids, and chlorides. This can often be achieved through the use inhibitors in a basic environment, which decrease the corrosive effect of acids and enhance the precipitation of corrosive elements.

SOME WELL-KNOWN INORGANIC ANTI-CORROSIVE PIGMENTS

Coatings industry suppliers are developing high-performance inorganic pigments to meet the growing demand for nontoxic inhibitive coatings that are both economical and highly effective. The section that follows discusses the chemistries, physical properties, functions, advantages, and disadvantages of some of the most common inorganic inhibitive pigments.

Wherever available, the specific gravity, color, pH, oil absorption, and water solubility of each pigment is recorded, supplied in most cases from pigment manufacturers' published data. Large discrepancies can exist between such data

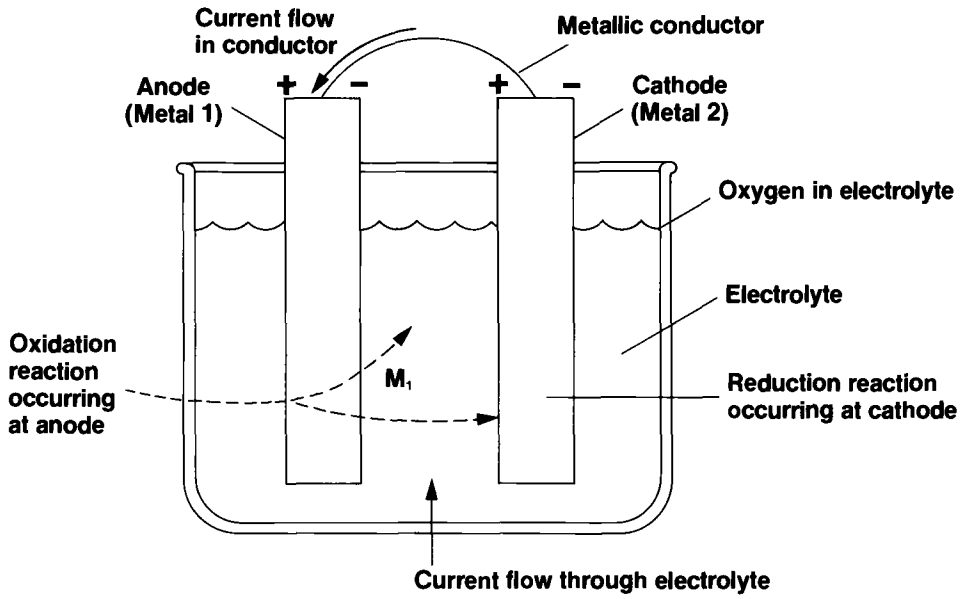

FIG. 2–Electrochemical corrosion. A simple cell showing the components required for cathodic and anodic corrosion processes (after Dean Burger, "Fundamentals and Prevention of Metallic Corrosion," *Corrosion and Corrosion Protection Handbook,* Philip A. Schweitzer, Ed., Marcel Dekker, Inc., New York and Basel, 1983).

and actual measurements, and verification of the published data is therefore recommended before any formulation project is initiated since significant differences in data can dramatically affect formulation performance. This author, for example, measured oil absorptions as high as 85 for some zinc chromate samples, although the published data report an oil absorption of approximately 25.

For the following pigments, *specific gravity* is expressed as g/cm^3; *color* indicates general appearance; *pH* is measured on a 10% slurry; *oil absorption* is expressed as g/100 g and normally determined by the spatula rubout method, ASTM D 281-84; and *water solubility* is expressed as percent soluble. Recommended loading levels for many of the pigments are also included for general formulation assistance, and these are expressed as a percentage of total weight based on typical paint density of 1200 g/L or 10 lb/U.S. gallon. If paint densities vary widely from these figures, simple extrapolations may be made.

Borates

A. Barium Metaborate ($BaO{\cdot}B_2O_3{\cdot}H_2O$) [*11-14*]

The grades shown in Table 1 indicate three grades of commercially available modified barium metaborate, the most commonly used borate inhibitor. Grade I is the primarily barium metaborate, and Grades II and III are modifications of Grade I which are said to decrease the reactivity of the pigment, thus increasing its formulation versatility. Grade II includes approximately 27% zinc oxide, and Grade III includes approximately 18% zinc oxide and 29% calcium sulfate.

Modified barium metaborates may be used in many kinds of applications in a broad range of solvent and water-based resin systems. The pigment's alkalinity contributes to inhibition, and the anodic passivation from the metaborate ion adds to the pigment's anti-corrosion performance.

TABLE 1—Typical properties of modified barium metaborates.

	Grade I	Grade II	Grade III
Specific gravity	3.30	3.70	3.30
Color	White	White	White
pH	10.0	9.1	10.0
Oil absorption	30	20	23
Water solubility	0.3%	0.2%	0.4%
Typical loading levels:	3 to 15%, based on total weight. Some heavy duty maintenance coatings may require up to 40%		

Barium metaborates are often considered environmentally acceptable alternatives to more traditional, toxic pigments; however, it must be remembered that soluble barium is an acute toxicant, and its presence in high levels may cause pigments to be classified as hazardous wastes.

The pigment has other disadvantages. As a soluble compound, it may be quite reactive with many systems. To control its solubility, it is often coated with a silica modification. When barium metaborate is formulated with certain acidic resins or acid-catalyzed baking systems, the resultant coating may exhibit stability problems. Therefore, care must be taken when formulating water-reducible and latex resin systems using this pigment to minimize its solubility and reactivity.

B. Zinc Borate

Zinc borate, usually used to provide flame retardancy in plastics and cellulosic fibers, is not normally thought of as an inhibitive pigment. However, recent research indicates that zinc borate, used in combination with modified barium metaborate or zinc phosphate, exhibits synergistic performance properties resulting in enhanced corrosion prevention. This

effect is most likely the result of the blended product's decreased solubility.

Chromates

Chromates have long been used as inhibitors since the soluble chromate ion is itself inhibitive and the chromate passivating ion is among the most efficient passivators known. Unfortunately, chromates are less widely used than in the past since hexavalent chromium pigments are either confirmed or suspected human carcinogens [*15*]. Evidence indicates that strontium, calcium, and zinc chromates are among the most carcinogenic forms of hexavalent chromium. Also, lead chromate is considered a suspected carcinogen by the American Conference of Governmental Industrial Hygienists (ACGIH), while zinc chromate is considered a confirmed carcinogen [*16*].

A. Zinc Potassium Chromate ($4ZnO{\cdot}6K_2O{\cdot}4CrO_3{\cdot}3H_2O$)

Specific gravity	3.45
Color	Yellow
pH	7.5
Oil absorption	25
Water solubility	0.1% [*17*]

This inhibitive pigment, also known as zinc chromate or zinc yellow, is the product of reactions among potassium dichromate, zinc oxide, and sulfuric acid. Versatile and highly efficient, zinc chromates are effective inhibitors even at relatively low loading levels. Because of their yellow color, they are generally limited to use as primers.

Although zinc chromates have a threshold limit value of 0.001 mg/m^3 and are therefore fairly toxic, these pigments are among the most widely used anti-corrosive products. In the United States, they still make up more than 30% of the entire inhibitive pigment market.

How do zinc chromates prevent corrosion? While the specific mechanism is not wholly understood, there are several theories on the subject, i.e.:

- Zinc chromates are anodic inhibitors.
- Zinc chromates improve the corrosion protection of the existing oxide film [*18*].
- The ferrous salts precipitated by zinc chromates contain a protective mixture of ferric and chromic oxides.

B. Zinc Tetraoxychromate ($ZnCrO_4{\cdot}4Zn[OH]_2$)

Specific gravity	3.65
Color	Yellow
pH	7.5
Oil absorption	53
Water solubility	<0.01%

Often referred to as basic zinc chromate, zinc tetraoxychromate is commonly used in the manufacture of two-package poly(vinyl butyryl) (PVB) wash primers, which consist of phosphoric acid and zinc tetraoxychromate dispersed in an alcoholic poly(vinyl butyryl) solution. These primers, also called etch primers or tie coats, are used to passivate steel, galvanized, and aluminum surfaces, improving the adhesion of topcoats. Because they are usually low in solids and are applied at fairly low film thicknesses, these wash primers have very poor hiding ability.

C. Strontium Chromate ($SrCrO_4$)

Specific gravity	3.70
Color	Yellow
pH	8.5
Oil absorption	35
Water solubility	0.05%

Strontium chromate is mainly used to prevent corrosion on aluminum, and primers containing this pigment are standard for the aviation industry. Strontium chromate is so effective at low loadings that it is often used to provide inhibition for coil coatings despite the fact that it is the most expensive chromate inhibitor.

The pigment is sometimes combined with zinc chromate in water-based formulations. In these cases, to avoid stability problems, loadings are kept at low levels, about 2% total chromate.

D. Other Chromate Inhibitors

Barium chromate, calcium chromate, and ammonium dichromate are also used to control corrosion and flash rust, but their use is very limited and merits no further discussion here.

Leads

Lead, though not a direct inhibitor, reacts with certain resin systems to form lead soaps which *are* active inhibitors. Lead pigments have proven themselves over the years to be outstanding anti-corrosives which perform particularly well over insufficiently prepared surfaces.

However, since it accumulates in body tissue, lead is generally considered an acute and chronic toxicant and has become the subject of strict environmental regulations, especially regarding waste disposal and worker protection. Although they are still used to produce heavy duty maintenance coatings and lead chromate colors, regulations have caused the use of lead pigments to decline.

A. Red Lead (Pb_3O_4)

Specific gravity	8.85
Color	Orange
pH	6.5
Oil absorption	6
Water solubility	<0.001%

One of the first recorded inhibitors and still one of the most effective, red lead has been widely used in primers for structural steel. The pigment is available in four grades containing from 85 to 98% Pb_3O_4.

While red lead is an oxidizing agent, its inhibitive mechanism is much more complicated than mere oxidation. When formulated with linseed oil, red lead forms soaps which, in the presence of water, release soluble lead compounds and organic acids. These soaps also improve the mechanical properties of the paint film and promote passivation through three mechanisms:

- Anodic adsorption of soluble lead compounds.
- Anodic adsorption of acid molecules.
- Anodic precipitation by oxidation [*19*].

Although soap formation is red lead's chief protective mechanism, use of the pigment is not restricted to oil-based paints. Epoxides, chlorinated rubbers, and vinyls are just some of the "oil-less" systems which are often formulated using red lead. There are questions regarding whether red lead functions as an inhibitor in these systems. It is more likely that the pigment exhibits the low oil absorption, pigment packing characteristics, and fine particle size of an ideal extender.

B. Basic Lead Silicochromate (BLSC)

Specific gravity	4.1
Color	Orange
pH	—
Oil absorption	14
Water solubility	<0.01%

Developed as a substitute for red lead, BLSC was once widely used in heavy duty maintenance coatings. It contains two active ingredients: monobasic lead chromate and gamma tribasic lead silicate. The former enhances the stability of the coating package and contributes a chromate ion, thus improving inhibition; the latter provides exceptional inhibitive characteristics.

BLSC offers several advantages over red lead:

- Reduced density minimizes problems with pigment suspension and settling and lowers the density of finished paint.
- Improved resistance to chalk and carbonation for better weather resistance and application in topcoats.
- Lower tint strength for a broader range of color formulation.

Because it contains both lead and hexavalent chromium, BLSC is no longer as widely used as it once was.

C. Other Lead Pigments

The following lead-based products have been used to inhibit corrosion in very specific or very limited applications: lead suboxide; basic carbonate white lead and lead cyanamide (mirror back coatings); basic lead silicate (electrodeposition primers); tribasic lead phosphosilicate; basic lead silicosulfate; dibasic lead phosphite; lead chromosilicate; lead sulfate; and calcium plumbate.

Molybdates

Molybdate-based pigments are anodic passivators, preventing corrosion by forming a protective layer of ferric molybdate on the surface. This layer is insoluble in neutral and basic solutions. However, since most commercial molybdate pigments contain zinc, the formation of inhibitive zinc soaps in oleoresinous systems may add to the anti-corrosive properties of molybdate products.

Although molybdate inhibitors are free of lead and chromate, they are limited in market value due to their expense. To make these more accessible, molybdate/phosphate compositions have been introduced, though these are difficult to disperse. Micronized versions of molybdate/phosphate are available to counteract the dispersion problem.

Following are the four most popular molybdate inhibitors available on the market today.

A. Basic Zinc Molybdate [20]

Specific gravity	5.06
Color	White
pH	6.5
Oil absorption	14
Water solubility	<0.01%
Typical loading levels	5 to 15%

Recommended for use in alkyds, epoxides, epoxy esters, polyesters, and other solvent-based resin systems.

B. Basic calcium zinc molybdate [21]

Specific gravity	3.0
Color	White
pH	8.5
Oil absorption	18
Typical loading levels	2.5 to 10%

Recommended for use in water-reducible and latex-based resin systems as well as two-component polyurethane and epoxy systems.

C. Basic Zinc Molybdate/Phosphate [22]

Specific gravity	4.0
Color	White
pH	5.5
Oil absorption	14
Water solubility	<0.01%

Recommendations are the same as for basic zinc molybdate. This product, however, is reported to provide enhanced performance over rusted steel substrates.

D. Basic Calcium Zinc Molybdate/Zinc Phosphate [23]

Specific gravity	3.0
Color	White
pH	7.5
Oil absorption	18
Typical loading levels	5 to 15%

This inhibitor, a mixture of basic calcium zinc molybdate and zinc phosphate, is reported to offer improved adhesion over ferrous metals. Recommended for use in both solvent- and water-based systems.

Phosphates

A. Zinc Phosphate [$Zn_3(PO_4)_2 \cdot 2H_2O$]

Specific gravity	3.2
Color	White
pH	7.5
Oil absorption	25
Water solubility	<0.01%
Typical loading levels	5 to 10% in water-based systems; 5 to 15% in solvent-based industrial systems; 10 to 30% in maintenance coatings

Zinc phosphate's formulation versatility has probably led to its status as one of the most widely used "nontoxic" inorganic inhibitors. Zinc phosphate can be readily used in a wide

variety of resin systems, including high acid number alkyds, water-reducible coatings, high-performance resins and acid-catalyzed baking systems. The pigment's low reactivity and low solubility give it a distinct formulating advantage over more basic, less stable nontoxic pigments.

Zinc phosphate is thought to inhibit corrosion in three ways:

- Through phosphate ion donation.
- By forming a protective anodic film.
- By forming anti-corrosive extracts in the presence of certain oleoresinous vehicles.

Zinc phosphate has a creditable track record of effective performance in real-world testing, but rates much lower in salt spray testing and other accelerated tests. This poor performance may be explained by the fact that salt water and high humidity often impair the performance of the pigment.

B. Modified Zinc Phosphates [24,25]

The coating industry has produced several variations of zinc phosphate that make use of other inorganic inhibitors and organic surface treatments to improve the pigment's performance in salt spray testing. The formulation versatility and recommended loading levels of these modified versions of zinc phosphate are about the same as those of standard unmodified zinc phosphate. Although the modified zinc phosphates appear to offer improved performance in accelerated testing, there is little evidence to uphold these claims in actual commercial applications.

Modified versions of zinc phosphate include:

Aluminum zinc phosphate—The higher phosphate content and solubility of this aluminum/zinc coprecipitated phosphate contribute to its enhanced corrosion inhibition.

Basic zinc phosphate hydrate—An organic surface treatment (claimed to be an electrochemically effective inhibitor) enhances the performance of this pigment.

Basic zinc molybdenum phosphate—This pigment makes use of a low level of molybdate (1.5%) to enhance inhibition.

Zinc silicophosphate hydrate—This pigment appears to be a complex composite of barium sulfate, silica, magnesium oxide, and sodium dichromate. Trace amounts of hexavalent chromium may account for the pigment's improved performance, but even these very low chromate levels could possibly present waste disposal problems.

C. Aluminum Triphosphate [26]

Available commercially in three grades (Table 2), aluminum triphosphate is a relatively recent chromate-free inhibitor. A condensation product, it is often modified with zinc ion or silicate to minimize its solubility and reactivity. Inhibition is thought to result from the tripolyphosphate ion's ability to chelate iron ions, as well as higher phosphate levels resulting from the depolymerization of the tripolyphosphate ion into orthophosphate ions. These pigments exhibit typical phosphate performance relative to loading levels.

Each grade is recommended for specific applications:

Grade I—For use in solvent-based primers (alkyds and epoxides). Grade I is modified with zinc and silicate.

Grade II—For use in solvent and water-based systems. The pigment's lower water solubility apparently makes it more suitable for water-based coatings. Grade II is modified with zinc and silicate.

Grade III—For solvent and water-based systems. Easier dispersion makes the pigment more effective in low build coatings. Grade III is modified with zinc.

TABLE 2—Typical properties of aluminum triphosphate.

	Grade I	Grade II	Grade III
Specific gravity	3.0	3.1	3.0
Color	White	White	White
pH	6.5	6.5	6.5
Oil absorption	37	32	30
Water solubility (max)	1%	1%	1%

Phosphites

A. Zinc Hydroxy Phosphite $\{[2ZnO(OH)_2 \cdot ZnHP_3O_3] \cdot X_2H_2 \cdot O$, where X = 1 to 17$\}$ [27]

Specific gravity	3.9
Color	White
pH	7.0
Oil absorption	18
Water solubility (Max.)	0.04%
Typical loading levels	10-25% in maintenance applications; 5-15% in general industrial and water-based applications

Zinc hydroxy phosphite (also called zinc phospho-oxide) results from the reaction between zinc oxide and phosphorous acid. Anodic passivation of the phosphite ion is the primary mechanism of inhibition, although the pigment's ability to form inhibitive zinc soaps in oleoresinous systems also contributes to corrosion prevention. While not recommended for use in high-acid-number or water-soluble resins, the pigment is compatible with a variety of resin systems.

Silicates

Silicate pigments contribute to corrosion inhibition in several ways, chiefly through anodic and cathodic passivation. In addition, in oleoresinous systems, these pigments form inhibitive soaps of barium, calcium, strontium, and zinc. The inhibitive value of silicate pigments is further enhanced by their alkalinity and solubility.

A. Calcium Borosilicate [28-30]

Available in three commercial grades (Table 3), calcium borosilicate is effective in a range of applications:

a. *Grades I and III*—Recommended for use in protective coating systems-based on traditional alkyd technology, these pigments differ primarily in their B_2O_3 content: 10.6% for Grade I and 15.6% for Grade III. They are generally used for such applications as trade sales, industrial maintenance, railroad and tank coatings, and shop primers. While they can be used in a variety of resin systems, including medium and long oil alkyds, epoxy-esters, and modified alkyds, they are not suited for use in high-acid-number resins, acid-catalyzed systems, water-based

TABLE 3—Typical properties of calcium borosilicates.

	Grade I	Grade II	Grade III
Specific gravity	2.65	2.71	2.65
Color	White	White	White
pH	10.1	10.1	10.1
Oil absorption	36	27	41
Water solubility (max)	0.35%	0.34%	0.37%
Typical loading levels	10–20%	10–20% in primers, 2.5–10% in topcoats and DTM finishes	10–20%

resins, epoxides, and other high-performance resins, or for immersion or semi-immersion service.

b. *Grade II*—This pigment, a low-oil-absorption version of the other two grades, is used primarily in high solids, medium gloss topcoats, direct-to-metal (DTM) coatings, and self-priming alkyd systems. PVC levels range from 40 to 45% in primers and 15 to 25% in topcoats and DTM coatings.

B. Phosphosilicates [31-34]

Four modifications (see Table 4), each representing a different commercial grade, are available for a variety of uses.

Calcium Barium Phosphosilicate (Grade I)—This pigment is for use in conventional and high solids solvent-based epoxy systems. The pigment is also used in organic zinc-rich primers as an anti-settling agent.

Calcium Barium Phosphosilicate (Grade II)—A low-oil-absorption version of this pigment, Grade II is for use in most water-borne systems, including latexes and water-reducible systems. When formulated in alkyds, this product, like many other phosphate pigments, will demonstrate excellent real-world performance, but poor performance in accelerated testing.

Calcium Strontium Phosphosilicate (Grade III)—This pigment is for use in most water-based acrylic lacquers, as well as water-reducible caulks and sealants. When the product used with zinc phosphate in water-based lacquer systems in a 1:1 ratio, a synergistic effect is produced which improves performance.

Calcium Strontium Zinc Phosphosilicate (Grade IV)—This grade is for use in a broad range of resin systems, including traditional and high-solid alkyds, latexes, epoxides, water-reducible alkyds, high-acid-number resins, vinylidene chloride latexes, and catalyzed baking systems. A recent development, Grade IV is the most versatile and effective of the phosphosilicate inhibitive pigments. Because of its fine particle size and low oil absorption, this pigment is effective in thin film applications and in systems requiring a high gloss.

TABLE 4—Typical properties of phosphosilicate inhibitors.

	Grade I	Grade II	Grade III	Grade IV
Specific gravity	2.97	2.97	2.90	3.01
Color	White	White	White	White
pH	7.9	8.3	7.8	7.0
Oil absorption	44.5	31.5	53.5	26.0
Water solubility	0.02%	0.02%	0.03%	0.02%
Typical loading levels	5–10%	5–10%	5–10%	2.5–15%

Miscellaneous Inhibitive Pigments

A. Ion Exchange Pigment

Specific gravity	1.8
Color	White
pH	9.2
Oil absorption	50 [35]

Claimed to be effective in all paint systems, this pigment uses the mechanism of ion exchange with corrosive species to prevent corrosion. Loading levels should be half the levels of typical corrosion-inhibiting pigments.

B. Zinc Oxide

Research has suggested that zinc oxide possesses both passivating and cathodic inhibitive capabilities [36,37]. Also, when used in latex metal primers and certain oleoresinous systems (such as SSPC Paint No. 25) [38], zinc oxide exhibits obvious anti-corrosive action.

Often used with more conventional active inhibitors such as zinc chromate and calcium borosilicates, zinc oxide appears to raise the cross-link density of many paint films, making them harder. Zinc oxide may also absorb ultraviolet light, thus protecting the resin. Since the pigment tends to have seeding problems and can cause film brittleness, care must be taken when using zinc oxide in inhibitive coating applications.

Zinc Metal in Primers

The prime focus of this discussion is inorganic inhibitive pigments which function through the mechanism of soluble inhibitive species; however, zinc metal—which functions through the mechanism of cathodic protection—deserves a brief mention.

In many applications, including the protection of steel structures, zinc-rich coatings offer the best corrosion inhibition available, especially when topcoated with either epoxy or urethane. Actual particles or flakes of zinc in the paint film protect the ferrous substrate by acting as the anode and corroding sacrificially. While the correct loading level of zinc metal in zinc-rich primers is still a matter of debate, these coatings usually contain 80 to 85% zinc metal. Zinc-rich primers can be formulated as inorganic coating systems (ethyl silicate binders) or organic systems (such as epoxides).

Zinc-rich primers require near-white blast surface preparation and must be fully cured before topcoating. Two major problems associated with zinc-rich formulation are pigment settling and hydrogen gassing.

Barrier Pigments

A. Aluminum Flake

Aluminum flake, typically supplied as a slurry, is produced by atomizing molten aluminum and ball-milling the powder into a solvent. The resultant flake is frequently used to improve the appearance and anti-corrosion performance of

coatings for tanks, bridges, roofs, railroad cars, automobiles, and office equipment.

Coatings containing aluminum flake stand up well to heat and moisture. They also resist the damaging effects of ultraviolet light, cooling the substrate and preventing deterioration of the binder.

Aluminum flake is available in two grades, leafing and nonleafing. A stearate coating on the leafing grade allows the pigment to float on the surface of a paint film. Because this coating is also associated with intercoat adhesion failure in primer coats, leafing grade aluminum flake is normally used in topcoat formulations. Typical loadings range from 20 to 25%. A disadvantage of using aluminum flake is that the pigment is very reactive with water, and hydrogen gassing may occur if moisture levels are not maintained below 0.15%.

B. Steel Flake

Stainless steel and a number of steel alloys are sometimes used to make steel flake, which is used in coatings for applications requiring maximum resistance to abrasion.

C. Micaceous Iron Oxide (MIO)

Specific gravity	4.9
Color	Dark Gray
Oil absorption	11
Typical loadings	30-50%

A naturally occurring form of hematite with an Fe_2O_3 content of about 92 to 95%, MIO has been used in protective coating formulations for over 100 years. Because of its lamellar structure, it is typically used in primers to improve their barrier resistance. Used in topcoats, MIO enhances resistance to ultraviolet light.

ENVIRONMENTAL CONSIDERATIONS

Health and safety factors have always been seriously considered during the development and evaluation of new protective coatings. Use of lead, hexavalent chromium compounds, and other toxic pigments is constantly monitored to ensure that current, acceptable limits are met. Environmental regulations have driven the inhibitive coatings industry to increase efforts to develop and evaluate new, nontoxic products to replace lead, chromates, and traditional inhibitors with long-standing performance records.

Two primary environmental concerns within the industry are worker protection and waste disposal. Several steps have been taken to ensure worker safety. For example, all workers have the right to know the dangers involved with handling the materials they are exposed to every day and the right to be offered the capability to handle these materials safely. Because absorption of toxic pigments through inhalation is a major concern, workers are protected by engineering controls (ventilation), respiratory controls (masks, filters, and other equipment), and extensive safety training. The preferred option is to completely eliminate the hazardous material and substitute a less toxic pigment, if possible.

Waste disposal pertains to plant waste produced by paint manufacturing and waste from painting operations. The latter includes overspray and spent blast abrasives contaminated with lead and chromate-based pigments. Under these regulations, containment and disposal of these materials could well increase the cost of a typical maintenance repainting project by tenfold. Regulations concerning the disposal of industrial wastes in the United States are strict, due in part to revisions of the Drinking Water Regulations of the Safe Drinking Water Act, which is an effort to prevent contamination of the water supply.

The coatings industry is under legislative pressure to develop environmentally acceptable, high-performance, long-lasting replacements for lead and chromate-based pigments and reduce levels of VOC. These are not easy tasks. Some of the formulation and application factors which affect the industry's efforts at compliance have already been discussed; the following is a look at some of the stringent techniques in use to evaluate the performance of new, less toxic inhibitors and protective coatings.

HOW FORMULATION AFFECTS THE PERFORMANCE OF INHIBITIVE PIGMENTS

When formulating with inhibitors, a host of formulation factors must be taken account since these factors often determine the selection of inhibitive pigments and greatly affect the development of inhibitive coatings. The most critical formulation factors include PVC (pigment volume concentration), selecting an extender pigment, solubility and reactivity (that is, selecting a vehicle and understanding how its components interact), and the complex interrelationships between all these factors.

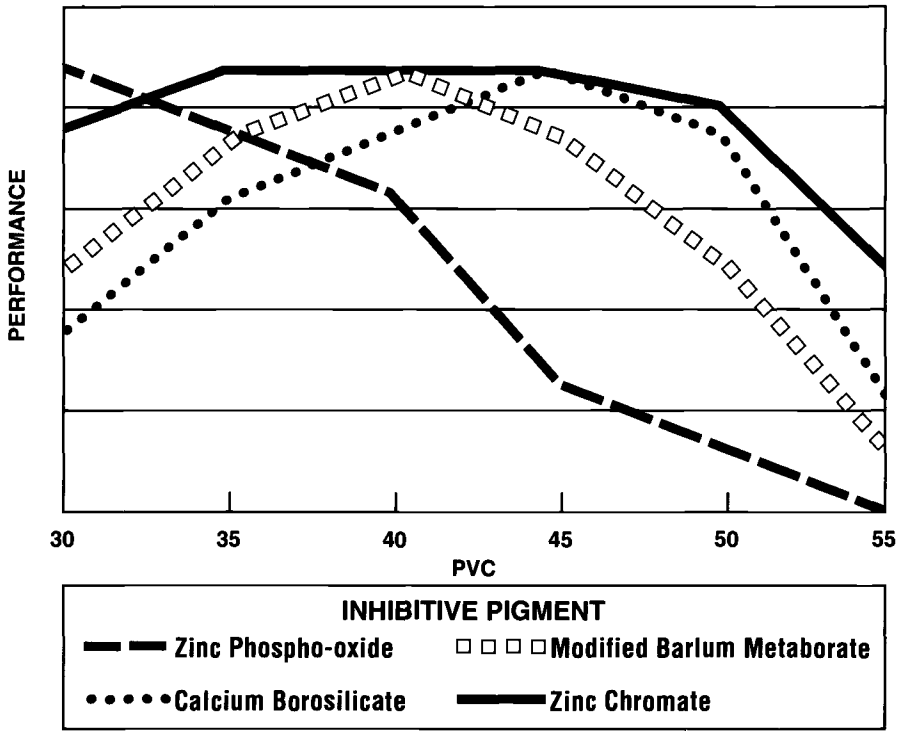
Pigment Volume Concentration

Pigment volume concentration (PVC) is the ratio of pigment volume to the total nonvolatile volume in a coating. Probably the most important formulation factor to consider when evaluating anti-corrosive pigments, PVC is especially crucial when two or more inhibitors are being considered for a given application.

Essential to the understanding of the importance of PVC is the concept of a "formulation window." This term represents the PVC range at which an inhibitive pigment will give its best performance and is clearly depicted in Fig. 3. Here, the performance in a salt fog cabinet of three popular chromate-free inhibitors is compared to that of zinc chromate in a medium oil alkyd primer. Loadings are equal—about 10% of total formula weight—across a PVC ladder at constant volume solids.

In the figure, the three nontoxic inhibitors each yielded performance equivalent to zinc chromate, but only within a specific PVC range, a rather narrow formulation window. Conversely, zinc chromate offered far greater formulation versatility, performing over a much broader PVC range.

The figure illustrates both the importance of addressing the variable of PVC and poses a problem facing the formulator: None of the environmentally acceptable inhibitors—including the three in the figure—come close to matching the traditional lead and chromate-based pigments for overall efficiency and formulation flexibility. While each of the three chromate-free inhibitors was formulated to equal the per-



PVC Loading Levels (Formulation Windows) of Chromate-free Inhibitors and Zinc Chromate

FIG. 3—Medium oil alkyd PVC ladder: salt spray performance. Formulation windows of four inhibitive pigments.

formance of zinc chromate, each performed at a much narrower formulation window, thereby severely restricting its use.

Many factors influence the formulation window of an inhibitive pigment in a given formulation. All these factors must be satisfied to maximize the performance of an inhibitor. Crucial factors to consider in association with PVC are: (1) specific gravity, oil absorption, and other physical properties of an inhibitor; and (2) the effect of these properties on CPVC (critical pigment volume concentration).

The concept of CPVC, introduced in the late forties, postulates the existence of a level of pigmentation in a dry paint film at which there is just enough binder to coat the pigment particles and fill the spaces between them [*39,40*]. Since many nontoxic inhibitors are lower in specific gravity and higher in oil absorption than more traditional inhibitors, it is easy to formulate anti-corrosive coatings which exceed CPVC and therefore deliver unacceptable levels of inhibition. To avoid this situation, it is necessary to evaluate inhibitive pigments across a PVC range to achieve optimum performance. To do this, coatings should be made at each extreme of the PVC range; then weight blends of these paints may be used to generate the intermediate levels.

Inhibitor Loading Levels

In the "old days" of inhibitive coatings formulations, before the advent of environmental regulations, the rule of thumb was to add as much inhibitive pigment as possible. The assumption: if a little was good, then a lot must be better. This "rule" worked as long as formulators used red lead and other lead-based pigments whose very high specific gravities and low oil absorptions permitted relatively high loadings. When large amounts of nonlead inhibitors are used in formulations, the resulting coatings often perform well in accelerated corrosion tests. However, most nonlead inhibitors are much more reactive in vehicle systems than lead-based inhibitive products, and this reactivity can lower the actual performance of coatings formulated with high inhibitor loadings.

In general, inhibitor loading should be carefully balanced, keeping in mind that more is not necessarily better, at least as far as less-toxic, more-reactive inhibitors are concerned.

Comparing inhibitive pigments—Certainly not as straightforward a matter as comparing apples to oranges, comparing pigments may be accomplished in several different ways: on the basis of equal volume, equal weight, equal cost, or equal performance. The choice of method can drastically affect the results of a formulator's evaluations.

Equal Volume—This is the easiest evaluation method and by far the least desirable. Replacing a given volume of one inhibitor with the same volume of another is simple and requires the least number of formulation changes. However, the wide variations in specific gravities of inhibitors (from a low of 2.5 to a high of 9.1) and oil absorptions, which vary from 10 to 70, make the results of these evaluations highly questionable.

Equal Weight—This is a valid method of evaluating inhibitors with loading levels equal to or exceeding 120 g per liter

(1 lb/gal). Care must be taken to adjust the levels of extender pigment and vehicle solids when replacing one inhibitor with another. This is to ensure that the inhibitors can be compared at a constant loading level over a given PVC range at constant volume solids.

Equal Cost—This method is valid if the inhibitor levels are less than 120 g per liter (1 lb/gal), as long as comparisons are conducted at a constant loading level over a PVC range at constant volume solids.

Equal Performance—The most tedious approach, this method ensures the most cost-effective formulation possible. Basically a combination of simultaneous evaluations of a PVC ladder and an inhibitor loading ladder, this approach permits the formulator to evaluate each inhibitor for its optimum formulation window.

Extender Pigments

Although a wide choice of extenders is available for inhibitive coatings formulation, extender selection traditionally has not received much attention. This may be the result of the former widespread use of lead and chromate-based inhibitors, whose excellent performance masked any flaw contributed by an extender. With emphasis on environmentally acceptable (and less effective) inhibitors, however, selection of suitable extenders is an important factor in the formulation of inhibitive coatings.

Figure 4 contains the results of work in latex maintenance coatings. The data here clearly show that the performance of extender pigments depends to a great extent on the type of vehicle and inhibitor used in the formulation, that is, the performance of extenders will vary from system to system. Selecting the appropriate extender, therefore, may be as crucial to coating performance as selecting the vehicle system or inhibitive pigment [*41*].

Reactivity and Solubility

Inhibitors should be carefully selected for compatibility with given coating systems to prevent common formulation problems arising from reactivity and solubility. For example, a pigment must have some solubility within a given system in order to participate actively in passivation. Also, a highly reactive pigment can react with binders and other ingredients in a coating system, causing instability. Adverse chemical reactions between the inhibitor and the vehicle in the can or the cured paint film can effect coating properties such as viscosity, drying time, cure, adhesion, and weatherability. Therefore, inhibitive pigments must be chosen carefully to prevent these formulation problems [*42*].

Some chemical reactions, such as the reactions between basic pigments and acid catalysts, neutralize inhibitive action by preventing film cure. Some reactions may even accelerate corrosion. Others may do good or harm, depending on *where* they occur. For example, the formation of metallic soaps on a paint film caused by a reaction between red lead and linseed oil acids promotes corrosion inhibition; however, if this same reaction occurs in the paint can, viscosity may increase to the point that the liquid paint becomes unusable.

Generally, inhibitive pigments retard or prevent blistering caused by corrosion in pinholes or scribes or by moisture drawn into the paint film by electrical activity of the corrosion cells. But use of inhibitors may lead to osmotic blistering, especially during humidity and condensation testing. Osmotic blistering is caused by the presence of water and soluble pigment at the juncture of the substrate and the coating film [*43*]. To prevent this condition, low-solubility pigments should be used.

APPLICATION AND PROTECTIVE COATING PERFORMANCE

Coating application (how, where, why, and for how long a coating will be used) must be carefully considered when formulating environmentally acceptable alternatives to traditional toxic inhibitors. The length of time a protective coating can effectively protect a ferrous surface has been said to

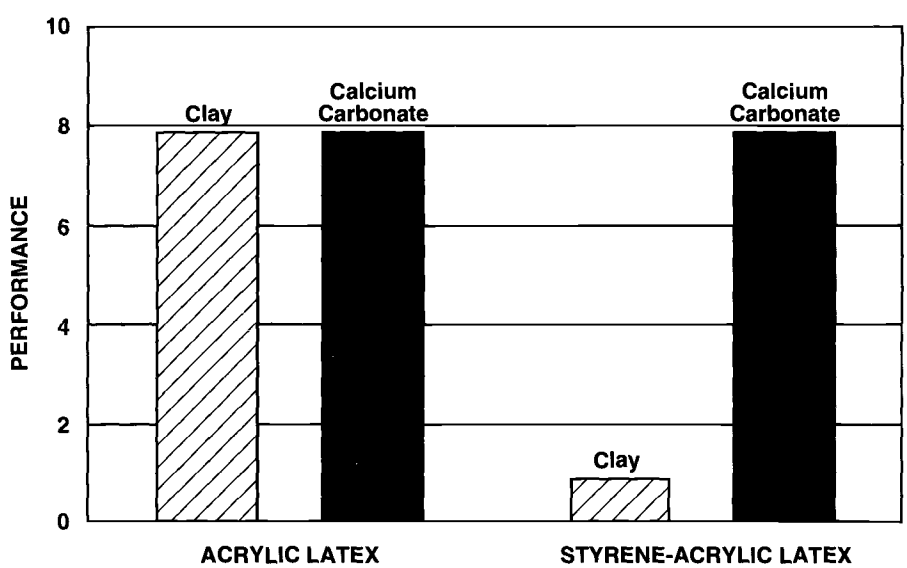


FIG. 4–Extender performance properties: accelerated performance measurements.

depend on the following application factors: the environment, how the coating is applied, the substrate, and the surface preparation of the substrate [*44*].

Consider the environment where the inhibitive coating will be used: Will the coating be exposed to harsh chemicals, abrasion, industrial atmospheres, heavy traffic, high heat, or other extreme conditions? Or will it be used in a rural setting, exposed to the elements? Answering these questions will help determine the proper vehicle system and application techniques to be used with the coating.

Other factors to consider when deciding how to apply a protecting coating include the type of applicator (brush, roller, spray, or dip), adequate and uniform film thickness [*45*], drying time, and temperature. Though application techniques are often given little attention, they can profoundly affect the performance of a protective coating.

Substrates are also important factors in testing protective coatings and inhibitive pigments. For example, untreated cold rolled steel generally shows more undercutting at scribes than sandblasted hot-rolled steel or treated steel. Because it is easier to differentiate between pigments on untreated steel, that substrate is frequently used to compare the performance of different inhibitive pigments. On the other hand, use of a phosphatized substrate seems to improve the performance of protective coatings, apparently enhancing adhesion, passivating the surface, and improving the coating's inhibitive properties.

A word of caution: When selecting substrates for testing inhibitive coatings systems, care must be taken to conduct final evaluations of a system on the substrate that the coating will be applied to in actual use. For screening purposes, however, evaluations may be conducted on any appropriate substrate.

Protective coatings are frequently applied to the following ferrous substrates [*46*]: cold-rolled steel; polished cold-rolled steel; zinc phosphate-treated cold-rolled steel; iron phosphate-treated cold-rolled steel; hot-rolled steel; abrasive blasted hot-rolled steel; pre-rusted hot rolled steel, and galvanized steel.

No matter what the substrate, the surface preparation of the substrate, or its condition, is vital to the evaluation of protective coatings and an important factor in determining the life expectancy of a coating system. In addition to cleaning a surface, improving adhesion, and maximizing the performance of the inhibitive pigment, surface preparation helps remove contaminants—such as chlorides and sulfates—from the substrate's surface [*47*].

Though many methods of surface preparation exist, their effectiveness varies widely. For example, studies suggest that a protective coating will last four times longer on a blasted surface than on a hand-cleaned or weathered substrate [*48*]. This improved longevity is attributed to better adhesion and a more intimate contact between substrate and coating, which allows the inhibitor to maximize its performance.

Some of the commonly used surface cleaning techniques are [*49*]: centrifugal blasting; metallic and nonmetallic abrasives; abrasive air blasting and water blasting; by hand and power tools; chemicals; pickling. Less common methods include hot gas, flame, bacterial, zinc shot, ice particles, and ultrasonic.

EVALUATING INHIBITIVE PIGMENT AND COATING PERFORMANCE

Pigment and coating evaluation techniques—especially accelerated laboratory tests—are more important now than ever before. The reason: Users and manufacturers alike demand that new inhibitive products not only meet environmental regulations, but also meet or exceed the performance standards set by established, environmentally unacceptable pigments. This discussion will deal with the two principle methods of evaluation used by the coatings industry: accelerated testing and "real-world" (natural atmospheric) testing.

Accelerated Corrosion Testing

In real-world applications, protective coatings are often expected to provide up to 20 years of service. Accelerated testing attempts to predict the life expectancy of a protective coating in a short span of time, from half a year to a year. This evaluative "fast forwarding" meets the needs of manufacturers and users alike, who demand prompt development and commercialization of new products. Though several kinds of accelerated testing procedures are in use, all have essentially the same purposes: to significantly shorten the time needed for a coating to fail and to evaluate the causes of its failure.

Although accelerated corrosion testing is the most commonly used evaluation method for inhibitive pigments and protective coatings, the results of accelerated tests correlate poorly with the results of real-world testing. Because of this, the validity of accelerated testing, particularly the salt spray test, has been the target of serious doubts and questions. Is accelerated testing relevant to real-world conditions? Do the tests accurately predict product performance? Evidence is growing to support the theory that many formulation variations used to enhance a coating's salt spray performance may actually detract from the coating's real-world performance.

It has already been demonstrated that, in many cases, accelerated testing is an unreliable predictor of a coating's long-term protective performance. Figure 5 clearly illustrates this deficiency, depicting salt spray results which totally contradict the results of natural exposure testing for two protective coatings.

Despite such strong evidence against the reliability of the salt spray test, its popularity continues. For good or bad reasons, it is the driving force behind the establishment of performance evaluation criteria for many protective coating systems and is often the *only* criterion used to evaluate an inhibitive coating. In some cases, raw material suppliers are forced to offer products based solely on their salt spray performance, often without regard to the coatings' performance in the real world. Another section of this book discusses this situation further and details the research the industry is doing to address the problem.

Real-World Corrosion Testing (Natural Atmospheric Exposure Testing

Considered by many researchers to be the most dependable method of predicting the performance of a protective coating, real-world testing exposes products to real-time, actual atmospheric conditions. In essence, the tests approximate the types of environments for which the coatings were designed.

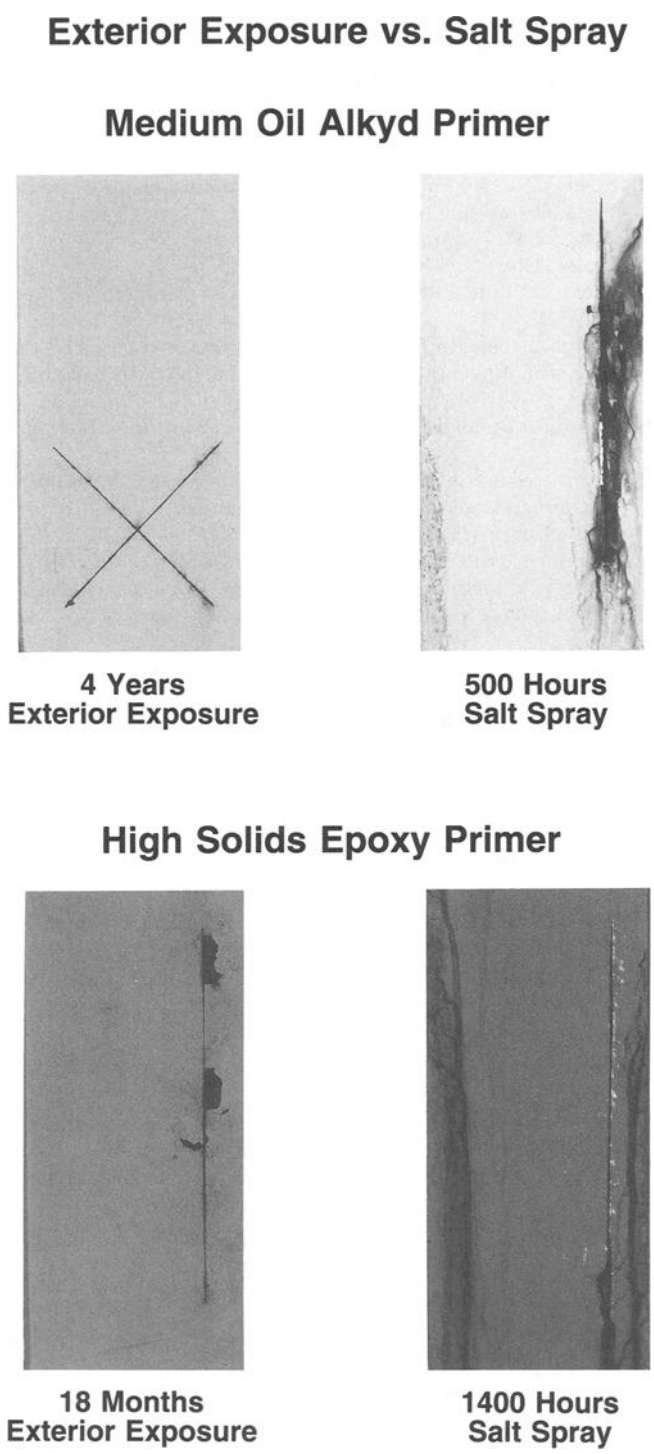

FIG. 5—Protective coating performance data.

Despite their excellent ability to measure and predict anti-corrosive coating performance, outdoor exposure tests have four obvious disadvantages compared to accelerated tests [*50*]:

1. *Long Duration*—Monitoring the degradation of protective coatings is a marathon task lasting from 5 to 20 years. To accelerate the rate of failure in outdoor exposures, testing labs have exposed the paints to very harsh environments or applied the coatings at lower-than-recommended film thicknesses. Neither of these procedures are effective, however, since neither represents the application for which the coating was designed.
2. *Lack of Controls*—Establishing controls and measuring a coating's consistency of performance is a real challenge in real-world testing. In outdoor exposures, environmental factors such as temperature and humidity change from year to year at the same site, making reproducible results next to impossible.
3. *Multiple Stresses*—Because a coating exposed to an outdoor environment encounters many stresses, it is not easy to determine the effects of each individual stress.
4. *Varying Environments*—In outdoor testing, establishing a standard test environment is virtually impossible. Environments vary dramatically from one part of the country to the other, from desert to seashore, from mountains to alluvial plains. Local industries and fluctuations in weather patterns also contribute to the problem.

In spite of these drawbacks, real-world testing is emerging as a viable alternative to traditional accelerated testing. Even comparatively brief exposures of six to eight months can yield important data. However, the value of these data depends on sound experiments and proper evaluation techniques. Formulators can no longer depend on "one paint/one panel" test designs.

Statistical Analysis

Another method of correlating performance data and predicting coating performance is the use of statistical analysis, which is growing in popularity. Various techniques used to design more meaningful, accurate evaluations include correlation methods, survival analysis, curve fitting, time series analysis, and reliability and life analysis.

Several techniques have been developed for assessing macroscopic damage to protective coatings. Though coatings have traditionally been assessed by visual inspection, these procedures can apparently detect early stages of corrosion, giving more relevant, accurate information in a shorter exposure period.

RECENT TRENDS AND DEVELOPMENTS

New Product Development

The Federation of Societies for Coatings Technology (FSCT) monitors the development and performance evaluations of many new products, many of which reflect the trend toward less toxic inhibitors [*51*]. Another growing trend is the development of products with lower oil absorption, necessary for the formulation of high solids vehicles.

Because proper use of auxiliary extenders can enhance inhibitive properties of protective coatings (especially those incorporating nontoxic inhibitors), the trend toward developing auxiliary extender pigments is likely to continue. Auxiliary pigments are standard extenders modified by surface treatments of silanes, titanates, ziconates, and other compounds. Some commonly used auxiliary pigments include calcium carbonates, clays, talcs, silicas, and wollastonite.

Other Testing Procedures

Driven by changing regulatory standards and the industry's need for prompt product development, a variety of alternative accelerated testing procedures are being researched and developed. The challenge is to make accelerated testing accurately reflect real-world conditions and yield meaningful, realistic results. The Corrosion Committee of the Federation of Societies for Coating Technology (FSCT) commissioned a survey [*52*] on this subject directed to manufacturers and users of protective coatings. The results of the survey showed that the participants were exploring the use of the following kinds of modified accelerated testing techniques: (1) cyclic tests; (2) cyclic natural exposures; (3) electrochemical testing; and (4) physico-chemical, physical, and mechanical testing procedures.

The Steel Structures Painting Council (SSPC) is evaluating the most promising of these accelerated cyclic corrosion tests. The survey itself is too extensive to be included here but is readily available from the FSCT.

CONCLUSION

Before the beginning of recorded history and ever since, protecting ferrous surfaces from the disintegrating effects of corrosion has been one of mankind's most common and perplexing battles. From the lead compound Homer's blacksmiths smeared on their wagon wheels to the sophisticated protective coatings used today, the science of preventing corrosion is as complex as the corrosion process itself. Over the years, many factors have arisen which demand consideration: substrate selection, surface preparation, vehicle and pigment selection, and PVC, to name just a few.

Now the coatings industry is engaged in a new approach to the age-old corrosion-protection problem: developing effective new nontoxic inhibitors to take the place of traditional lead and chromate-based pigments. The research is well underway, and the next ten years may well see the widespread acceptance of these safe, high-performance alternatives. This progress will be accomplished not by scientific curiosity or commercial demand alone, but also by concern for the protection of our fragile human habitat.

Oil Absorption of Pigments*

by Joseph V. Koleske[1]

MIXING A PIGMENT WITH LINSEED OIL and making a paste is a preliminary test applied to pigments that has been in use in a systematic manner for almost a century and perhaps even longer in a less defined manner. Results from the test are usually qualitative in character and give an approximation of color and texture. If the test is conducted in a quantitative manner, the amount of oil needed to make a stiff paste is obtained. It has been felt that the oil absorption test is a measure of an oil-based paint's resistance to flow or consistency. For example, Mills [*2*] indicated that if equal volumes of "oil absorption paste" are mixed or thinned with equal volumes of thinners, the paints prepared have equal resistance to flow, viscosity, or consistency. Also, Stieg [*3*] found that if the oil absorption value is determined by the ASTM rub-out method (described below) and expressed on a volume basis, it is proportional to the critical pigment volume concentration. This test is also related to the pigment packing factor (PPF) and critical pigment volume concentration (CPVC).

MECHANISM

When the oil absorption test is performed, the surface of each pigment particle is wet and saturated to a certain extent with oil and thus is encased in an oil shell that has been estimated to be as thick as eight molecules [*3,4*]. The amount of oil needed depends on the specific pigment area, which is a function of particle size, roughness, and porosity. With temperature and humidity constant, the oil adsorption value depends on the duration and vigor of the rubbing operation and on the affinity of the oil for the pigment. As oil is added beyond the particle encasement stage, the interstices between the oil-encased particles become filled with oil. The amount of oil required for this stage of the test is a function of the type packing taken on by the particles. Packing can range from rhombehedral to cubic. In addition, the presence of aggregates, which are clusters of pigment not broken up by the rubbing process, and agglomerates, which are clusters of pigment formed after the pigment has been wet, have an effect on the amount of oil needed. Agglomeration is affected by the nature of the oil, and linseed oil that meets ASTM D 234: Specification for Raw Linseed Oil [*5*], except that it should have an acid number of 3 ± 1, is used. More extended discussions of oil absorption theory and practice can be found in the literature [*6–10*].

METHODS FOR DETERMINING OIL ABSORPTION

There are two ASTM methods for determining oil absorption that will be described briefly as well as related methods that, for the most part, are tabulated and referenced (Table 1).

Gardner-Coleman Method

This classical method or some variation of it [*11*] has been in use for about three quarters of a century. The current method, ASTM D 1483: Test Method for Oil Absorption of Pigments by Gardner-Coleman Method [*12*], has been in use for over 32 years. In this test, a soft paste is formed from the pigment by drop-wise addition of raw linseed oil with an acid number of 3 ± 1 from a burette to the gently stirred pigment. As the oil is slowly added, the mixture is continuously stirred and folded so the oil strikes dry pigment as long as any remains. The mixture is not vigorously rubbed as in the rub-out method. Eventually the mixture collects in small lumps that gradually coalesce. The rate of oil addition is reduced as the end point is reached. The amount of oil required to form a paste is used to calculate the oil absorption value. The end point for paste formation is taken to be the point when the lumps of wet pigment form a single ball or when an excess of oil smears the wall of a container (Fig. 1). This will take place within one or two drops of oil. It is important that there is no rubbing or grinding when this test is carried out. Although the current test calls for use of a steel spatula with particular dimensions and a glass flask for the test, variations of these tools have been used [*13,14*].

Oil Absorption, A, is expressed as grams of oil per 100 g of pigment and is calculated as follows

$$A = \left[\frac{M \times 0.93}{P}\right] \times 100$$

where M is the mL of oil used, P is the amount of pigment used in grams, and 0.93 is a constant that represents the density of the linseed oil. Test results by a single operator and between operators in different laboratories that differ by more than 9.9 and 15.3%, respectively, are suspect. Oil ab-

TABLE 1—Various non-ASTM methods for determination of oil absorption values.

Method	Comment	Reference
Azam	Method same as ASTM D 281 except end point is where paste just adheres to the spatula. See text.	15
Bessey-Lammiman	An indirect method. Pore volume of a compressed pigment wafer is determined. From this, an oil adsorption number is calculated.	8
British Standards Institution	Method is similar to ASTM D 281, but differs mainly in acid value of oil, 7.5–8.5; rubbing is done for 20–25 min.	16
Density End Point	Assumes density of pigment and oil are additive. Can have void volume errors associated with it.	17
National Lead Company	Method is similar to ASTM D 281 and Azam methods, but an attempt is made to regulate rubbing pressure and contact area of spatula and rubbing plate.	18
Smith-Stead	Pigment is added to oil in this method, and a mechanical muller is used to better define the rubbing effort.	19

sorption values obtained by this method and the following rub-out method are given in Table 2.

Spatula Rub-Out Method

ASTM D 281: Test Method for Oil Absorption of Pigments by Spatula Rub-Out [*12*] is another classical test that was first published by ASTM in 1928 and updated from time to time with the latest reapproval in 1989. It is approved for use by agencies of the U.S. Department of Defense. In this test, a stiff, putty-like paste is formed by adding linseed oil in a drop-wise manner to the pigment while it is being thoroughly rubbed with a spatula. It differs from the prior method in that ASTM D 1483 requires only gentle folding and stirring, whereas the rub-out test requires a thorough rubbing action of the pigment and oil with a steel spatula.

Raw linseed oil that meets ASTM D 234 but with an acid number of 3 ± 1 is slowly added in a drop wise manner to a known amount of pigment. After the addition of each drop of oil, the oil is incorporated into the pigment by working or rubbing the two together with the spatula. The end point is taken to be the point where sufficient oil has been incorporated into the pigment to produce a very stiff, putty-like paste that does not break up. Various stages in the spatula rub-out test are described in Fig. 2. The weight of oil is determined, and the oil adsorption value is calculated as the grams of oil used per 100 g of pigment. Test results by a single operator and between operators in different laboratories that differ by more than 14.3 and 38.0%, respectively, are suspect. Oil absorption values obtained by this test and the above Gardner-Coleman test are given in Table 2.

Azam Method

The Azam Method [*15*] is essentially the same test as ASTM D 281 with the main difference being a more rigorously defined end point. The end point is defined as the point where the paste just adheres to the spatula and the paste was termed a "complete" paste. Azam found that a complete paste absorbed no more oil when immerse in oil, but an "incomplete" paste would absorb oil in an amount sufficient to make it a "complete" paste. The end point check was made by immersing the rub-out mass in a known amount of oil and then determining the change after two or three days.

PLASTICIZER ABSORPTION BY PIGMENTS

Although linseed oil is used to obtain the oil absorption values, it is obvious that a variety of liquids can be absorbed by pigments. Typical data for selected plasticizers as well as raw linseed oil are given in Table 3.

CRITICAL PIGMENT VOLUME

For a long time, the paint industry formulated on a weight basis. In 1926 Calbeck [*20*] concluded from a statistical study of house-paint test results that the pigment/binder system should contain at least 28 vol% pigment. Not long after this, Wolff [*21,22*] related optimum performance of exterior paints to their critical oil contents, and simple graphical methods for determining this parameter were devised [*23*]. When Elm [*24*] investigated this concept, he confirmed Wolff's findings, but found it necessary to reverse the point of reference so it expressed the critical composition in terms of pigment content as in the work of Calbeck. Later Vannoy [*25*] studied the matter and concluded that replacement of certain pigments by others on a volume basis was the manner in which formulating should be approached. From such studies, the relationship known as the pigment volume concentration (PVC) came into use. It is a simple percentage calculated in the following manner:

$$\text{PVC} = \left[\frac{\text{Pigment Volume}}{\text{Pigment Volume} + \text{Vehicle Solids Volume}}\right][100\%]$$

Studies such as these led to the critical pigment volume concentration (CPVC) concept, and its importance to paint formulation was established by Asbeck and Van Loo [*26*]. When there is just sufficient binder present to fill the voids between pigment particles in the dry paint, the paint is said to be at the CPVC. This is the point of commonality at which a variety of properties show marked change. These properties include corrosion resistance as evidenced by blistering and rusting, ease of stain removal, gloss, hiding, scrub resistance or washability, water-vapor permeability, as well as others.

For example, it is readily understood that gloss decreases as pigment volume increases, that permeability and rusting are relatively constant until the pigment concentration reaches relatively high values after which marked decreases

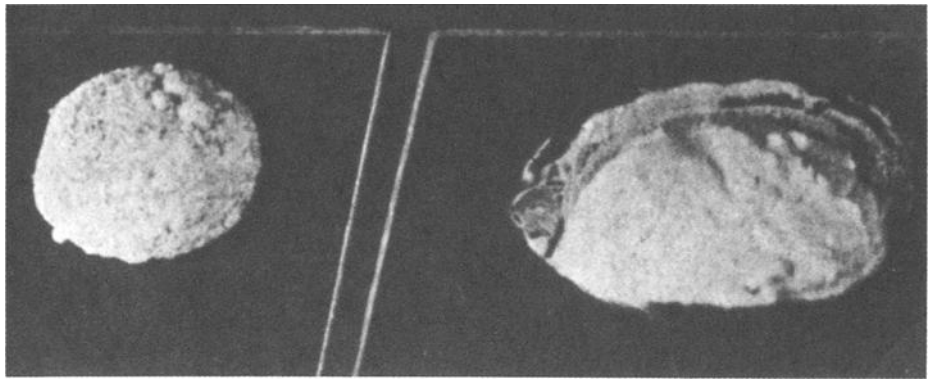

FIG. 1 [*1*]–Critical states in the Gardner-Coleman test. Left photograph is the oil/pigment mass just before the end point where the mass retains its rigidity. The right photograph is the mixture at the end point where the mass undergoes slight flow and smears the glass.

TABLE 2—Oil absorption values, grams of oil/100 g of pigment, of some common pigments [*1*].

Pigment	Gardner-Coleman Test	Spatula Rub-Out Test
Barytes	13.5	...
Basic carbonate of white lead	18	13.0
Basic sulfate of white lead	30	12.8
Blanc fixe	30	15.0
China clay	51	30.0
Gypsum	33.5	...
Lithopone	33	21.5
Silica, crystalline	23	...
Silica, amorphous	32	29.0
Talc	60	...
Titanox	26	18.5
Whiting	32	17.5
Zinc oxide	52	19.5

in performance takes place, and so on. It is at the CPVC that the marked changes take place. When two vehicles—latex, oil-base, etc.—are compared in a given formulation, one may have a higher CPVC than the other. Predictably, the one with a higher CPVC formulation should have better permeability characteristics, such as stain and scrubbability, than the other. Pigment or vehicle could be added to one paint or the other, and a paint with comparable properties can be prepared. The selection of which paint to modify by increasing pigment or vehicle is made on the basis of additive economics.

Different end-use requirements impose different pigment volume concentrations that are above or below the CPVC. For example, a ceiling paint does not need to have excellent washability, and usually this paint type only requires low to moderate gloss. Therefore, a paint such as this can be formulated at or even above the CPVC. In contrast, many exterior paints that have a high gloss as well as glossy enamels are formulated well below the CPVC, and it is PVC rather than CPVC that has significance. Although the parameter was devised for oil-based paints, the concepts involved are important to other types of coatings.

The pigment volume is often expressed as bulk, which is the volume occupied by a given weight of pigment. It is calculated by multiplying pigment specific gravity by the weight of a gallon of water or 8.33 (1 kg/L). For example, if a pigment has a specific gravity of 2.0, its bulk can be calculated as follows

$$\text{BULK} = \left[\frac{2.0\ \text{g/cc}}{1.0\ \text{g/cc}}\right]\left[\frac{8.33\ \text{lb}}{\text{gal}}\right] = \frac{16.66\ \text{lb}}{\text{gallon}} = \frac{2.0\ \text{kg}}{\text{litre}}$$

Since the paint industry is usually interested in gallons of product, the bulk is often expressed as the reciprocal of this number or 0.06 gal/lb (0.5 L/kg) or as bulk per 100 lb, 100/16.66 = 6.00 gal/100 lb in this example. From this example, it is apparent that the higher the bulking value of a pigment, the more advantageous it is from a cost standpoint. If pigment is lower in cost than vehicle, and assuming equivalent performance, a pigment with a higher bulking value over another would be selected.

Asbeck-Van Loo Method of Determining CPVC

The Asbeck-Van Loo [*9,26*] method of directly determining the CPVC is based on the observation that the packing pattern of a pigment in a paste persists when the dispersion is diluted for sedimentation tests if nonpolar liquids are used for the dilutions. Thus, to measure the voids in a dry paint film, it is only necessary to obtain the pigment in the form of a filter cake and measure the volume of the cake. Then, the cake volume is subtracted from the actual volume of the pigment calculated from density data. The ratio of the actual volume of the pigment to the volume of the cake is the CPVC.

Pigment Packing Factor

Asbeck and coworkers [*9*] proposed the term "pigment packing factor" (PPF) as a name for a pigment parameter that replaces or supplements the oil absorption value. PPF is the CPVC for a single pigment in a standard vehicle with the term CPVC being applied to a single or mixture of pigments present in a paint. The investigators suggested a blend of 4 mL of heat-bodied linseed oil and 50 mL of naphtha as the dispersing vehicle. The PPF is determined by placing 54 mL of the vehicle in a ¼-pt can or glass jar that is half filled with steel balls. To this, 6 mL of pigment (the weight in grams of pigment equal to the specific gravity times 6) are added. The system is dispersed by machine shaking for exactly 3 min.

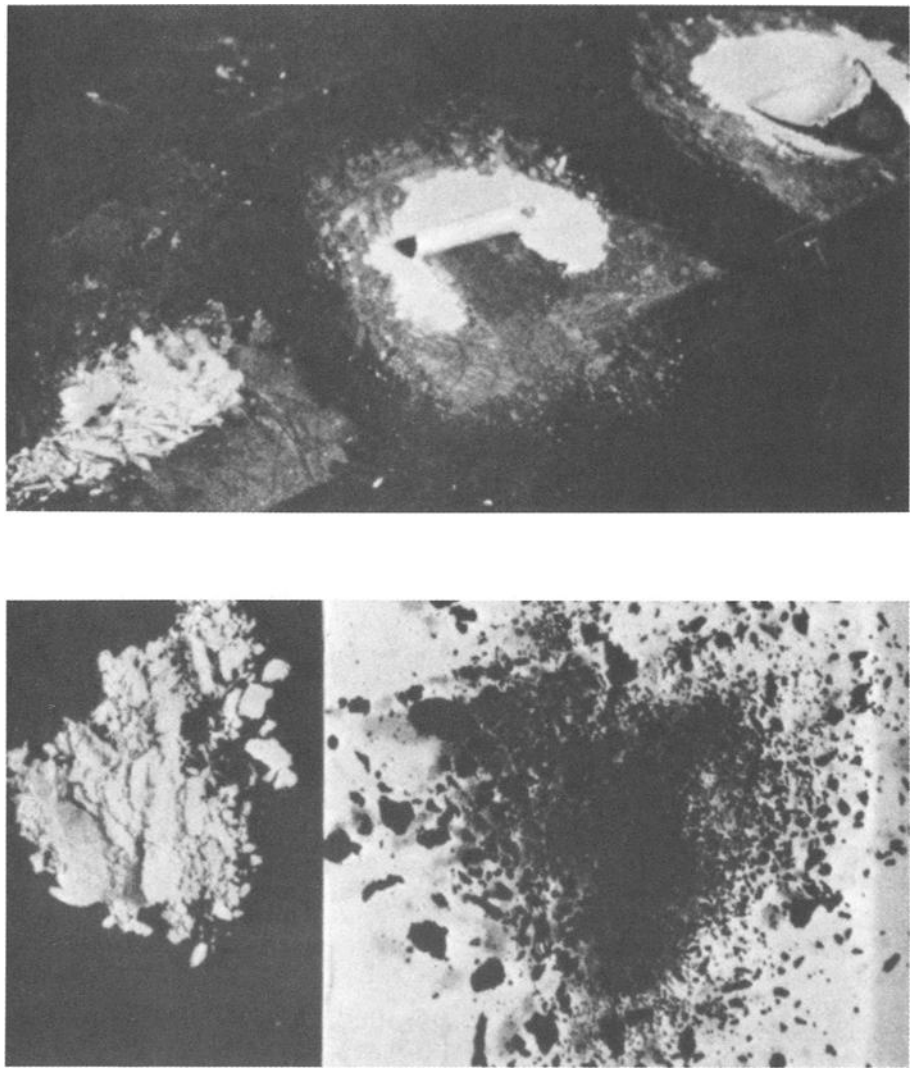

FIG. 2 [*1*]–A, B, and C in the top photograph represent 1 g of zinc oxide that has been mixed with increasing amounts of linseed oil. Rub-Out A (top) is crumbly and breaks up when an attempt is made to lift it with a spatula. Rub-Out B (lower left) is coherent and tends to form a roll when deformed with the spatula. Rub-Out C (lower right) contains too much oil and does not roll. It can be lifted as a sheet and the mixture is beyond the end point. The bottom two photographs are additional examples of the mixture condition just before the end point is reached. A single drop of oil will convert the crumblings into coherent masses.

Twenty millilitres of the dispersion are then used to determine the PPF using the same procedure as that used for CPVC. If the PPF is to be compared with oil absorption values, it must be converted to a weight basis, PPF_{weight}, by means of

$$PPF_{weight} = \left[\frac{(100 - PPF)(\text{specific gravity of oil})}{(PPF)(\text{specific gravity of pigment})}\right](100)$$

Cole Method for CPVC

The CPVC depends on pigment particle packing or orientation [*9,26*], and Cole [*27*] noted that spherical particles may pack similarly in both liquid and dry films. To demonstrate this, a dry-film method was developed. The method is based on the fact that below the CPVC dry film volume, V, is a sum of the pigment, V_p, and binder solids, V_b volumes

$$V = V_p + V_b$$

and that above the CPVC the volume of the voids must also be considered with

$$V = PV_p$$

where P is the relative pigment packing factor (the ratio of bulk volume to true volume). Two graphical and calculation methods were used to obtain CPVC.

Pierce-Holsworth Method for CPVC

This method [*28*] also used paint films, but it treated the data in a different manner by introducing specific volume

TABLE 3—Plasticizer absorption for some typical pigments [*1*].

Pigment	Absorption, g, Plasticizer/100 g Pigment		
	Tricresyl Phosphate	Dibutyl Phthalate	Raw Linseed Oil
Barium titanox	27.6	24.2	17.0
Carbon black, super	179.0	147.0	106.0
Calcium titanox	37.2	39.4	22.0
CP cadmium red	26.0	26.2	14.0
CP cadmium yellow	48.4	50.5	37.2
CP Chinese blue	145.0	136.5	41.1
CP chromium oxide	29.5	24.7	17.0
CP chrome orange, medium	19.5	21.0	7.5
CP glen green DD	78.0	72.5	28.9
Chromium hydroxide, green	80.0	76.6	53.0
Lampblack	118.0	126.0	145.0
Lithol toner	65.0	50.5	50.0

Ultramarine blue	65.0	55.0	31.6
Zinc Oxide	28.3	25.2	14.5
Zinc Sulfide	37.2	34.1	15.7

concepts. The specific volume, v, of a dry paint film can be expressed as

$$v = \frac{V}{W} = \frac{V}{W_p + W_b} = v_p f_p + v_b f_b$$

where V is the dry film volume, v, v_p, and v_b are specific volumes of the dry film, pigment, and binder; W, W_p, and W_b are weights of dry film, pigment, and binder; and f_p and f_b are weight fractions of pigment and binder, respectively. Since the sum of f_p and f_b is unity, the expression can be arranged to

$$v = (v_p - v_b)f_p + v_b$$

If v is plotted as a function of f_p, a straight line of slope $(v_p - v_b)$ and intercept of v_b should result.

Above the CPVC, the volume of the film is given by

$$V = Pv_pW_p$$

where P is a packing factor. If both sides of this expression are divided by W, the expression

$$v = Pv_pf_p$$

is obtained. If dry film specific volume, v, is plotted against the weight fraction of pigment, f_p, a straight line of slope Pv_p passing through the origin results. The intersection of this line with the previously described straight line should occur at a value of f_p corresponding to the CPVC. Results obtained by this method are presented in Table 4 along with the CPVCs obtained by tensile strength, elongation, and water vapor permeability. The good agreement is apparent.

A number of papers detailing studies of CPVC and its importance [*29–34*] as well as information relating CPVC, OA, and viscosity [*35,36*] can be found in the literature.

CRITICAL PIGMENT VOLUME CONCENTRATION AND OIL ABSORPTION

Oil absorption and CPVC are accepted to be interrelated [*29–31*] and actually are two ways of stating the same concept: i.e., CPVC is the concentration of pigment in a pigment-binder system that contains just sufficient binder (oil) to fill the space between the pigment particles [*1*]. If the parameters are to be equated, it is necessary to determine the oil absorption value (*OA*) by the spatula method and to express the results in volume terms. If *OA* is expressed as X volumes of oil per Y volumes of pigment, then

$$\text{CPVC} = \frac{Y}{X + Y}$$

When *OA* is expressed as the fraction X/Y and Y is set to one, then $X/Y = X$ and

$$OA = \frac{\text{CPVC}}{1 - \text{CPVC}}$$

and

$$\text{CPVC} = \frac{1}{1 + OA}$$

The PPF and *OA* values are compared in Table 5. If values are ranked from highest to lowest, the values calculated from the PPF are highest, those from Gardner-Coleman fall next, and those from the spatula rub-out test are lowest. Explanations [*1,9*] for the difference based on conditions existing at the end point are tabulated in Table 6.

Investigation of the effect of pigmentation on selected properties of flat wall paints has indicated that optimum levels of pigment concentration for color uniformity and enamel holdout corresponded to the CPVC [*32,33*]. In addition, the study indicated that rub-out *OA* values are a good indication of the CPVC. Stieg [*31*] points out that any one

Zinc oxide	27	45	19	12

operator of the spatula rub-out test can reproduce personal test results with a reasonable degree of accuracy. It seems that interpretation of the end point and not reproducibility is the source of variation between operators in these tests. Oil adsorption of pigment mixtures has been treated by Armstrong and Madson [*37*].

CHARACTERIZATION OF DISPERSIONS AT THE OIL ABSORPTION POINT

Examination of the dispersions (pastes) formed between oil and pigment at the oil absorption point is a source of considerable information. Large differences exist in such pastes with some being long, stringy, and soft in character. Others are tough and short, others have a high gloss, others have a dull appearance, others are soft and easy to spread, and still others are stiff and require a large pressure spread or flatten. The amount of oil needed is not closely related to these attributes, and one is led to the conclusion that pigments with essentially the same oil absorption value can yield pastes with markedly different character.

Daniel and Goldman [*38*] developed a scheme for evaluating dispersion character by using the paste obtained at the end of the spatula rub-out test. The amount of liquid needed to wet the pigment and produce flow are determined. From this information and the types of flow exhibited by the pastes, dispersions are classed as good, fair, or poor. From 10 to 20 g of dispersion is worked with a fairly stiff steel spatula in the test. The oil absorption value is called the *wet point*. From this point, oil addition is continued until the *flow point* is reached. In well-dispersed systems, the flow point is the stage where a substantial portion of the paste flows from a vertically held spatula without leaving jagged flow edges. In poorly dispersed or flocculated systems, the flow point is the stage where the paste drops from a vertically held spatula. Cases intermediate to these two are difficult to define. At the instant when paste drops from the spatula, it elongates at the edge. If a paste does not flow after addition of 10 to 20% more liquid than is required for the wet point, a portion of the diluted paste is placed on the tip of a horizontally held spatula. The spatula is then tapped near the handle with a finger. The tapping is gentle at first and then more vigorous. The paste

TABLE 6—Physical conditions that exist at the end points of pigment packing factor and oil absorption test [*1,9*].

Parameter	PPF	Gardner-Coleman	Spatula Rub-Out
Dispersion	Aggregates are completely broken down.	Only a few of the largest aggregates are broken down and the interstices are filled with oil.	More aggregates are broken down than in the Gardner-Coleman methods and the interstices are filled with oil.
Electrokinetic equilibrium	Agglomeration is complete because of high system fluidity.	Agglomeration is incomplete because of low system fluidity.	Agglomeration is incomplete because of low system fluidity.
Pigment surface requirements	Satisfied	Not completely satisfied	Substantially satisfied
Work of dispersion	Defined and very high (approaching maximum)	Undefined but low	Undefined but relatively high
Work of packing	Defined and very low (approaching zero)	Undefined but low	Undefined but relatively high

TABLE 7—Characteristics of pastes from oil absorption studies [*1*].

Observation Point	Good Dispersion	Fair Dispersion	Poor Dispersion
At wet point	Shines without tapping or with light tapping; dry and difficult to knead	Shines when sharply tapped	Remains dull even when sharply tapped
At intermediate stage	...	Flows only on tapping; occasionally has a resistance to suddenly applied pressure	Rises on tapping; has no resistance to suddenly applied pressure; has a high yield value
At flow point	Flows without tapping; offers resistance to suddenly applied pressure	Falls with elongation at breaking line; no resistance to suddenly applied pressure; has visible thixotropy	Falls without elongation at breaking line
Gap between wet and flow points	Very small	...	Very large

may then become glossy and flow over the edge of the spatula, in which case it is passively dilatent, or it may tend to rise or otherwise decrease the interface between it and the blade, in which case it is flocculated. Characteristics of pastes tested in this manner are given in Table 7. A test such as this can yield practical rheological results without sophisticated testing equipment.

Bactericides, Fungicides, and Algicides

by Vanja M. King[1]

THE VARIED METABOLIC CAPABILITIES of microorganisms enable them to cause many problems in paints and coatings, from manufacture through storage and application. These problems can usually be controlled with the effective use of microbicides (bactericides, fungicides, and algicides). The organisms involved are also discussed elsewhere in this manual. Knowing the type of organisms against which a microbicide is to provide protection is very important in selecting the best types of chemicals to use.

Other considerations in the selection of the treatment chemicals include the intended application of the end product, the composition of the product being preserved, and the desired level of performance. The physical parameters are also of great importance. Some types of organics and inorganics, pH levels, temperature at the time of addition, and ultraviolet (UV) exposure of the film may deactivate the biocide used [*1,2*]. A thorough knowledge of the biocides available will help the chemist select the proper materials for his or her system and help minimize the occurrence of unpleasant surprises.

Environmental considerations and public opinion are also of great importance. Strong feelings have evolved about antimicrobials like mercury and tin. Some toxicological concerns regarding biocides are: exposure during manufacturing, storage, application, clean up (washing), and disposal of wash waters.

Definition of Terms

Following are definitions of the terms used:

- A *biocide* is a substance that kills organisms. The use in this section is synonymous with microbicide. Occasionally the terms are further defined (bactericide, fungicide, algicide) to include the types of organisms killed.
- A *microbiostatic* agent is one that prevents the growth of microorganisms and their spores, but does not necessarily kill them.
- A *preservative* is an agent that slows down the biodeterioration of a material. (An important factor to remember is that bacterial endospores only need to be kept from germination and outgrowth because endospores are nonmetabolizing and cannot cause deterioration or spoilage.)
- *Toxicity* is the deleterious effect on organisms other than the target organism. Aquatic toxicity of a fungicide would be an example of a fungicide's effect on fish, etc.
- *Efficacy* is the effect of a microbicide on the target organism or group of organisms. Efficacy could be measured in percent kill compared to control, but should be defined in the test method. The result is usually expressed as the minimum inhibitory concentration (MIC) against a specific organism.
- *Colonization* refers to the establishment of growth of organisms on a surface.
- *Spectrum* is a term describing the efficacy of a microbicide; *broad spectrum* means that the microbicide is effective against more than one group of microorganisms.
- *Microbial pigments* refers to colored substances produced by microorganisms. These include both water-soluble and water-insoluble compounds.

DESCRIPTION OF MICROBIAL PROBLEMS

In-can Preservation

Problems frequently associated with unpreserved, water-based paints have increased in recent years, mainly because water-based paints have become much more common. These formulations are susceptible to attack by bacteria and unicellular fungi (yeasts) and occasionally filamentous fungi. There are several food sources available for growth of microorganisms in common coatings formulations; cellulosic thickeners, surfactants, and defoamers are all molecules used as a carbon source by microorganisms. Good discussions can be found in Refs *3–5*. The problems most commonly encountered in water-based paints include those shown in Table 1.

To prevent these problems from occurring, an effective biocide should be incorporated into the coating. It must be cost effective, be compatible with coating ingredients, impart no color to the formulation, have no objectionable odor, be nonyellowing in the dried film, and be environmentally acceptable in manufacture, handling, and release into the environment.

The best understood problem in coating film preservation is the disfiguring growth of organisms on the exterior surface of the film itself [*6,7*], such as on ships, bridges, and interior and exterior walls of buildings. Less understood are problems associated with loss of adhesion from fungi growing underneath the coating film and the corrosion problems on equip-

TABLE 1—Problems caused by contamination of water-based paints.

Type of Problem	Common Cause
Gassing—swelling or exploding cans	CO_2 released by bacteria or yeasts.
Viscosity loss	Cellulase enzymes produced by bacteria or fungi attacking thickeners.
Odors	Organic acids and other metabolic byproducts of microbial metabolism.
pH change/physical instability	Organic acids produced can lower pH of paint.
Loss of paint film fungicide/algicide	*Pseudomonas* sp. bacteria are well known for detoxifying antimicrobials; *Cladosporium resinae* is reported to deactivate methylparaben.
Gelation	*Pseudomonas* sp. have been implicated.
Discoloration	Both bacteri and fungi/yeasts growing in and on in-can materials can produce water-soluble and insoluble pigments.
Slime formation	Biofilm formation by slime-forming bacteria and fungi can produce clumps in the liquid and slime on the sides of pipes and cans.

ment from the moisture produced by the respiration of fungi. Fungicides are needed to control these problems.

There is a continuing need for sanitizing and disinfecting paint films. In this case, there is more need for a bactericide than a fungicide. For example, the hospital environment continues to be conducive to so-called nosocomial infections (those acquired in the hospital) and, with the rise in numbers of immunocompromised and elderly patients, paints containing long-lasting bactericides are needed. Many compounds may not remain active the length of time needed for them to work.

Microbicide toxicity and efficacy are often concerns when preserving coating films. Fungicides and algicides are frequently more toxic than most common bactericides since fungal and algal cells share many similarities with cells from higher organisms, while bacterial cells are distinctly different. Most microbicides are limited to efficacy against one group, and some of the more effective antimicrobials target specific metabolic pathways unique to one group of organisms.

Several recent studied [*8,9*] have shown a relationship between bacterial growth, their polysaccharides, and subsequent colonization of surfaces by fungi or other organisms. It appears that colonization succession occurring on dry films is similar to that occurring on ship bottoms. This implies that there should be a bactericide *and* a fungicide incorporated for coating film protection. Some biocides can provide both functions. In tropical climates, disfiguring growth of algae on the exterior of the films is also a problem [*10,11*]. Table 2 indicates problems in paint and coating film preservation.

TABLE 2—Problems in paint and coating film preservation.

Type of Problem	Common Cause
Discoloration/dirt entrapment	Algae and/or fungi.
Loss of adhesion	Fungi.
Corrosion	Moisture produced by fungi.
Need for sanitizing agents in film	Microorganisms on hospital walls.
Antifouling paints on marine crafts and structures	Bacteria, fungi, algae, barnacles, hydroids, etc.
Production of growth promoting substances	Algae and fungi.
Destruction of cultural objects	Algae, fungi, and bacteria growing on paintings, statues, and buildings.

GROUPS OF MICROORGANISMS RELATED TO BIOCIDAL EFFICACY

It is important to know the activity of a particular preservative/biocide against the types of organisms encountered by the formulation. For this purpose, the most important groups of microorganisms are:

Bacteria

Aerobic bacteria
- Gram positive bacteria
  - endosporeforming bacteria
- Gram negative bacteria

Anaerobic bacteria
- Gram positive bacteria
  - endosporeforming bacteria
- Gram negative bacteria

Fungi

Multicellular (molds)
Unicellular (yeasts)

Algae

Green algae
Blue-green algae (cyanobacteria)

NOTE: All of these organisms are described in more detail elsewhere.

MODE OF ACTION OF MICROBICIDES/ SPECTRUM OF ACTIVITY

It is very important to note the difference in the activity of a particular biocide against the different organisms within a group, and differences are to be expected. The most important consideration is to know which organisms one is trying to protect against and to use an effective agent. When the mode of action of a biocide has been elucidated, it frequently explains the differences in activity. The lists below are not meant to be comprehensive. They describe some materials well known to the industry and report on the organisms against which the compounds are most effective [*12–14*].

Another important factor related to the spectrum of activity is concentration. Some biocides are effective against bacteria in one concentration and effective against fungi in a much higher concentration; the reverse can also be true. Furthermore, a biocide may be microbiostatic in a low concentration and microbicidal in another. The general definition of "microbiostatic" is that it interferes with some activity of the organisms without necessarily killing them. A "-cidal" compound kills the organisms. The definition of a microbiostatic/microbicidal compound is here broadened to include concentration. The underlying principles to the mode of action are generally agreed upon to be one of two mechanisms:

1. Membrane-active compounds such as quaternary compounds.
2. Electrophilic agents (react with nucleophilic groups on or within cells).

Table 3 shows some metal microbicides used in paints and coatings.

Because of environmental concerns, the use of many heavy-metal-containing biocides traditionally incorporated in coatings has become more limited [*15*]. An example is the recent (1988) ruling by the EPA regarding the maximum release of tributyl tin. The Organotin Antifouling Paint Control Act essentially restricts the use of organotin antifouling paints to commercial and military crafts. In 1990, the U.K. revoked the use of tributyl-tinoxide (TBTO) in surface biocides for professional and amateur use. Mercury-type compounds are losing favor with a large segment of the coatings industry and the public, and it appears likely their use will continue to decrease as nonmercurials replace them in the future. The toxicity of some mercurial compounds, notably methyl mercury, also makes them very potent and long lasting preservatives with a broad spectrum of activity.

Some positive effects of the metal compounds on the properties of coatings should also be noted. Barium metaborate, a pigment, has been reported [*2*] to act as a corrosion inhibitor and a UV light stabilizer. Zinc oxide further enhances drying of the paint film (which is a desirable property) and makes it more resistant to fungi [*12*]. Table 4 shows some nitrogen and/or sulfur-containing microbicides used in paints and coatings.

For an excellent summary of the chemistry of many of the compounds shown in Table 4, please see Ref *16*.

Table 5 indicates some nitrogen and/or sulfur-containing microbiocides used in paints and coatings. Many of the biocides listed in Table 5 are important to this industry, especially from a general housekeeping standpoint. The importance of cleanliness in the production of all types of materials should be emphasized since heavy contamination of a product is difficult to overcome with any preservative. Disinfection of pipes and vessels along with a general washup will remove the surviving, more resistant organisms.

MODE OF ACTION OF SOME ANTIMICROBIAL AGENTS

The following is not intended to explain all possible modes of action, but to give a general overview of the terms used in the biocide listings. More detailed explanations can be found in the references listed at the end of this chapter.

Agents that React with Acetylacetone

This term describes chemicals that, when treated with acetylacetone (Nash's reagent), will yield formaldehyde. Some of these act as preservatives by releasing formaldehyde, while others (manufactured through condensation reactions with a starting compound and formaldehyde) may not necessarily act through the release of formaldehyde. The release of formaldehyde is also related to pH. At alkaline pH, little or no formaldehyde is released.

Formaldehyde interacts with amine groups on proteins in a condensation reaction, thereby deactivating them. Proteins are common on the outer layers of microorganisms and many also produce extracellular proteins (enzymes) for metabolism of large molecules like cellulose. Deactivated proteins hinder metabolism or growth or may actually kill the organism. A common result is the leakage of the contents of the cell into the environment.

Because of the current public unease concerning formaldehyde, few biocide producers like to call their products formaldehyde releasers. However, this is probably the most common mode of action among the bactericides. It is very

TABLE 3—Some metal microbicides used in paints and coatings.

Composition	Effective Against	Putative Mode of Action
Barium metaborate	Broad spectrum	Enzyme inhibition
Copper (II) 8-quinolinolate	Fungi	General coagulation
Phenylmercuric acetate and other organo-mercurials	Broad spectrum	Protein deactivation (coagulation), etc.
Tributyl tin oxide and other tributyl tins	Broad spectrum, except gram negative bacteria	Chelation, enzyme inhibition
Zinc oxide	Fungi, algae	Chelation, protein inhibition
Zinc-dimethyl dithiocarbamate + Zn_2-mercaptobenzothiazole	Fungi	Chelation of necessary metals; possibly interferes with oxidative phosphorylation
Zinc 2-pyridinethiol-N-oxide	Fungi	Chelation of necessary metals

TABLE 4—Some nitrogen and/or sulfur-containing microbicides used in paints and coatings.

Composition	Effective Against	Putative Mode of Action
4,4-dimethyl-oxazolidine + 3,4,4-trimethyloxazolidine	Bacteria	Reacts with acetylacetone
5-hydroxy-methyl-1-aza-3,7-dioxabicyclo (3.3.0.) octane*	Bacteria	Reacts with acetylacetone
2(hydroxymethyl)-aminoethanol	Bacteria	Inhibits active transport; coagulates protein
2[(hydroxymethyl)-amino]-2-methyl-1-propanol	Bacteria	Reacts with acetylacetone
Methylenebis(thiocyanate)	Bacteria/fungi/algae	Attacks cellular thiols; inhibits oxidative phosphorylation
1,2-dibromo-2,4-dicyanobutane	Bacteria/fungi/algae	Has several highly electron withdrawing centers
2-(4-thiazolyl)benzimidazole	Fungi	*Low:* inhibits ergosterol synthesis *High:* membrane damage; interacts with DNA synthesis; blocks oxidative phosphorylation
2-mercaptobenzo-thiazole	Fungi/bacteria (?)	Chelation of necessary metals
1,2-benzisothiazoline-3-one	Bacteria/fungi/yeast	Interacts with nucleophilic components
5-chloro-2-methyl-3(2H)-isothiazoline + 2-methyl-3(2H)-isothiazolone	Fungi/bacteria Bacteria	At physiological pH, reacts oxidatively with thiol-containing compounds; thio-acyl chloride formation
4-(2-nitrobutyl)-morpholine + 4,4′-(2-ethylnitrotrimethylene dimorpholine	Fungi/bacteria	Interferes with membrane synthesis (fungi); ergosterol synthesis
Zinc 2-pyridinethiol-N-oxide*	Fungi	Chelation of necessary metals
Tetra-hydro-3,5-di-methyl-2H-1,3,5-thiadiazine-2-thione	Bacteria/fungi	Detected with acetylacetone
N-trichloromethyl-thio-4-cyclohexene-1,2-dicarboximide	Fungi	Reacts with thiols = disulfide; inhibits respiration
Hexyhydro-1,3,5-tri-ethyl-s-triazine	Bacteria	Detected with acetylacetone
2-n-octyl-4-isothiazoline-3-one	Fungi	Reacts with thiol-containing compounds
1-(3-chloroallyl)-3,5,7-triaza-1-azonia-adamantane chloride	Bacteria	Detected with acetylacetone
1-methyl-3,5,7-triaza-1-azonia-adamantane chloride	Bacteria	Detected with acetylacetone
2,4,5,6-tetrachloro-isophthalonitrile	Fungi	Reacts with thiols; inhibits oxidation of glucose
3-iodo-2-propynyl butyl carbamate	Fungi	Chelation?
N-(trichloromethyl-thio)phthalimide	Fungi	Reacts with thiols = disulfide; inhibits respiration
2-(thiocyanomethyl-thio)benzothiazole	Fungi/anaerobic; bacteria/algae	Reacts with thiols/inactivation of metal enzyme complexes
Diiodomethyl-p-tolyl sulfone	Fungi	?
Potassium N-hydroxy-methyl-N-methyl-dithiocarbamate	Fungi	Chelates necessary metals
2-(thiocyanomethyl-thio)benzothiazole + methylenebis (thiocyanate)	Bacteria/fungi/algae/anaerobic bacteria/mollusks	Uncouples oxidative phosphorylation; reacts with SH-groups
Sodium 2-pyridinethiol-1-oxide	Fungi	Chelation; ATP; transport; protein synthesis

*Other actives also present in the formulation.

TABLE 5—Some other microbicides used in the coatings industry.

Composition	Reported Effective Against	Putative Mode of Action
Glutaraldehyde	Bacterial spores, bacteria, fungi, algae	Reaction with proteins
Parabens (ethyl, or propyl, methyl, or butyl parahydroxybenzoate)	Fungi	Membrane activity and integrity
Quarternary ammonium compounds	Bacteria, algae	Generalized membrane damage
Chlorine biocides	Broad spectrum	Deactivation of proteins

effective against bacteria, but it is less effective against yeasts and multicellular fungi.

Formaldehyde in its mode of action could also be classed with the electrophilic agents, which are agents that react with nucleophilic components of a cell.

Agents that React with Nucleophilic Groups

Thiols are nucleophilic groups on amino acids (building blocks of proteins) or proteins found in all living cells; some are reducing agents containing S groups. The cytoplasm of cells of all types of organisms contain a pool of amino acids and proteins. Biocides that contain electrophilic groups react with the nucleophilic areas of the cell, and deactivation of the organism occurs.

Such biocides can also react with coating components that contain nucleophilic groups. This results in the loss of some activity commensurate with the concentration of each reactant. Reversal of biocidal activity or deactivation could result from the addition of such materials. As the biocide reacts, it is being used up and unavailable for further activity.

A review of the chemistry of a preservative molecule could reveal one or more electron withdrawing centers that would be able to react with nucleophilic groups. There are many compounds in this category.

Agents that Chelate Metals

Metals are necessary as trace elements for organisms. The metals are frequently parts of enzymes or vitamins needed for growth and metabolism. It is postulated that chemicals that chelate metals would deactivate microorganisms by withdrawing the metals needed for life.

Cationic Agents

Cationic polymerics are frequently used as sanitizing agents. Such molecules would react with anionic constituents, inorganic and organic (such as those present on the surface of the microbial cell wall). The cationic material causes leakage of materials from the cell through the destabilized cell wall, causing death of the cell.

Other Mechanisms

Coagulation is a term denoting a general deactivation of proteins or cells without specifying the molecular action. Interference with active transport (of food molecules into cells) may be from deactivation of transport proteins or by adsorption of molecules onto the cell surface, blocking the transport proteins. Ergosterol is an important lipid component of the fungal membrane, and interference with its synthesis would be fungistatic in low concentrations and fungicidal in high. Inhibition of respiration (oxidative phosphorylation) results in the cell being unable to generate energy (ATP or adenine triphosphate) through metabolism, eventually killing it. Interference with DNA (deoxyribose nucleic acid; chromosome material), RNA (ribose nucleic acid), or protein synthesis would hinder reproduction and metabolism, eventually killing the cell.

STRATEGIES FOR MINIMIZING RESISTANT STRAINS

The topic of resistance to antimicrobials is mentioned frequently in industrial preservation discussions, probably because we are all familiar with resistance of disease-producing microorganisms to therapeutic antibiotics. The issue of resistance seems less obvious when dealing with industrial biocides.

The most important factor for minimizing contamination and resistant strains is general housekeeping. Leaving water in pipes and vessels that previously contained preserved material would provide diluted biocide in nonlethal concentrations to which microorganisms could become resistant.

There are different opinions regarding genetic resistance to disinfectants and antimicrobials. It frequently appears that, when an organism becomes resistant to one biocide (such as quarternary ammonium compounds), it will also be resistant to several, chemically unrelated biocides (such as thiazolinones) [*17*]. This, of course, happens more readily when similar biocides are used (such as formaldehyde releasers). Therefore, changing the biocide may not be the solution to resistant organisms; rather, it may make matters worse by widening the materials to which resistance is observed.

Testing of biocides should utilize organisms isolated from the manufacturing plant and spoiled materials. Plant isolates are almost always more resistant to biocides than stock cultures maintained on artificial media. Also, selection of a good broad spectrum biocide minimizes the possibility of resistant organisms. Finally, a thorough knowledge of the chemistry of available biocides will keep one from using products with similar modes of action consecutively.

ANALYSIS AND DECONTAMINATION

It is of considerable importance to be able to accurately analyze for the presence and concentration of the antimicrobial agent. One reason is the ability to ascertain that the material was, in fact, added and in the right concentration both as a quality control measure parameter and in case of a failure in the field.

Available methods vary with the type of active ingredient utilized. Preferably, the molecule should be determined without employing a destructive method since one could not determine if breakdown had occurred in the container or if breakdown occurred because of the method of analysis. For example, it would be preferable to determine the intact molecule of a formaldehyde releaser rather than determining the formaldehyde present after breaking up the molecule. The formaldehyde release could have occurred before analysis was attempted. Nondestructive methods include NMR (nuclear magnetic resonance) methods.

The information literature on a preservative product frequently contains procedures for deactivation of the biocide. This information is necessary for several reasons. A spill can always occur, and a puddle of chemical would need to be neutralized and cleaned without danger to personnel. In addition, when testing for efficacy of preservatives, small concentrations remaining even after dilution for enumeration may be at microbiostatic levels. If the organisms had not been killed, there is a chance for regrowth and spoilage. A method for neutralizing the biocide should, therefore, always be used in the growth medium when performing preservative efficacy tests.

FACTORS THAT IMPACT THE EFFICACY OF SOME COMMON ANTIMICROBIAL AGENTS

The importance of physical and chemical factors on the growth of microorganisms is discussed elsewhere; however, many of the same factors are also important because of their impact on the activity of biocides. The impact is frequently detrimental [*18*], but can also be positive. Some factors are described in Tables 6 and 7.

TABLE 6—Factors that positively influence biocide efficacy.

Inclusion of pigments that have antimicrobial activity.	Such components could possibly cut down on the amount of preservative needed.
Inclusion of other materials in the formulation that have antimicrobial activity (e.g., propylene glycol) or resist degradation	Some components are less readily used as a food source (e.g., choices of carboxymethylcelluloses).
Many biocides are more effective at acid pH, while others are more active at an alkaline pH.	Adjusting the pH to suit the biocide, if no effects are seen in the formulation, could be helpful.
Difference in solubility of different biocides.	Combining biocides with different solubilities may increase efficacy. An example of this is to use several different parabens, each of which has its own independent solubility.
Synergism resulting from combining biocides with different spectra of activity.	This effect, in most cases, appears to be additive instead of true synergism (when the whole is more than the individual components together). Whichever case, antimicrobial agents are frequently complemented by combination, e.g., the isothiazolones and methylene bis(thiocyanate)/2-(thiocyanomethylthio)benzothiazole).

TABLE 7—Factors that decrease biocidal efficacy.

pH	Knowledge of the chemistry of a biocide should include its activity at different pHs. It is easier to find a biocide that is effective and stable at acid pH than at alkaline, but many are described as being alkaline stable/effective. However, many are considerably less effective at alkaline pH, making an increased concentration necessary. Stability is not to be equated with efficacy since a biocide that is stable at alkaline pH (such as many dithiocarbamates) may not have much efficacy at alkaline pH, except after a long period of time.
Addition temperature	Examples of biocides affected by addition temperatures are the parabens, which need to be added at temperatures below 50°C. It is typical of biocides that they are deactivated to various degrees based on temperature, although this temperature effect varies considerably from biocide to biocide. Increased concentration may alleviate this problem. Typically, increase in pH and increase in temperature is synergistic in deactivating sensitive biocides.
Nonionic surfactants	Biocides that are deactivated by these include the parabens, phenolics, organic acids, and aromatic alcohols.
Low solubility	Preservatives need to be water-soluble to the concentration needed for efficacy. This means that the solubility should not be too high, or that a combination of a soluble and less soluble agent would be most effective.
Leachability	A coating film preservative must maintain an effective concentration within the film to remain antimicrobial. Water-soluble materials would be quickly compromised in this situation. However, some movement may be necessary to transport the antimicrobial through dirt layers that accumulate. This balance may be hard to maintain.
Can components	Can components could adsorb the antimicrobial agent from the content.
Formulation components	Formulation components could deactivate the biocide. Such components are proteins for formaldehyde releasers and thiols for electron withdrawing biocides.
Stabilizing agents	Inclusion of components may keep other biocides from yellowing the film. Sodium sulfite reportedly decreases the chance of 1-(3-chloroallyl)-3,5,7-triaza-1-azonia-adamantane chloride yellowing the paint film. However, such components may deactivate biocides since they are frequently listed as neutralizing materials in preservative brochures.
UV light frequency	UV light frequency decomposes coating film fungicides and algicides. The photolysis products are less effective and efficacy is lost. The inclusion of products that make the film more UV stable alleviates this problem.

METHODS FOR DETERMINATION OF BIOCIDE EFFICACY

There are numerous methods described in the literature for determining the efficacy of a proposed biocide, both for in-can preservation and for paint film use. The appropriate ASTM methods are: D 2574-86, Test Method for Resistance of Emulsion Paints in the Container to Attack by Microorganisms; D 3273-86, Test Method for Resistance to Growth of Mold on the Surface of Interior Coatings in an Environmental Chamber; and D 3456-86, Practice for Determining by Exterior Exposure Tests the Susceptibility of Paint Films to Microbiological Attack. These methods are contained in Section III, "Microbiological Contamination and Biodeterioration Assessment," of *ASTM Standards on Materials and Environmental Microbiology*, first edition, 1987 [*19*]. Several other methods in this section are also of interest. A complete fungicide testing program is described in Ref *20*, and an electronic rapid method for determining contamination in coating raw materials (and by extension, preservation efficiacy) has recently been published [*21*]. Other methods are described in Ref *22*. Testing of algicides for tropical locations is described in Ref *23*.

CONSIDERATIONS FOR THE FUTURE DEVELOPMENT OF ANTIMICROBIAL AGENTS

While it is clear the development of new microbicides is both expensive and full of frustrations [*24*], some important results could ensue. The public is well aware of the potential harm to which people and the environment have recently been exposed and is pressuring the industry to move away from such products. However, few people will accept the purchase of a deteriorated material, and consumers expect the product to perform adequately once in use. Therefore, potentially less environmentally negative preservatives which are still effective have a place in the market and should be developed. Since the expense is exorbitant, this is going to be a slower process than one would like but should, nevertheless, proceed. The costs come from maintaining research and development departments, as well as application and development costs. The highest costs are incurred from required and necessary toxicology testing. With the goal of developing less toxic and more environmentally friendly biocides, these costs will surely increase with broader testing.

Thickeners and Rheology Modifiers

by Gregory D. Shay[1]

LIST OF ABBREVIATIONS

AQ	Aqueous
ASE	Alkali-swellable and/or soluble emulsion
ATRM	Associative thickener and/or rheology modifier
BCARB	Butyl Carbitol®
BP	Biopolymer
CMC	Carboxymethyl cellulose
CTRM	Conventional thickener and/or rheology modifier
DS	Degree of substitution
DUEV	Dynamic uniaxial extensional viscosity
EHEC	Ethyl hydroxyethyl cellulose
HASE	Hydrophobe modified alkali-swellable/soluble emulsion
HBMC	Hydroxybutylmethyl cellulose
HEC	Hydroxyethyl cellulose
HEEASE	Hydrophobe modified ethoxylate ester alkali-swellable/soluble emulsion
HEMC	Hydroxyethylmethyl cellulose
HENN	Hydrophobe modified ethoxylate nonionic non-urethane
HEUR	Hydrophobe modified ethoxylate urethane
HEURASE	Hydrophobe modified ethoxylate urethane alkali-swellable/soluble emulsion
HMC	Hydrophobe modified cellulosic
HNS	Hydrophobe modified nonionic synthetic
HMEHEC	Hydrophobe modified ethyl hydroxyethyl cellulose
HMHEC	Hydrophobe modified hydroxyethyl cellulose
HPG	Hydroxypropyl guar
HPMC	Hydroxypropylmethyl cellulose
HSV	High-shear viscosity
ITRM	Inorganic thickener and/or rheology modifier
LIQ	Liquid
LSV	Low-shear viscosity
MC	Methyl cellulose
MS	Molar substitution
MSV	Medium-shear viscosity
NA	Data not available
ORG	Organo or organic
PAA	Polyacrylic acid
pEO	Polyethylene oxide
PG	Propylene glycol
PVC	Pigment volume concentration
RM	Rheology modifier
SOLV	Solvent
T	Thickener
TRM	Thickener and/or rheology modifier
VOC	Volatile organic components
XCPS	Xanthamonas campestris polysaccharide (Xanthan gum)

INTRODUCTION

DEMANDS ON THE APPLICATION and flow properties of coatings have increased substantially, and because thickeners and rheology modifiers (TRMs collectively) play a key role in performance, they are among the most important components in a coatings system. Although TRMs are used in minor amounts in most formulations and are generally considered additives, aqueous coatings usually contain at least one, often two, and sometimes several to obtain the desired balance of properties. Due to present-day environmental concerns and the use of TRMs predominantly in aqueous coatings, the focus of this chapter is on water-borne, and especially latex-based systems. TRMs also find utility in solvent-borne coatings where they function primarily as flow modifiers and thixotropes. These products are discussed in later sections of this chapter.

Thickeners

Thickeners, as traditionally defined, are components that substantially increase viscosity (resistance to flow) at relatively low concentrations. For coatings, thickeners are normally used to increase viscosity at moderate shear rates approximating those encountered during pouring, stirring, or mixing. The viscosity in this shear rate range is often referred to as the coating "consistency" or medium-shear viscosity (MSV). To be effective, a thickener should produce the desired consistency at a low-use level that is often expressed in units of lb thickener solids per 100 gal of liquid coating (g/L where metric units are used). For architectural coatings, the total amount of thickener typically used is less than about 15 lb/100 gal (~18 g/L) and can be as low as 3 lb/100 gal (~4 g/L) or less, depending on coating solids, pigment volume concentration (PVC), vehicle type, and other components present in the formulation. As discussed later, selection of components

Copyright© 1995 by ASTM International

is particularly important with associative thickeners. The units of shear rate are reciprocal seconds (s^{-1}), and the shear rate range for measurement of consistency is about 10 to 1000 s^{-1} and more typically about 100 s^{-1}.

A change in a coating's consistency can be sensed subjectively. For example, the depth of fluid vortex in a container at a given mixing speed can be observed visually, or the increase in resistance to flow during hand stirring can be felt. The consistency of the coating can also be measured using an appropriate viscometer or rheometer that operates in the medium shear rate range (such as at 10 to 1000 s^{-1}). The high end of this range also correlates with "pumpability," which is critical in some automated manufacturing operations. Several popular instruments for measuring consistency are described later in this chapter under **Coating Consistency (Medium-Shear Viscosity).**

Rheology Modifiers

Presently, there is no universally accepted definition of the term "rheology modifier." In fact, the terms "thickener" and "rheology modifier" are often used interchangeably in commerce, especially for associative TRMs. All thickeners modify rheology to varying degrees when incorporated; consequently, all thickeners, technically, are also rheology modifiers. Some modify rheology in a positive way, and others modify rheology adversely depending on the desired effect. Although all thickeners can be considered rheology modifiers, not all rheology modifiers are considered thickeners, and herein lies a distinction. For purposes of classification, rheology modifiers are defined here as additives which influence viscosity at high and/or low shear rate (generally above 1000 s^{-1} or below 10 s^{-1}) but contribute little to consistency (that is, they change rheology but are inefficient thickeners). If a rheology modifier as defined was used as the sole thickener for consistency, typically more than about 15 lb/100 gal (~18 g/L) would be required, and 30 to 60 lb/100 gal (~35 to 75 g/L) would not be unusual. When used as primarily intended (as a rheology modifier with one or more other thickeners present), amounts much less than this normally suffice.

Like thickeners, rheology modifiers may also influence the elastic or elongational (extensional) properties of coatings, which can be measured on some relatively sophisticated rheometers. Frequently, a single thickener or combination of thickeners is effective in meeting all of the rheological requirements (low, medium, and high-shear) of a given coating formulation, and a rheology modifier is not needed in this situation. If the rheological requirements cannot be met with thickeners alone, a rheology modifier is often included to augment flow properties. A common example of this is the incorporation of a rheology modifier to raise the high-shear viscosity (HSV) of a coating. This increases viscosity on application which, in turn, provides increased film build (film thickness) for improved substrate protection or one-coat hiding.

In some situations, a rheology modifier is efficient enough to function as an effective thickener such as in the presence of a small-particle-size latex, water-insoluble coalescing aids, at high binder concentrations, or at high-volume solids. This effect, which will be discussed in detail later, especially applies to associative rheology modifiers where strong interactions occur between the TRM and other coating components.

INCORPORATION OF TRMs

Coating manufacturing operations generally consist of several stages of processing, and TRMs are important in each. Some common stages are the "premix" (ingredients added prior to pigments), "grind" (pigment added and reduced in size for optimum dispersion), and "letdown" (where polymer or latex is normally added). Some but usually not all of the thickener is added to the premix to increase viscosity in the grind for improved pigment dispersion (deagglomeration). Under laminar flow conditions, rate of shear during grinding is set by the tip speed of the impeller and the depth of the shear gradient. One theory suggests that increased viscosity allows better energy transfer by decreasing turbulence at the impeller, which, in turn, increases the shearing collisions that attrite the pigment agglomerates. However, too much thickener at this stage impedes mixing and actually slows down the grinding process. The remaining thickener is usually added to the letdown to provide proper suspension and product consistency. Finally, post-adjustments with additional thickener or rheology modifier may be required to bring the product "into specification" for application and appearance properties.

RHEOLOGY AND VISCOSITY

Because viscosity and rheology modification are the very essence of primary TRM function, a basic understanding of rheological concepts is helpful to fully appreciate differentiation in product performance. A thorough treatment of this subject is found elsewhere in this book. The following subsections provide a general overview of the two primary types of flow encountered during the preparation, storage, and application of coatings that are affected by the choice and amount of TRM present [*1–5*].

Shear Flow

Most low, medium, and high shear rate coating phenomena involve shear flow that is normally characterized in the laminar regime (where the shear field produces Reynold's Numbers below the critical characteristic for the fluid). Shear flow in the Turbulent regime (high Reynold's Numbers) is not normally characterized, since most parameterizing equations fail here. The vast majority of viscometers produce shear flow and measure the ratio of shear stress to shear rate (viscosity). With coatings, it is useful to determine viscosity at several shear rates to obtain a complete rheology profile which is normally represented in log-log form. These profiles are also conveniently divided into three shear rate regions—"at rest," "processing," and "application," which correspond to the low-shear, medium-shear, and high-shear regions, respectively, as depicted in Fig. 1. Optionally, the viscosity profile can be approximated by single-point measurements of low-shear viscosity (LSV), medium-shear viscosity (MSV), and high-shear viscosity (HSV). Some of the coating processes and

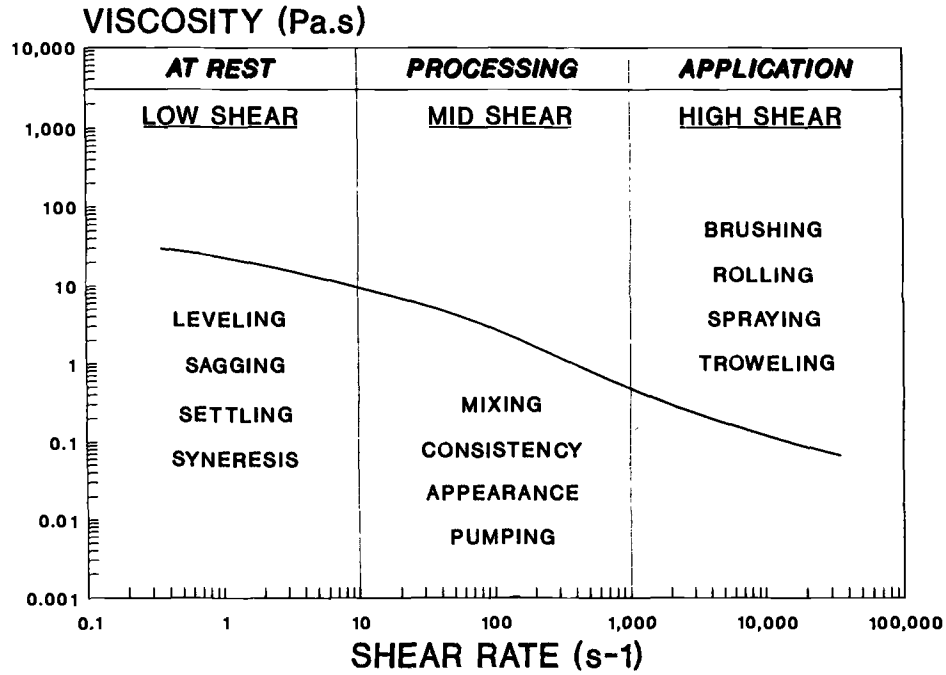

FIG. 1–A typical architectural coating viscosity profile, three important shear rate ranges, and the coating parameters affected and operating in each shear rate range.

properties affected in each region are also shown in Fig. 1 and are further discussed later in this chapter under **TRM FUNCTIONS.**

Time-dependent shear thinning (thixotropy) and zero-shear yield value are two other rheological coating properties that may be very important. For example, a thixotropic fluid with high yield value may exhibit good leveling if the time required to rebuild viscosity is long compared to the time needed for flowout. The viscoelastic properties of a coating may also be important. The elastic component of shear can be determined on some advanced cone-plate or parallel plate rheometers either by measuring the shear storage modulus (G') in oscillatory simple shear or by measuring normal forces (for example, first normal stress difference, N_1), which are perpendicular to the plane of shear.

Elongational Flow

In addition to the simple shear flow fields generated during the mixing and application of coatings, elongational (extensional) flows may also be induced during the application processes of spray, roll, or blade coating. The study of extensional flows and their importance in coatings has been examined [*6–11*]. During these application processes, the fluid is accelerated as it approaches the applicator orifice or nip, and the TRM polymer molecules become stretched and aligned. The viscosity related to the induced elongational flow is termed by Glass [*7*] as the "dynamic uniaxial extensional viscosity" (DUEV). One coating property that has shown some correlation with DUEV is roller spatter that can be rated using ASTM Test Method for Measurement of Paint Spatter Resistance to Roller Application (D 4707-87). Other properties that have shown some correlation with DUEV are ribbing, web formation, and misting in roll coatings, and the atomization process in spray coatings. Until recently, the measurement of DUEV on disperse phase coating systems was difficult; however, a commercial instrument is now available for measuring DUEV on undiluted coatings directly. As a class, associative thickeners tend to impart lower DUEV than conventional (nonassociative) thickeners, which improves some of the application properties described. Comparative representations of shear and elongational (extensional) flow are depicted in Fig. 2.

TRM CLASSIFICATION

Polymeric organic thickeners for aqueous media are often classified into two basic types: "conventional," which thicken predominately by hydrodynamic and flocculative mechanisms, and "associative," which thicken predominantly by associative mechanisms. Unfortunately, these are mechanistic

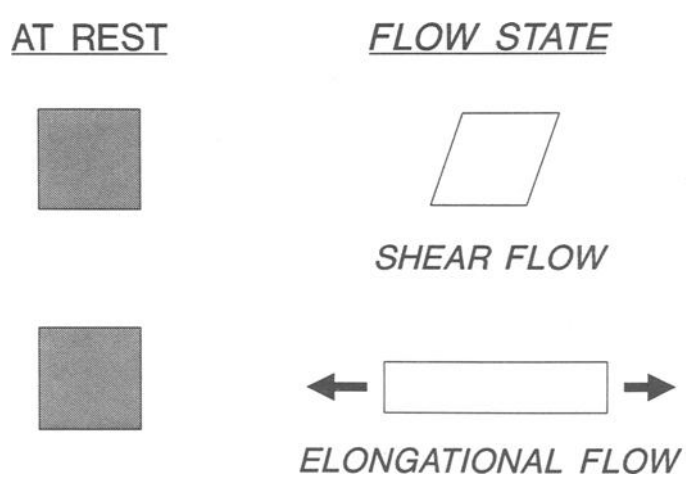

FIG. 2–Types of induced flow in coatings.

definitions that are subject to some variability and exception. A clear distinction, however, can be made for purposes of classification based on composition. Conventional (nonassociative) thickeners (CTRMs) are defined here as high-molecular-weight water-soluble polymers with relatively uniform hydrophilic backbones lacking hydrophobic groups. Lower-molecular weight species of similar chemical composition (analogs) are less efficient as thickeners but may serve as rheology modifiers. Associative thickeners (ATRMs), on the other hand, are defined here as water-soluble polymers of comparatively lower molecular weight which contain hydrophobic groups at the ends within or pendant to the hydrophilic backbones. The hydrophobes in these polymers are capable of nonspecific hydrophobic associations similar to those of conventional surfactants, and these associations are primarily responsible for generation of viscosity with these thickeners. Variation in chemical architecture, the number of hydrophobes present, and a further reduction in molecular weight can produce associative polymers which function primarily as rheology modifiers. It becomes readily apparent that, with proper hydrophobe modification, virtually any CTRM can be converted to an associative polymer, and this is what has been done in the design of several commercial ATRM products. The advantages and disadvantages of CTRMs and ATRMs have been reviewed in the literature [*12,13*] and will become more apparent in the following sections. A clearer distinction between these two major classes of TRMs will be apparent on examination of the thickening mechanisms involved. Although nearly all inorganic thickeners are conventional with respect to their thickening mechanisms, these TRMs will be treated separately later of this chapter under **INORGANIC THICKENERS FOR AQUEOUS AND SOLVENT-BORNE COATINGS.**

THICKENING MECHANISMS

The three primary thickening mechanisms for polymeric water-borne thickeners are "hydrodynamic," "flocculative," and "associative." Each of these mechanisms may be further divided into subclasses, if desired, which have their own individual rheological and coating characteristics. Consequently, it is important to consider these mechanisms when making TRM selection for increasing coating consistency, for rheology modification, or for other coating properties.

Thickening is often a complex process. For example, the flocculation mechanism is frequently a byproduct of hydrodynamic thickening but may also occur in associative systems that are improperly formulated or in those where a controlled degree of flocculation is desired. Some associative thickeners (for example, alkali-swellable types) are sufficiently high in molecular weight that an appreciable hydrodynamic component of thickening is also present. Depending on their chemical architecture, strength of the hydrophobic associations, and other formulation components present, some ATRMs actually function to varying degrees with several associative and nonassociative mechanisms at the same time. Outlined in Table 1 are some possible thickening mechanisms for conventional and associative thickeners.

TABLE 1—Thickening mechanisms for organic polymers in aqueous media.

I. *Hydrodynamic (CTRMs)*
(A) High MW soluble polymers
(B) Insoluble swellable polymers
II. *Associative (ATRMs)*
(A) Hydrophobe interactions
(B) Ion-dipole interactions
III. *Flocculative (CTRMs and ATRMs)*
(A) Depletion flocculation
(B) Bridging flocculation

NOTE: The flocculative mechanisms occur in disperse phase systems only and almost exclusively in the presence of CTRMs.

The Hydrodynamic Mechanism

Prior to the introduction of associative thickeners, nearly all organic thickeners used for aqueous coatings were water-soluble polymers of high molecular weight (MW) without hydrophobe modification, which is the collective criteria for their classification as conventional thickeners. The molecular weights of the conventional polymers that function as thickeners for water-borne coatings are generally greater than about 10^5 and can be as high as 10^6 or more. Polymers with stiff backbones (for example, cellulosics) at the lower end of the MW range are as effective in thickening in the high end of this range with flexible backbones (for example, polyethylene oxide). When conventional thickeners dissolve in water, the polymer chains occupy a large hydrodynamic volume in solution and immobilize large volumes of water within the coils of their backbones. This increases viscosity of the continuous water phase dramatically. For a given polymer type, higher molecular weight generates higher viscosity. In fact, the solution viscosity of conventional polymers in water or nonaqueous solvents is one of the common methods used for determination of molecular weight. As previously stated, sufficiently low-molecular-weight polymer analogs can function as true rheology modifiers since they do not contribute appreciably to consistency (MSV). However, these have been replaced to a large degree with associative rheology modifiers in many coatings applications.

Some conventional thickeners are lightly cross-linked to make them water-swellable rather than water-soluble. In aqueous media, these polymers swell significantly to produce viscosity by a hydrodynamic mechanism. When the polymers are made by emulsion polymerization, they may swell to many times their original particle size. Examples of conventional water-soluble or water-swellable thickeners used extensively in coatings are hydroxyethyl cellulose, hydroxypropyl methyl cellulose, and alkali-swellable/soluble copolymer emulsions (ASEs). These and some other CTRMs are discussed later in this chapter under **CONVENTIONAL TRMs (CTRMs).**

Flocculative Mechanisms

Because CTRMs take up so much volume in solution, they induce flocculation in coatings, forming latex-rich and thickener-rich domains by a mechanism commonly referred to as 'volume restriction," "volume exclusion," or "depletion" flocculation. This process is now recognized as the primary mode of thickening for conventional thickeners in disperse phase systems (such as, in coatings with pigment or latex particles

present) and has been examined in both experimental [*14–16*] and theoretical treatments [*17,18*] and more recently modeled by computer simulation [*19*]. The process begins when latex particles randomly approach each other, and when they are close enough (on the order of a random-coil thickener molecular diameter), thickener molecules are "excluded" from the interparticle region. The concentration gradient formed causes water to be osmotically "pumped" from between the particles driving them even closer together, which further concentrates the thickener molecules in the aqueous phase. Eventually, the latex particles touch, forming flocs which are readily observable on microscopic examination. This mechanism of thickening can adversely affect gloss and hiding and also may impart more shear thinning character and more viscoelasticity. Since these polymers are of high molecular weight, they also tend to impart high extensional viscosity to coatings. The combination of viscoelasticity and high extensional viscosity results in a tendency for spatter and increased rib pattern in roll coatings [*20*].

Another flocculative mechanism is "bridging" flocculation. In this mechanism, the polymer molecules partially adsorb onto latex or pigment particles. If the thickener molecules are sufficiently long and have a strong affinity for other particles, bridging can occur, forming flocs.

ASSOCIATIVE MECHANISMS

The primary thickening mechanism for ATRMs is via intermolecular hydrophobic association and association of the thickener hydrophobes with disperse phase (colloidal phase) hydrophobic components in the coating formulation [*21–24*]. When a water-soluble polymer contains both hydrophilic and hydrophobic moieties, the potential for associative interaction exists. Among the simplest associative structures are nonionic surfactants. These molecules have a hydrophilic polymer segment on one end (usually polyethylene oxide) and a hydrophobic group on the other (typically a long chain alkyl or alkyl aryl group). At a sufficiently high concentration known as the critical micelle concentration (CMC), these surfactants spontaneously form micelles in aqueous solution. At or above this concentration, the hydrophobes aggregate at the interior of the micelle, and the hydrophilic tails orient outward into the water phase. The key driving force for micellization is not the London Van der Waals attractive forces between hydrophobes, but rather the change in free energy on transfer of a hydrophobe in the aqueous phase to a more oil-like environment at the interior of the micelle.

If a hydrophobe is chemically attached to the other end of a nonionic surfactant, a simple associative thickener is formed. However, because the thickener has a hydrophobe at each end, micelle formation is not a favorable process and is not observed except for certain chemical architectures at extremely low concentrations. Instead, the associative molecules aggregate into a three-dimensional network structure that inhibits flow and raises the viscosity of the aqueous solution or coating. The driving force is similar to that for micelle formation. Although each associative polymer type has an optimum molecular weight, high molecular weight is not a requirement of associative thickeners, and most are significantly lower in molecular weight (typically <50 000) than conventional thickeners. To be viable in commerce, ATRMs usually have a few repeat hydrophile-hydrophobe units to increase molecular weight, thereby increasing the hydrodynamic contribution and also the association efficiency.

Another aspect of ATRMs is their interaction with colloidal components in a coating formulation. Whenever latex particles or hydrophobic pigments are present in a coating formulation, the hydrophobes on the associative thickeners can adsorb onto the hydrophobic particle surfaces, which results in a further increase in system viscosity and possible modification of rheology. The strength of the association is important, and depending on degree, a polymer can induce several types of equilibrium phase behavior including nonassociative volume restriction and associative bridging flocculation [*26*]. For comparison, diagrammatic representations of a conventional thickener and an associative thickener in the presence of latex particles are depicted in Figs. 3 and 4, respectively.

Although hydrophobe interaction is the predominate associative mechanism for ATRMs, some evidence suggests an additional associative mechanism which is hydrophilic rather than hydrophobic in nature. The proposed hydrophilic association is an ion-dipole interaction between surface carboxyl groups on the latex with the polyethylene oxide (pEO) segments in the associative thickeners [*25*]. When the ATRMs contain both carboxyl and ethoxylate functionality in the same molecule (for example, associative alkali-swellable/soluble polymers), both intermolecular and intramolecular ion-dipole associations are theoretically possible.

TRM FUNCTIONS

The primary function of TRMs are the control of viscosity and rheology throughout the applicable shear rate spectrum: consistency is measured and adjusted in the medium-shear-rate range, application properties in the high-shear-rate range, and film formation and container storage properties in the low-shear-rate range. The viscosities associated with these ranges may be referred to as the medium-shear viscos-

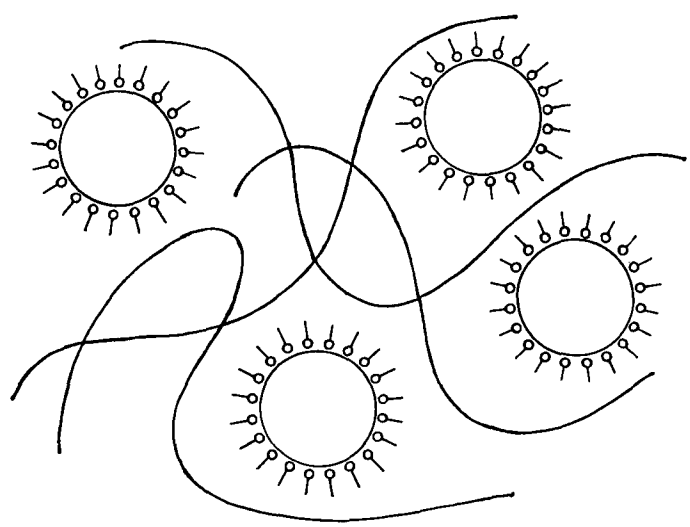

FIG. 3–Conventional (nonassociative) thickener molecules in the presence of aqueous latex particles.

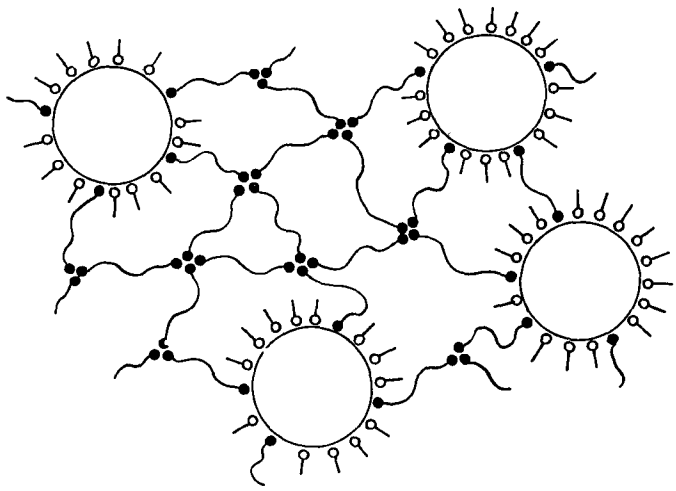

FIG. 4–Associative thickener molecules in the presence of aqueous latex particles.

ity (MSV), high-shear viscosity (HSV), and the low-shear viscosity (LSV), respectively. Several film properties are also affected and may be manipulated by the appropriate choice and amount of TRM in the coating [27]. Two examples of coatings improperly formulated with TRMs are represented in Fig. 5. A clear understanding of the rheology profiles depicted and their impact on application and film properties will become apparent in the following subsections.

Coating Consistency (Medium-Shear Viscosity)

Measurement of MSV in the previously defined medium-shear domain provides an indication of the consistency of a coating that relates to its appearance and feel on mixing. It is common practice for formulators to adjust coating viscosity in the medium-shear range by varying the amount of thickener added. The target viscosity is normally based on prior experience or on a previously established specification range for a particular type of coating. One popular rheometer used for measuring and facilitating consistency adjustment in architectural coatings is the Stormer® viscometer. Viscosity determination with this instrument is conducted in accordance with ASTM Test Method for Consistency of Paints using the Stormer Viscometer (D 562). This rheometer provides a paddle-type mixing action during measurement that is similar to stirring, and viscosity is expressed in Krebs Units (KU). Many coatings fall within the range of 60 to 120 KU, and a typical specification range for a semigloss architectural coating, for example, might be 90 to 95 KU.

The Brookfield® viscometer is another popular instrument for determination of consistency when operated at higher speeds (for example, 20 to 100 rpm). It is also useful at lower speeds (for example, 0.3 to 5 rpm) for determination of low-shear processes such as leveling [see later in this section under **Leveling, Sag, Syneresis, Settling (Low-Shear Viscosity)**]. Both of these measurements can be conducted in accordance with ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D 2196). Both the analog and digital Brookfield models provide viscosity in centipoise (mPa·s), and cylindrical spindles are commonly used for the measurement. Another Brookfield viscometer recently introduced has a paddle configuration similar to the Stormer viscometer. Readout on this model is in Krebs Units.

The Rotothinner® is another viscometer which can be used to determine consistency. It provides an even greater mixing action that is capable of stirring the entire container contents while the viscosity measurement is being made. While this instrument can be used for more conventional coatings, it is

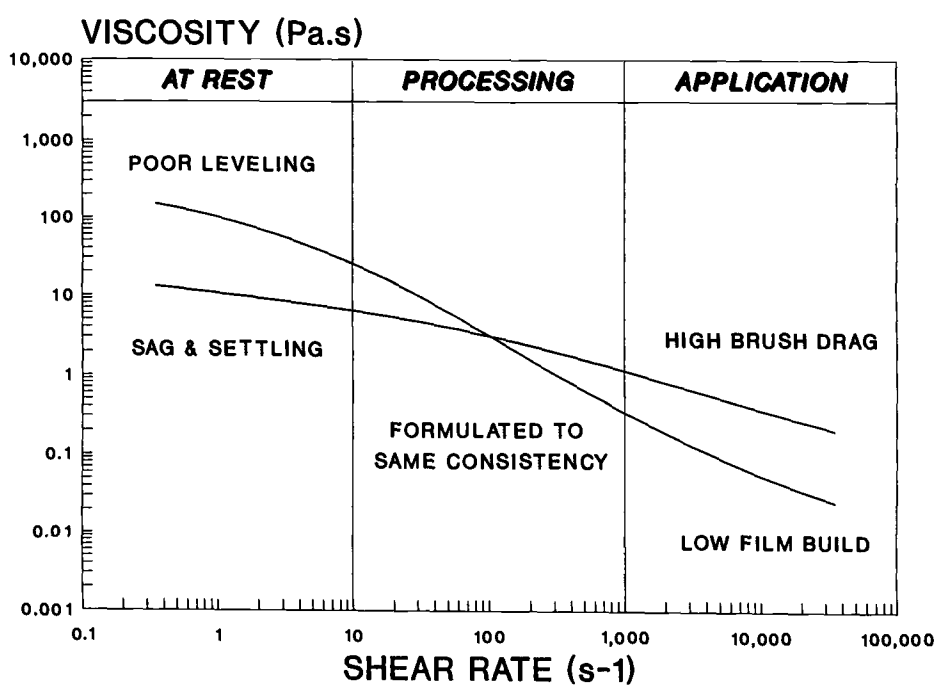

FIG. 5–Shear profile examples of inadequate TRM formulation for a premium architectural coating.

ideally suited for breaking down the structure of thixotropic fluids to obtain a sheared viscosity.

Application Properties (High-Shear Viscosity)

Most brush, spray, or blade coating operations are relatively high-shear processes. This is also true for roll coating applications when the circumferential velocity of the roll is significantly different than the linear velocity of the substrate. The shear on application for these operations is generally greater than about 10^3 s^{-1} and is typically about 10^4 s^{-1} for brushing and as high as 10^6 s^{-1} for some high-speed roll coating, blade coating, and spray operations. There are several high-performance rotational rheometers for measuring the HSV, and most use cone/plate or plate/plate geometry. One general purpose instrument that is popular for laboratory and quality control of HSV measurement is the ICI cone-plate viscometer by ASTM Test Method for High-Shear Viscosity Using the ICI Cone/Plate Viscometer (D 4287-88). This instrument has a fixed shear rate of 10^4 s^{-1}, and viscosity measured is a good predictor of film build when a coating is applied by brush or paint roller. The higher the ICI viscosity, the more resistance a brush or roller encounters on application, which results in a thicker applied film. HSVs at this shear rate are typically from about 0.5 to 2.5 P (50 to 250 mPa s) for architectural coatings. If the HSV is too high, the coating will require too much effort to apply, will have a low spread rate, and may sag. If the HSV is too low, a second coat may be required to hide the substrate. Subjective brush drag by actual application is often conducted in accordance with ASTM Test Method for Comparison of Brush Drag in Latex Paints (D 4958).

Conventional thickeners generally produce coatings with low HSV, while most associative thickeners and particularly associative rheology modifiers produce high HSV. Although not common, some associative thickeners produce low HSV that may be desirable depending on the application and film thickness desired. These thickeners tend to be very efficient in the medium-shear region, and the low HSV is primarily a consequence of less thickener being used. As a general rule for a given thickener type, the more thickener required to obtain desired consistency (MSV), the higher the HSV will be. Therefore, if an increase in HSV is desired, a less efficient thickener or a rheology modifier may be needed. As an option with associative thickeners, efficiency in the medium-shear region can be suppressed or enhanced by adjustment of other components in the coating formulation. By proper TRM selection or TRM blending, the desired HSV can be obtained without adversely affecting MSV or LSV.

Leveling, Sag, Syneresis, Settling (Low-Shear Viscosity)

After a coating has been made or applied, an appropriate LSV is needed to prevent container separation (pigment settling and syneresis) and to promote film formation (leveling and sag resistance). The applicable shear rates for LSV are generally less than about 10 s^{-1} and more practically in the range of 10^0 to 10^{-3} s^{-1}. The low-shear applied in these processes is primarily due to the effects of gravity for container separation and sagging and due to capillary pressure (generated by surface tension and surface curvature) for leveling. In architectural coatings, LSVs that are too high result in poor leveling, and brush or roller pattern is very apparent. The degree of leveling is often determined by simple inspection of brush marks or roller pattern after the applied film has dried. Optionally, a notched applicator on a horizontal surface may be used in accordance with ASTM Test Method for Leveling of Paints by Draw-Down Method (D 4062). In contrast, LSVs that are too low may allow sagging on vertical surfaces and in-can settling or syneresis. Sag ratings are often conducted in accordance with ASTM Test Methods for Sag Resistance of Paints using the Multinotch Applicator (D 4400).

A variety of viscometric techniques have shown some correlation with leveling. Among these is a stress-relaxation procedure [*28*]. In this method, the coating is first sheared at a moderately high rate to break down structure to simulate brushing or rolling. The shearing is then stopped, and the declining shear stress versus time is recorded. The area under the relaxation curve is then integrated to obtain a "leveling viscosity" (that is, the product of stress and time has the dimensions of viscosity).

A relatively simple one-point technique which generally provides good correlation with leveling is a viscosity measurement at low rpm (for example, 0.3 rpm on a Brookfield® viscometer). At the low shear rate produced at this speed, excellent leveling would be indicated for coatings with measured viscosities of less than about 250 P (25 Pa·s) as might be obtained with a high-performance associative thickener. Too much flow would be indicated below about 100 P (10 Pa·s), and sag would be predicted on vertical surfaces. By the same technique, poor leveling would be indicated at about 1000 P (100 Pa·s) as might be obtained from a moderately high MW conventional thickener, and little or no flow at 2000 to 3000 P (200 to 300 Pa·s) for some very high MW conventional or special associative thickeners. Another common method conducted on a Brookfield® viscometer is the measure of "pseudoplastic index." This is a two-point determination that is the ratio of two viscosities a decade apart in shear rate (for example, 0.3 rpm/3.0 rpm or most commonly 6 rpm/60 rpm). LSV is probed by extrapolation of viscosity to lower shear rates (lower rpm).

From the prior discussion, it follows that a high LSV is generally needed for suspension or low flow characteristics, while a low LSV or low yield value is needed to promote flow and leveling. Due to the associative mechanism, most, but not all, ATRMs provide low LSVs to impart excellent leveling characteristics. However, some alkali-swellable associative thickeners impart uncharacteristically high LSVs, and like very high MW CTRMs, these thickeners have utility as antisag or antisettling agents or for use in highly structured coatings (for example, texture paints). Although these thickeners are definitely associative by examination in aqueous solution, their unusual behavior in coatings may be due to their ability to impart a degree of flocculation. Although not as low as CTRMs, lower gloss levels observed for some of these thickeners support this conclusion. However, some of these thickeners actually produce very high gloss levels, which suggests that aqueous phase networking has a larger influence on rheology than expected and/or that the dispersant character for these thickeners is greater than expected. Conventional thickeners, on the other hand, nearly always are highly shear thinning with high LSVs due to the hydrodynamic and floc-

culative mechanisms operating. Consequently, the gloss and hiding imparted from these thickeners tends to be lower.

CONVENTIONAL TRMS (CTRMS)

In the broadest definition, conventional TRMs (CTRMs) are water-soluble polymers lacking hydrophobe modification (that is, they are nonassociative). The higher-molecular-weight polymers function primarily as thickeners, and the lower-molecular-weight polymers function as rheology modifiers. Their primary thickening mechanisms are hydrodynamic and flocculative. Although there are many different types of water-soluble polymers which could be used as TRMs in architectural and industrial coatings, only a few have been accepted for use due to factors relating to economics, bio-stability, water sensitivity, compatibility, production quality, ease of handling, or rheology. Those CTRMs which are currently used in coatings, some widely and others infrequently, are discussed in the subsections which follow. These fall into two major categories: polymers of biological origin (polysaccharides) and the synthetic alkali-swellable/soluble emulsions (ASEs). The polysaccharides may be further subdivided into modified cellulosics, guar derivatives, alginates, and "biopolymers." The bipolymers are of more recent origin and employ microorganisms as a means of production or modification. Table 2 lists conventional water-soluble polymers used as thickeners in both coatings and noncoatings applications. With respect to coatings only, nearly all have been tried, many were found unacceptable, some are currently used, some have been used in the past, and others may have future potential particularly if modified with hydrophobes for conversion to ATRMs. Table 3 details some important domestic (U.S.) suppliers of CTRMs and their respective products.

TABLE 2—Conventional water-soluble thickeners for coatings and noncoatings applications.

Cellulosic polysaccharides
Carboxymethyl cellulose (CMC)
Carboxymethyl hydroxyethyl cellulose
Ethyl hydroxyethyl cellulose (EHEC)[a]
Hydroxyethyl cellulose (HEC)[b]
Hydroxypropyl methyl cellulose (HPMC)[b]
Methyl cellulose
Biopolymer polysaccharides
Gellan gum

Whelan gum
Xanthan gum (XCPS)[a]
Other polysaccharides
Guar gum
Hydroxypropyl guar (HPG)[a]
Sodium alginate
Synthetic hydrocarbon polymers
Poly acrylamide and copolymers
Poly ethylene oxide (PEO)
Poly hydroxyethyl (meth)acrylate
Poly (meth)acrylic acid copolymers (ASE)[b]
Poly olefinic sulfonate copolymers
Poly vinyl alcohol (PVOH)
Poly vinyl pyrolidone[a]
Poly styrene/maleic anhydride (SMA)
Poly methylvinyl ether/maleic anhydride

NOTE: [a]These have some use in architectural coatings. [b]These have significant use in architectural coatings. All others have little or no current use in architectural coatings.

Cellulosics

Prior to the introduction of ATRMs, conventional cellulosics were by far the most commonly used TRMs in aqueous coatings. They still dominate, but their use is in decline today. The reduction has been somewhat offset with the introduction of associative cellulosics, which are discussed later in this chapter under **Hydrophobe Modified Cellulosics (HMCs).** Cellulose $(C_6H_{10}O_5)_n$ is a naturally occurring polysaccharide composed of repeating anhydroglucose units. Because of its relatively straight and stiff polymer chain and strong intermolecular and intramolecular hydrogen bonding, the polymer itself is highly crystalline and consequently insoluble in water. Nonetheless, with chemical modification, cellulose can be readily converted to amorphous water-soluble polymers. Hydroxyethyl cellulose (HEC), hydroxypropyl methyl cellulose (HPMC), carboxymethyl cellulose (CMC), and ethylhydroxyethyl cellulose (EHEC) are among those that have been used in aqueous coatings.

The reactions used to produce water-soluble cellulose polymers are relatively uncomplicated. They typically involve treatment of cellulose with alkali to swell the polymer, followed by the chemical addition of the appropriate substituent. Each of the commercial polymer types is available in a variety of grades that are differentiated by molecular weight, levels of substitution, uniformity of substitution, and treatment for ease of dispersion. As molecular weight increases for a given polymer type, the amount of thickener required for constant MSV decreases (thickening efficiency improves). At the same time, LSV increases and HSV decreases. The effect on film build is predictable (lower); however, some investigators have actually reported improved leveling with higher MW cellulosics. The modifications are defined in two ways: the degree of substitution (SD), which is the average number of hydroxyl groups which have been substituted per anhydroglucose unit, and the moles of substitution (MS), which is the average number of moles of substituents per anhydroglucose unit for those substituents which generate repeating units (such as ethylene oxide in HEC).

HEC

Of the cellulosics, hydroxyethyl cellulose unquestionably has been the most popular TRM used in coatings. HEC is a nonionic polysaccharide manufactured by reacting ethylene oxide with the reactive hydroxyls on the anhydroglucose units of cellulose. The ethylene oxide also reacts with previously substituted hydroxyls, resulting in short pEO side chains (usually two or three units in length). The ratio of molar substitution (MS) to degree of substitution defines the number of EO groups per side chain. The most popular products have MS values in the range of 1.5 to 3.0 and DS values of about 0.85 to 1.35. Optimizing reaction conditions results in a more uniform distribution of substitution to produce bio-resistant polymer grades.

Presently there are two major international producers of HEC, and the products are available in several regular and enzyme-resistant grades. Of these, the medium- and high-molecular-weight bio-resistant grades have been of greatest utility in coatings as thickeners. Low-molecular-weight grades are used as secondary TRMs to modify rheology (improve flow or film build). Some grades also have surface treat-

ments to slow down the rate of hydration to minimizes lumping. Until recently, HEC was only available in solid form. Moderately viscous "fluidized dispersions" are now available which improve handling and increase the rate of incorporation. To minimize the dispersion viscosity of the supplied product, proprietary salts are incorporated. Various test methods for HEC are found in ASTM Test Methods for Hydroxyethylcellulose (D 2364).

HPMC

Hydroxypropyl methyl cellulose, a derivative of water-soluble methyl cellulose (MC), is another nonionic polysaccharide which has wide acceptance in coatings. Two other lesser known water-soluble analog derivatives of MC are hydroxyethyl methyl cellulose (HEMC) and hydroxybutyl methyl cellulose (HBMC). Grades of HPMC vary in molecular weight [*29*], the ratio of methyl to hydroxypropyl substitution on the cellulose backbone, and the degree of substitution. Commercial grades of HPMC have average DS for the methyl groups in the range of 0.9 to 1.8 and MS for hydroxypropyl groups in the range of 0.1 to 1.0. Variations in these parameters affect solubility, thermal properties, and resistance to enzymes. Both MC and HPMC exhibit lower critical solution temperatures (i.e., they possess the somewhat unusual property of being soluble in cold water and insoluble in hot water). Solutions of these polymers form gel structures on heating. With modifications in processing, DS, MS, the gel temperature, and gel texture are altered. Because of its structure, HPMC is also inherently more resistant to bio-organisms compared to some other polysaccharides. Various test methods for the

characterization of HPMC may be found in ASTM Test Methods for Hydroxypropyl Methylcellulose (D 2363).

EHEC

Ethyl hydroxyethyl cellulose is another water-soluble polymer with utility in water-borne paints with many properties similar to HPMC. The principal commercial product line consists of two series where the degree of molar substitution for the hydroxyethyl group is 0.8 and 2.1, respectively, and the ethyl group is the same for all grades with DS of approximately 0.8. All grades are also available with surface treatment for fast dispersion and adjustable dissolution rate. Like HPMC, EHEC is soluble in cold water and insoluble in hot water. Increasing hydroxyethyl substitution increases water solubility, improves salt tolerance, and decreases the tendency for gellation on heating.

CMC

Sodium carboxymethyl cellulose (CMC) is an anionic water-soluble polymer which has been of limited use in coatings because the modification constituent (sodium carboxylate) leaves the dried films more water-sensitive than most nonionic polysaccharides. CMC is prepared by reaction of cellulose with monochloroacetic acid after treatment with alkali. Commercial grades have DS for carboxylate substitution ranging from 0.4 to 1.4, and the most popular products are MS 0.7 to 0.8. As with most other conventional polysaccharides, the viscosity is primarily controlled by varying the molecular weight of the cellulosic chain. Some technical grades of CMC contain by-product salts (primarily sodium chloride and sodium glycolate) that further limits their use in coatings applications (for example, to dry-mix paints where the CMC functions to control viscosity and wet edge). A purified grade referred to as cellulose gum is preferred for use in latex paints. Various procedures for characterization of CMC may be found in ASTM Test Methods for Sodium Carboxymethylcellulose (D 1439).

Hydroxypropyl Guar (HPG)

Of the noncellulosic polysaccharides available for use in coatings, only hydroxypropyl guar (HPG) has found significant application. HPG is a chemical modification of guar gum which is a high-molecular-weight galactomannan obtained from the seeds of two leguminous plants (*Cyamopsis tetragonalobus* and *psoraloides*). Like the biopolymers described below, this polymer produces coatings which are more shear thinning (more pseudoplastic) than the cellulosic products. Hence, compared to cellulosics, HPG tends to have better suspension and antisag characteristics but produces more roll spatter and is less bio-resistant. Another limitation for HPG is that it is available in only one grade. Compared with its parent (guar gum), solutions of HPG are more bio-resistant, less electrolyte sensitive, and have improved solubility and clarity. Utility of HPG is primarily as a secondary thickener or for use in flat, texture, and dripless paints.

Biopolymers

The use of biopolymers in paints and coatings has also been limited; nonetheless, at least two products are being used as either primary or secondary thickeners to provide suspension characteristics. Commercial biopolymers are polysaccharides; however, they differ from the cellulosic and guar products described above in that they are enzymatically produced rather than being made by chemical modification. The biopolymer synthesis is typically conducted in a fermentation broth with bacterium or yeast. Seemingly common to the biopolymers is their ability to suspend or gel, their salt tolerance, and their stable viscosity over a wide temperature range. As with HPG, a limitation is that there are only one or two grades available from each supplier. Among the commercial biopolymer products which are available are Xanthan gum, Rhamsan gum, Welan gum, and Gellan gum.

Xanthan Gum

Perhaps the most well known and commercially important biopolymer is Xanthomonas campestris polysaccharide (XCPS), better known as Xanthan gum. This polymer was initially "cultured" in USDA laboratories using fermentation technology with the bacterium *Xanthomonas campestris* [*30*]. Xanthan gum is a high-molecular-weight (approximately 2×10^6), branched polysaccharide which is characterized as having high yield values and a high degree of pseudoplasticity (high LSV and low HSV). Total and immediate recovery of viscosity after shearing is also characteristic. Other features are its relative insensitivity to pH, temperature, and the presence of most salts. Applications for Xanthan are similar to those for HPG with somewhat better efficiency and even more shear thinning rheology (higher LSV). Xanthan gum is normally sold as a solid; however, liquid versions of this polymer (Xanthan broths) are now available that are easier to handle—supplied at relatively low concentrations (3 and 15%) with viscosities of about 4000 and 14 000 mPa·s, respectively. The side-chain functionality of the fluid polymer is significantly different (much higher in pyruvate content) from conventional solid Xanthan, but the rheology is still very shear thinning. The active biopolymer in these products is also claimed to be a more effective viscosifier than solid Xanthan.

Rhamsan Gum

Rhamsan gum is another biopolymer that has some application in coatings. One of the more outstanding characteristics of this polymer is its exceptional suspending power (produces very high LSV in coatings). In approximate order of decreasing suspending ability are Rhamsan gum > Xanthan gum > HP guar > CMC > HEC < CMC. Rhamsan gum also reportedly has good salt tolerance and improved stability to high-shear mixing.

Alkali-Swellable/Soluble Emulsions (ASEs)

ASEs are among the few conventional synthetic hydrocarbon thickeners to be used in substantial amounts in coatings. Conventional ASEs are carboxyl functional copolymers produced by the free-radical emulsion polymerization of ethylenically unsaturated monomers [*31*]. They are low-viscosity water-insoluble latexes at low pH as supplied, but exhibit thickening on dissolution or swelling of the latex particles when the pH is raised (generally above pH 5.5). Copolymers of methacrylic acid and ethyl acrylate are most common and

may contain a small amount (generally less than 1%) of a polyfunctional monomer to lightly cross-link the polymer to enhance swellability. Since most coating formulations are finished on the basic side, the ASE polymers are fully neutralized in most applications. They achieve their maximum viscosities above about pH 7, and, ideally, viscosity generated should be constant between about pH 7 to 10 so that slight changes in pH have little effect on coating consistency. Although ASEs impart rheology similar to other conventional thickeners, their primary advantages compared to the polysaccharides are in ease of handling and bio-stability. ASEs may be more water sensitive than most nonionic polysaccharides; however, unlike CMC, which is supplied as a sodium salt, neutralization of ASEs is normally with ammonia or volatile aminoalcohols which leave the film on drying. Hydrophobe modification of conventional ASEs to produce associative TRMs (HASEs) has greatly increased the popularity of the emulsion thickeners. These are discussed later in this chapter under **Hydrophobe Modified ASEs (HASE).**

ASSOCIATIVE TRMS (ATRMS)

Because of the increasing importance of rheology modification in coatings, the use of ATRMs continues to grow with many product offerings now available. Presently, three broad classes of commercial ATRMs represent many older and newer products. They are hydrophobe-modified nonionic synthetics (HNS), hydrophobe-modified cellulosics (HMC), and hydrophobe-modified alkali-swellable/soluble emulsions (HASE). Contained within the major classes are important subclasses all of which are discussed in detail below. Table 4 summarizes the commercial product classification scheme for ATRMs, principal subclass examples, and the designated acronyms. Those acronyms that are prominent in the literature as well as those which are newly assigned are indicated. Table 5 lists some important U.S. suppliers of ATRMs, their representative products, and the product's classification.

Coating components and coating formulation variables are known to affect the rheological performance of associative thickeners [*32,33*]. Some specific parameters which have been examined are volume solids [*34*], type of latex binder [*35,36*] latex binder particle size [*14,15*], particle surface acid groups [*25,37*], surfactants and cosolvents [*38*], coalescing aids [*39*], and some clay pigments [*40,41*]. The steady shear and linear viscoelastic properties of associative thickener solutions have also been characterized [*42*].

TABLE 4—Classification of associative thickener/rheology modifiers (ATRMs).

HNS—*Hydrophobe modified nonionic synthetic*
Subclass Example:
HEUR—Hydrophobe modified ethoxylate urethane
HENN—Hydrophobe modified nonionic non-urethane
HMC—*Hydrophobe modified cellulosic*
Subclass Example:
HMHEC—Hydrophobe modified hydroxyethyl cellulose
HMEHEC—Hydrophobe modified ethyl hydroxyethyl cellulose
HASE—*Hydrophobe modified alkali-swellable/soluble emulsion*
Subclass Example:
HEEASE—Hydrophobe modified ethoxylate ester alkali-swellable/soluble emulsion
HEURASE—Hydrophobe modified ethoxylate urethane alkali-swellable/soluble emulsion

NOTE: HNS, HENN, and HEEASE are new acronyms for which there were none previously. All others are those of general acceptance in ACS and other technical publications.

Hydrophobe Modified Nonionic Synthetics (HNS)

The HNS ATRMs are nonionic condensation polymers of synthetic origin. Common to these polymers are hydrophilic pEO segments which alternate with hydrophobic groups. The polymers tend to be much lower in molecular weight than conventional thickeners, and the repeat units (pEO segment plus hydrophobe) are generally less than about 20. Main chain ends and any side chains are typically terminated with hydrophobic groups. The two principal subclasses are hydrophobe-modified ethoxylate urethanes (HEUR) and hydrophobe-modified nonionic nonurethanes (HENNs). Differentiation in this classification scheme is simply the presence or lack of urethane functionality.

HEUR (Subclass of HNS)

The HEUR polymers are the major subclass of the nonionic synthetics (HNS). They are among the most popular ATRM products, and presently there are several domestic and international suppliers. Common to all HEUR polymers are the presence of three chemical components (terminal hydrophobes at the ends of side or main chains, internal hydrophilic pEO segments, and urethane linkages). The HEUR polymers are generally considered to be among the best of the associative products with respect to rheology modification. Being low in molecular weight and highly associative, they tend to provide the most Newtonian rheology (low LSVs and high HSVs) for superior flow/leveling and film build and also impart low extensional viscosity and low viscoelasticity for superior spatter resistance.

Nearly all HEUR polymers are supplied as moderately viscous solutions in a combination of water and cosolvent (for example, Butyl Carbitol® or propylene glycol). The cosolvent is present to suppress viscosity for ease of handling. Since HEURs are nonionic, they should have inherently low water sensitivity. However, they are generally less efficient than cellulosics or ASEs, and they are also much lower in molecular weight, which may limit their use in some exterior applications. Because the HEUR products have very low LSVs for superior flow, they may permit sagging, syneresis, or pigment settling, particularly when used as the sole thickener. They are also very sensitive to other coating components, and proper formulation balance is necessary for optimum performance. The HEUR products have been the subject of numerous technical investigations [*43–45*].

HENN (Subclass of HNS)

Synthetic nonionic associative thickeners lacking urethane functionality are the latest entry into the ATRM arena. At this writing, there is one commercial offering and two developmental products. Being synthetic, nonionic, and containing terminal hydrophobes, the chemical makeup of HENN polymers is generally similar to HEUR with the exceptions that the polyether segments may not be limited to ethylene oxide alone (that is, EO-PO blocks may be present), the molecular weights may be lower than some HEURs, and the products lack urethane linking groups (may contain ether, amide, or

some other linkage). Like the HEUR polymers, HENN thickeners contain cosolvent and are supplied as moderately viscous aqueous solutions. Little information is currently available; however, based on advertising claims for chemical composition and performance, the rheological characteristics of these products are expected to be similar to HEUR ATRMs. The chemical composition and physical form would also suggest that the handling and performance limitations are similar to those of HEURs. Improved color acceptance, color stability, and block resistance are claimed for the commercial product, and improved shear stability due to lower molecular weight is claimed for the developmental products but at the expense of thickening efficiency [*46*].

Hydrophobe Modified ASEs (HASE)

The HASE polymers were among the first ATRMs to be developed, and their commercial significance dates back to the late 1960s [*47–49*]. The popularity of these products continues due to their relatively good economics, bio-stability, rapid viscosity equilibration, lack of cosolvents (0 or low VOC), and low-viscosity liquid form as supplied. Like ASEs, the HASE products are synthetic addition polymers produced by emulsion polymerization of carboxyl functional monomers. Consequently, they are of relatively high molecular weight (higher than HNS but lower than conventional thickeners) and thicken by a hydrodynamic mechanism in addition to the associative mechanism. The predominate mechanism operating depends on several factors including the molecular weight and the amount and type of associative functionality.

Typically, HASE products are terpolymers of ethyl acrylate, methacrylic acid or itaconic acid, and an associative macromononer. The macromonomer usually contains pEO units (typically 10 to 100 mol ethylene oxide) terminated with a hydrophobe (typically alkyl or alkylaryl). The associative side chain linkage to the main chain backbone is predominately either ester (HEEASE) or urethane (HEURASE) per the classification scheme of Table 4. The patent literature does describe other linkages, and although some have been used in

the past, they are not commercial today (for example, products with ether linkages were marketed in the 1960s but were later discontinued). Like ASEs, the HASE polymers may also be cross-linked to varying degrees with small amounts (typically less than 1%) of a polyfunctional monomer to increase swellability. Although HASE polymers are anionic and, therefore, predicted to be more water sensitive than nonionic ATRMs, many HASE products are more efficient (less thickener is required for consistency), which minimizes the effect of the anionic character. Additionally, performance of HASEs in exterior coatings can be improved with ZnO or zinc complexes which cross-link the carboxyl functionality present [*50,51*], which is lacking in the HNS polymers. Being polyanionic, the HASE polymers also have dispersant character that contributes to hiding and gloss. The carboxyl groups in HASE polymers can also covalently cross-link with melamine, urea, and epoxy resins in thermoset coatings, and being acidic, they catalyze the cross-linking process.

HEEASE (Subclass of HASE)

The HEEASE polymers are one of two major HASE subclasses. Prior to the recent introduction of HASEs containing urethane linkages, the many commercial HEEASE polymers were the only representatives of the HASE class. Consequently, HASE usually implied HEEASE in the literature. Since there are now several commercial urethane functional HASE polymers, subclassification was needed, and like the HEUR and HENN polymers, differentiation here relates to the presence or lack of urethane linking functionality. The associative side chains of HEEASE polymers contain ester linkages, and like most other ATRMs, some HEEASE polymers are true rheology modifiers [*48*], and others are primarily thickeners providing relatively good associative rheology [*37,52*]. Because of the dual thickening mechanisms, the molecular weight and type and amount of associative functionality are among the processing variables that can be altered to effect change in performance. With respect to rheology, the HEEASE thickener performance is generally similar to the associative cellulosics.

HEURASE (Subclass of HASE)

The HEURASE ATRMs are a relatively new technology, combining much of the chemical architecture and advantage features of the anionic ASE and nonionic HEUR thickeners [*53–55*]. Like conventional ASEs, HEURASE polymers are prepared by emulsion polymerization and supplied as low-viscosity, low-pH latexes. However, the associative side chains in HEURASE contain the same three functional components found in HEUR thickeners (terminal hydrophobes, pEO segments, and urethane linkages). Because of this and the relatively high level of associative monomer present in these terpolymers, rheology modification approaching that of the premium HEUR thickeners is claimed without many of the HEUR and HENN limitations. Although most HEURASE thickeners provide the expected Newtonian rheology, some atypically impart suspension characteristics (high LSV) for use in antisag, antisettling, or texture paint applications. The extensional viscosity imparted by HEURASE products is low and comparable to some HEUR thickeners [*54*].

Hydrophobe Modified Cellulosics (HMCs)

Like the HNS polymers, hydrophobe-modified cellulosics are condensation polymers but of biological origin. These polymers are prepared by modifying standard or special grades of conventional cellulosics with hydrophobes. And, like the other ATRMs described above, the hydrophobes are typically alkyl or alkylaryl, but the pEO chains are comparatively very short. Presently there are two commercial subclasses of HMCs: hydrophobe-modified hydroxyethyl cellulose (HMHEC) and hydrophobe-modified ethyl hydroxyethyl cellulose (HMEHEC). These HMCs are presently all nonionic; however, the potential exists for future products which may be either nonionic [for example, hydrophobe-modified hydroxypropyl methyl cellulose (HMHPMC) and the like] or anionic [for example, hydrophobe-modified carboxymethyl cellulose (HMCMC) and the like].

HMHEC (Subclass of HMC)

The first commercial associative cellulosic thickener on the market in the late 1980s was hydrophobe-modified hydroxyethyl cellulose (HMHEC). This product has overcome many of the limitations of conventional HEC including improved film build, improved leveling, and better spatter resistance [*56*]. The associative behavior (adsorption onto latex and pigment particles) and the rheology of this polymer have been characterized [*57*] along with various solution properties [*58*]. The improvement in rheology (more Newtonian for better leveling and increased film build) over HEC is generally similar to the HEEASE thickeners, but since HMHEC is nonionic, the water sensitivity of coatings made with it tends to be better. The methods of preparation and solution properties of HMHEC have also been described [*59,60*]. HMHEC is prepared by attaching hydrophobes to conventional HEC via the hydroxyl groups along the polymer backbone. The degree of substitution and molecular weight grade of HEC chosen for this modification are important. Presently, there are two domestic commercial suppliers of HMHEC. One employs alkylaryl hydrophobe modification and the other aliphatic hydrophobe modification. Unlike other classes of ATRMs, the ethoxylate content between hydrophobe and HEC backbone is small (generally one to a few units). Because HMHEC is a solid, the handling limitations are similar to those of HEC and other solid thickeners. To party overcome this limitation, developmental fluidized aqueous dispersions of HMHEC are now available which are analogous to those now commercial for conventional HEC. The viscosity of the fluidized products as supplied is still moderately high and similar to that of the HEUR and HENN products.

HMEHEC (Subclass of HMC)

Associative EHEC polymers were introduced in 1992 and are the most recent HMC products. Being relatively new, little is known about them; however, their chemical construction and performance is expected to be similar to HMHEC. At this writing, there is currently only one nondomestic supplier of these products.

INORGANIC THICKENERS FOR AQUEOUS AND SOLVENT-BORNE COATINGS

Most inorganic thickeners and rheology modifiers (ITRMs) are supplied as powders. When they are properly dispersed into a coating, they usually function as suspending or gelling agents and some may have secondary utility as extender pigments. Rheologically, ITRMs tend to have high yield values and are characterized as "thixotropes." The viscosity of the coating decreases with time under constant shear as its gel structure is broken down. When the shear is removed, the coating gradually recovers to its original viscosity. The rate of recovery can be very rapid (complete within seconds) or can take several minutes or even hours depending on the degree of thixotropy and prior shear history. Certain grades or mineral types of ITRMs are useful for thickening aqueous systems and others for solvent-borne coatings. Utility in one media or the other is mostly a function of the thickener's particle surface, which is often modified with organic treatments to render it hydrophilic (usually for water-borne coatings) or hydrophobic (usually for solvent-borne coatings). ITRMs are also sometimes added to aqueous formulations as secondary thickeners to impart some degree of antisag, antisettling, or antisyneresis to coatings containing primary conventional or associative thickeners. The most common types of modified and unmodified ITRMs are attapulgite clays, bentonite clays, organoclays, and treated and untreated synthetic silicas [*61*]. Table 6 details some important domestic (U.S.) suppliers of modified and unmodified ITRMs for aqueous and solvent-borne coatings systems.

Attapulgite Clays

The attapulgite clays are the most commonly used ITRMs in latex paints because they are economical and also function as extender pigments. The principal mineral in attapulgite

clays is attapulgite, which is chemically described as hydrated magnesium aluminum silicate. The lath-shaped particles of this mineral as supplied are colloidal (less than 0.5 μm), and the crystal structure is chain-like. In an aqueous environment, attapulgite is nonswelling and essentially inert. Thus, coatings containing attapulgite clay thickened not by swelling, but instead by the structured reflocculation of the pigment particles into a colloidal interaction network after shearing. In coating preparation, attapulgite clays can be added as powders or as pregelled dispersions throughout the formulation process. However, they are normally added in the grind using high-speed mixers for dispersion and hydration. The thickening power of these clays is high, and salts have little or no effect on viscosity. However, like many other ITRMs, the amount of attapulgite clay required for thickening is generally higher than for organic TRMs, and the water demand is high (water is pulled from the aqueous phase to wet the particle surface, thereby increasing effective coating solids).

Bentonite Clays

Bentonite clay is obtained from the mineral montmorillonite (a Fuller's earth mineral), which is described as an aluminum silicate with varying degrees of aluminum replacement with magnesium, calcium, and sodium. The crystal structure is a three-layer sheet which forms flake-like colloidal particles of less than 0.5 μm. In aqueous media, bentonite is naturally hydrophilic and readily dispersible. The water is taken up between the mineral laminae, causing the lattice structure to stretch and swell. Thickening is due to a combination of swelling and particle network interaction, and purified forms of unmodified bentonite are highly effective as thickeners in aqueous coatings. Although the thickening mechanism is rather different than that of attapulgite clays, most bentonite clays also require wetting, high-shear for dispersion, and time for complete hydration. Some modified grades are, however, readily dispersible with conventional agitators. For effective incorporation, pH must be carefully regulated. If it is too high, excessively rapid hydration occurs, and if it is too low, hydration times are long with loss in thickening efficiency. The presence of salts (electrolytes) may cause flocculation, rendering bentonite ineffective in highly ionic environments.

Organoclays

Many different grades of organoclays are available for both solvent-borne and aqueous coatings. Although these products differ in modification, the mechanism for thickening and rheology control is substantially the same. Bentonite clay is one of the principal minerals used to prepare organoclays, and, being both hydrophilic and oleophobic in its natural form, it must be modified for dispersion in organic solvents. Only after a sophisticated purification process followed by cation exchange with organic ammonium bases is the surface rendered sufficiently organophilic for use in nonaqueous media. As supplied, organoclay thickeners are in the form of agglomerated platelet stacks. Conventional organoclays require wetting and shear for deagglomeration and the addition of a chemical polar activator for full rheological development. The chemical activator serves to disperse the organoclay and also carries water into the hydrophobic organic solvent to insure full hydrogen bonding. Some newer products still require wetting and shear but are functional without the chemical polar activator. Although not essential, elevated temperatures are preferred for efficient processing. High-performance organoclays have recently been developed with greater thixotropy and improved sag resistance [*62*].

Special grades of organoclays (organophilic clays) have also been designed for aqueous coatings. Some of these depend on shear, wetting, and hydration for full rheological performance, while others are available in readily activated slurry form. The efficiency of these products is generally independent of pH [*63*].

Synthetic Silicas

Another class of inorganic thickeners are certain types of synthetic amorphous hydrophilic and hydrophobic silicas. Both are widely used in solvent-borne coatings; however, excessive hydration generally limits the utility of the hydrophilic silicas in aqueous media. Two forms of amorphous hydrophilic silica are commercially available and get their names, "precipitated silica" and "fumed silica," from the manufacturing processes. A proposed thickening mechanism for these silicas is based on hydrogen bonding between the silica particles and with other coating components to form a three-dimensional structure. High water demand may also contribute to thickening with these products.

Precipitated Silica

Precipitated silica is obtained in a wet process by the neutralization of sodium silicate solution. This results in a polar, fully hydroxylated surface. Consequently, hydrogen bonding is strong, and excellent thickening comparable to that of fumed silica is obtained especially in nonpolar media. However, because of the competition between hydroxyls on the silica and those in the continuous phase, precipitated silica tends to be less efficient than fumed silica in polar (for example, aqueous) media.

Fumed Silica

Fumed silica is fumed silicone dioxide which is prepared by hydrolysis of silicon tetrachloride vapor in a hydrogen-oxygen flame. The product gets its name from the smoke-like appearance as it forms in the flame. In the fuming process, a partially hydroxylated surface containing silanol, siloxane, and hydroxyl groups is generated, which is somewhat less polar than that of precipitated silica. pH does have a significant effect on the thickening efficiency of fumed silica in aqueous systems. To be effective, pH must be below about pH 7.5. Above this pH, electrostatic repulsion keeps the particles far enough apart to inhibit hydrogen bonding.

Organosilica

Hydrophobic silica is produced when freshly manufactured hydrophilic fumed silica is treated with organosilane or organosiloxane compounds [*64*]. This is a chemical modification in which many of the surface hydroxyl groups are replaced with organic functionality. After treatment, these products have minimal surface silanol groups left for hydro-

gen bonding, and the amount of carbon incorporated into the fumed silica (on the surface) is typically on the order of 1 to 5%. Hydrophobic silicas are generally superior to hydrophilic silicas in water-reducible systems; however, order of addition can be important.

ORGANIC TRMs FOR SOLVENT BORNE COATINGS

Besides the inorganic products described above, a variety of organic additives also function as thickeners, rheology modifiers, and thixotropes in solvent-borne systems. These products are mostly available in liquid paste and powder form. Many require some dispersion and activation for thickening, and the recommended process temperatures often depend on the strength of the solvent present in the coating formulation. Careful formulation procedures are required to avoid seeding, "false body," or loss in thickening efficiency. Among the many types of organic products available for use as thickeners and flow control agents for solvent-borne systems are castor oil derivatives [*62*], modified acrylic copolymers, polyethylene glycol, polyamides [*65*], polymerized oil derivatives, organic esters, complex polyolefins, and aramid pulp fibers [*66*]. Because of the number of products, their diverse nature, and the fact that little information is available on many due to their proprietary status, no attempt will be made here to classify or categorize these products and their suppliers. Resources for this information are available elsewhere (for example, see McCutcheon's Functional Materials in the Bibliography).

Part 8: Physical Characteristics of Liquid Paints and Coatings

31

Density and Specific Gravity

by Raymond D. Brockhaus[1]

INTRODUCTION

Why Concern Ourselves with Density?

The World of the Producer and the Customer

MATERIALS ARE EXCHANGED FOR AN agreed-upon value based upon a "cost per unit material." The "unit of material" is in terms of what the user wants to do with the material expressed in physically measurable units such as volume or weight. The customer does not want to be shorted, and the provider does not want to give away material. Accurate measurements are expected to keep both parties happy. When a customer wants a gallon of paint, the manufacturer blends the component materials together by weight and fills out by weight. Balances are easy devices to place and use with filling lines. Delivery of constant volumes, on the other hand, is not an easy task, as will be explained later. Measurement of the weight of a known volume of the paint generates a relationship defined as density. With this relationship, the producer can fill by weight and then sell to the customer on a by volume basis. The customer wants volume; the producer wants to work in weights. The relationship—density—enables the transformation to make life easier for both groups.

Measure of Quality

In the open marketplace, the business person and the customer have this rule of thumb—let the buyer beware. Testing for quality of the shipment is best done on-the-spot, quickly, and in a way that is highly reliable. If you are in charge of the wine and ale stocks of a restaurant, one method of determining the quality of the goods obtained would be verification of the density with flotation probes called hydrometers. Similarly, the purchasers of metals such as gold, lead, silver, and copper could use various methods of determining density to keep from being cheated and assuring quality.

In our more modern world, with instruments capable of assaying individual chemical compounds in complex mixtures, verification of density has become a manufacturing tool for in-process control. Density measurement becomes an indirect assurance that the ingredient(s) of interest exists in the material of exchange at the proper concentration. For paint, ingredients such as solvents, polymers for binders, and pigments have a different range of density typical of that material. Partial omission of a major component, for example, a solvent, can make the paint density change from the formula loading target. Quick approximate estimations of density can be done with inexpensive equipment that acts as a screening tool, catching special-cause errors like wrong material shipped. Common-cause errors of minor contamination are usually not caught this way.

The use of density measurements as a measure of quality is declining in favor of testing tuned to providing measurements of ingredient concentrations and chemical functionality. This is most often a balance between spending time, money, and manpower on testing and risking the liability of inadequate product performance.

Regulatory Concerns

In addition to customers and producers, government can express concerns in the exchange of materials. Government's concern is for regulation. Paints or other similar heterogenous materials are mixtures in which only the nonvolatile portion of the bulk material being exchanged is of true value to the customer. The "carrier" portion of the bulk material must be accounted for because it is a discarded material and thus a "pollutant." The carrier portion, solvents, and viscosity reducers are used to aid in transporting the solids to the work surface to form a thin film. These pose disposal problems and impact landfills, air and water quality, which are under government regulations. Paint volume solids and critical pigment volumes are two significant concepts which must be understood and accounted for when dealing with modern government regulations [*1*].

Definitions—Density—Static and Dynamic Mathematical Models

Static Model

Density is the weight in vacuo, that is, the mass of a unit volume of a material at any given temperature [*2*]. In vacuo is specified because measurement of weights in gaseous or liquid environments may require a buoyancy correction. If the volume of the mass being weighed is large, a correction must be made for displacement of the environmental media (air or a liquid).

For some samples, however, vacuum conditions will cause vaporization of the sample. Therefore, "in vacuo" is usually a theoretical condition rather than a normally experienced one and deals with the surrounding environment. The balance used to weigh the sample must also be in vacuo.

The Greek letter ρ (rho) is used to denote density.

$$\rho = (m/V) \tag{1}$$

[1]Research Associate, E. I. Du Pont, Automotive Products, 400 Groesbeck Highway, Mt. Clemens, MI 48043.

Copyright© 1995 by ASTM International

where m is mass, and V is volume expressed in units consistent with the mass units.

$$\rho = (W/V) \tag{2}$$

where W is weight (a function of mass), and V is volume expressed in units consistent with the mass units.

Dynamic Model

Density is a mathematical value describing a balance of physical forces acting on a material called mass occupying a known volume of space under known temperature conditions. This equation is identical to that given in the static model. Density is expressed as a single value, but is really an average value of forces dynamically fluctuating, both internal to the material and external as the surrounding environment.

Two definitions are included here. The first (static) is the traditional model. It has changed only slightly over the ages, being upgraded with the terms "mass" in place of weight and "in vacuo" after vacuum bell jars were developed. The second (dynamic) is a more fundamental model, dealing with materials on a molecular level, where the concepts of chemical functionality, kinetic and potential energy, and interfacial boundaries come into play. With the second model, we can understand and deal with mixtures of chemicals and mathematically deal with how a single component's densities interact when mixed.

The attractive forces exerted on a primary mass or collection of particles by a second mass much larger than the first mass is called *weight*. This is an attractive action, resulting in compression and increasing the density of the primary mass. The dispersing forces are caused by thermal energy absorption, resulting in particles of increasing motion or kinetic energy. This manifests as temperature of the material.

The volume of space occupied by a mass of particles that exists at an average kinetic energy level expressed as the temperature of the physical material is the *volume*. This includes the voids of space between the particles on a molecular level.

The average kinetic energy level of the material is expressed in the motion of the particles of the material. Material is made up of many small particles that are independent in their motion. These motions are random, such that the overall motion in the X, Y, and Z directions cancel each other and the net motion of the total mass is zero. As the kinetic energy level, expressed as temperature, increases, the distances between particles increase and the material is identified as expanding.

Special cases used as standard measurement reference points:

- One cubic centimetre (cm^3) of pure water (H_2O) at 4.0°C is defined to weigh 1.0000 g.

$$\text{Density}_{\text{water}} = 1.000\ \text{g}/1.000\ \text{cm}^3$$

- 1.000 mole of a gaseous compound occupies 22.4 L of volume at 0°C (273°K) at 1.000 atmosphere pressure (a molar volume).

For air, whose composition is 22% by weight oxygen and 78% by weight nitrogen (ignoring other gases), 1 mole weight = (32 g × 0.22) + (28 g × 0.78) = 28.88 g. Density = 28.88 g/22 400 cm^3 = 0.001 29 g/cm^3 or 1.29 g/L [*3*].

Relative Density, also referred to as specific gravity, is the ratio of a density determined for Material A at Temperature T_1 divided by the density of a reference material at some temperature, T_2. For solids and liquids, the reference material is pure water. For gases, the reference material is air.

$$\text{Density}_{\text{Relative A}} = \frac{\text{Determined Density A at } T_1}{\text{Determined Density Water at 0°C}} \tag{3}$$

If a Liquid A has the same density as water at T_1, when determined by a bouyancy device, then the density can be determined from a table of known density values established for pure water over a range of temperatures.

When T_2 equals 4.0°C, the relative density for pure water equals the measured density. As temperature increases, water expands. For a constant volume, the mass of water must be decreased to fit into a given volume. Thus, water's density value must decrease with increasing temperature. Relative density is a ratio of two values carrying the same units. Therefore, relative density is a unitless number.

Specific Gravity—An old term; the term *relative density* is identical and is less misleading [*4*].

Apparent Density—A density value for powders and macroscopic particulate solids which are compacted by vibration. Air is still present in the voids between the particles and in pockets or voids at the irregular surface of the macroscopic particles. This means the volume is greater than just for the solids, and the density is smaller in value than if the material was a liquid or compacted such that no voids existed. Pigments used in paint are mechanically worked with solvents and resins to fill in these voids. The *true density* of the pigment, which is needed in paint calculations, is that obtained without any of the air (void) contribution.

Fundamental Concepts—Material, Objects, Volumes, Masses, and Weights—What Really is Density?

Density is more than just the mathematical numerical value identified above. It also incorporates units of measure which are, in turn, based upon more general and fundamental concepts. These units of measure assume a set of definitions which will be explored in very general terms. These

TABLE 1—Density of water, grams per cc [*2*].

Temperature, °C	Density, g/cm^3
15	0.999 099
16	0.998 943
17	0.998 744
18	0.998 595
19	0.998 405
20	0.998 203
21	0.997 992
22	0.997 770
23	0.997 538

25	0.997 044
26	0.996 783
27	0.996 512
28	0.996 232
29	0.995 944
30	0.996 565 6

units are crucial to understanding the dynamic model of density and in allowing microscopic concepts to be explored.

Material—Anything (a physical entity) which exists for a duration of time, occupies space, and has mass. Mass is a stable configuration of atoms individually loosely organized as elemental atoms or joined together chemically to form molecules.

Object—A collection of materials, homogeneous or heterogeneous, localized to a portion of volume (space). The material can be in any one of three states: solid, liquid, or gaseous. The shape of the volume of space occupied by the object plays a role in dealing with density but does not define the object itself.

Volume is based upon measurement of distance in three directions at right angles to each other as in Fig. 1.

The physical universe in which we live is often described in three dimensions in terms of distance, which is a scalar property. When dealing with three dimensions, the term *distance* is described as length, width, and depth. An object having all three is described as having *volume*. The mathematical value for volume is the product of multiplication of the three scalar values. Volume can exist without objects occupying that space. This condition is called a vacuum. Vacuum's volume and object's volume can both be of very irregular and nonmatching shapes, yet they can equal in the scalar value of the volumes. Examples are shown in Fig. 2.

Problems with Volume Measurements

Customers often make use of material based on volume as applied and want to purchase these products in containers recognized to hold standard volumes. Materials have the property of responding to temperature changes with expansion or contraction of their volume. Products that experience wide temperature ranges during filling, shipping, storage, or in use must also have extra unfilled volume to accommodate expansion or the material forces leak and material is lost. This problem is most severe with liquid materials. Material suppliers use containers with larger than exact volume required to allow for expansion. These vessels must be marked in some way to indicate the volume increments if they are to be used for filling by volume. Producers seldom can or want to control temperature during packaging. Temperature control devices will add expense without making a difference in the material's performance. Without temperature control, filling at a constant volume will produce units of varying amounts of material. Use of density overcomes these problems and permits correct volumes to be filled out.

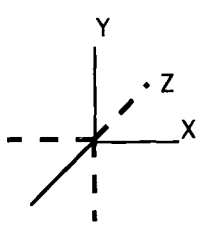

FIG. 1–Coordinates in three dimensions.

Weight and Mass

A fundamental attribute of a physical entity is *mass*. This is one of the indefinable mechanics [*4*]. Two physical objects exhibit an attraction for each other in proportion to the quantity of mass in each object. The greater the mass, the greater the attraction. When the ratio of two masses is grossly unequal, such as the planet Earth and an object on its surface, the larger mass is assumed to be constant and the second object is described to have a "weight" relative to this larger object. The mass of the planet is effectively unchanging and thus constant. Our moon is also a very large object, but smaller than the earth, thus its attraction to a second object would be weaker than for the Earth. Mass is the unchanging, fundamental property.

But we are human, and we deal in the measurement of weight, which is a force. While weight is a vector quantity having both scale and direction, the direction portion is taken for granted and weight is usually treated as only a scalar value. Figures 3 and 4 graphically depict this issue.

Weight, w, is defined as a force of gravity, F_g, [*4*].

$$w = F_g = G\frac{mm_E}{R^2} = mg \tag{4}$$

where

G = a gravitational constant for Earth = 6.670×10^{-11} N·m²/kg m²,
m_E = mass of the Earth = 5.98×10^{27} g, and R is the radius of the Earth = 6370 km,
m = mass of a second body (Newton's law) [*5*],
g_E = 9.80 m/s² or 32.0 ft/s², and
g_{Moon} = 5.333 ft/s² or ⅙ that for Earth.
$g_{\text{Distance from Earth}} = 1.0 \times 10^6\,\text{km} = g_E/[(1.0064 \times 10^6\,\text{km})^2/(6370\,\text{km})^2] = 0.004\,g_E$

These values are given as constants in physics calculations but actually represent average values. In the real world, the value of g varies from location to location for a variety of reasons. Table 2 and Figs. 5 and 6 about mountains and dense buried masses of rock demonstrate this.

Example 1: A gallon of paint produced in Galvaston, Texas has a weight of 10.000 lb/gal. The product finds its way to

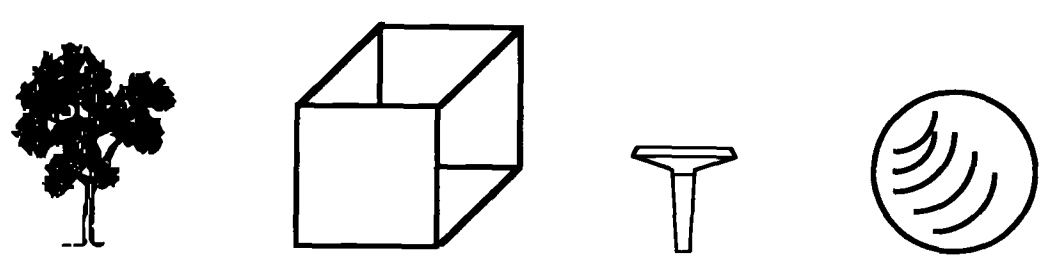

FIG. 2–Examples of physical objects.

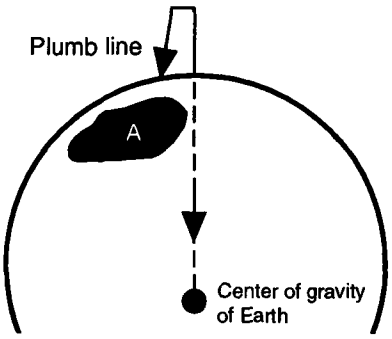

FIG. 6–Large buried mass concentration effects on objects on the earth. From *The New Book of Popular Science*, 1993 Edition. Copyright 1993 by Grolier Incorporated. Reprinted by permission.

Eagle City, Alaska. Here it has a gallon weight of 10.03 lb/gal. The difference is minor but real. If the paint specification is a density in the range of 9.90 to 10.10 lb/gal, the +0.03 lb leaves only 0.07 lb for testing errors before the material is identified as out of specification. As environmental regulations on the volatile organic content (VOC) increase in importance, these minor differences will play a larger role and should not be overlooked for their contributions to relationships such as density.

The pull of gravity is not as strong at a mountaintop, A, as it is on the plain, B. The reason is because A is at a greater distance from the center of gravity than B. The plumb line in Fig. 6 does not point exactly to the earth's center of gravity because it is attached to A, which is a dense part of the earth's crust [*5*].

Example 2: The weight of a gallon of paint in New York City is recorded at 9.5 lb. The distance from the center of the Earth is 6370 km at this location. At a distance of one million kilometres from the earth, the same gallon of paint would weight 0.003 78 lb.

Has the amount of mass changed? No. Has the weight changed? Yes, because of distance. Has the volume of the material changed? Possibly. If the gallon container is surrounded by air at 1 atm, the container shape is retained and the material in it will not overflow. But, in the new location, the fluid does not want to remain together. It forms droplets and wants to float off in all directions. It has lost the cohesiveness provided by gravity. Has the density of the material changed? By definition, yes, drastically! By fact, little. The same physics rules apply in both locations, but the environment has changed and with it our appreciation for the term *mass*.

TABLE 2—Values of *g*, the acceleration due to gravity [*5*].

[a]Centimetres per second per second. Use of centimetres emphasizes the differences which are occurring in the second through sixth numerical place.

Example 3: A 1.00 m^3 Styrofoam cube of material is created on earth in our atmosphere (air) at 20°C and 1.0 atm. This is a heterogeneous material because it has trapped air in the foam. Let's say it weighs 900 g on a balance on an open desk top.

$$\text{Density}_{\text{earth}} = 900\,\text{g} \div 1.00\,\text{m}^3 = 900\,\text{g/m}^3$$

Next, this cube is taken to the moon (gravitational factor = ⅙ Earth) and kept inside a building with 1.0 atm at 20°C.

$$\text{Density}_{\text{moon}} = (900\,\text{g} \times \tfrac{1}{6} \div 1.00\,\text{m}^3) = 150\,\text{g} \div 1.00\,\text{m}^3 = 150\,\text{g/m}^3$$

Next, the cube is taken out onto the moon's open surface, where there is no atmosphere (vacuum conditions).

Now, two things happen to this cube.

1. There is no air to displace when weighing the cube. It can thus exhibit a heavier weight since there is no buoyancy correction: 1 m^3 of air weighs 1.29 g on Earth and 0.215 g on the Moon. So the weight would be 150.215 g.
2. The material can also lose the air entrapped in the foam. This may be a slow process, but it can happen. Now the cube will appear to lose weight. Let's say it loses 0.050 g by moon weight and now weighs 150.215 − 0.050 g.

$$\text{Density}_{\text{vacuo,moon}} = 150.165\,\text{g} \div 1.00\,\text{m}^3 = 150.165\,\text{g/m}^3$$

Return the cube back into the building on the moon with 1.0 atm and the weight might now be 149.95 g if the foam structure is strong enough to retain the cubic shape without crushing from the external pressure. Its density is now 149.95 g/m^3.

Density is a very simple, straightforward concept and relationship. Still, as noted before, physical reality can and does impact on it, adding subtle perterbations that should be understood. What appears to be homogeneous may not be. Physical reality is a source of variability, and affects must be taken into consideration when arriving at results we will share with one another.

Solids, Liquids, and Gases—As Concepts and Under Ideal Conditions

Materials exist in one of three states: solids, liquids, or gases. For an equal amount of weight, solids usually occupy less volume than liquids, which occupy much less volume than a gas. Solids also retain a shape and flow or distort very slowly. Liquids take on the form of a containing vessel. Gases have no shape and are bounded and shaped by their container. Techniques exist to determine densities for all three states.

Solids—Figure 7 is a depiction of a solid in which the particles are atomic or molecular in scale. The distance between particles is a regular, repeatable distance. Most kinetic energy is gone. Only external pressure can shorten the distance between particles. This shortening is called compression and affects the ratio of weight present and the actual volume occupied by that mass of material. If the solid remains compressed after the external pressure is released, the material is called inelastic. If it returns to the original volume, it is elastic. Density of solids can depend on the processing history.

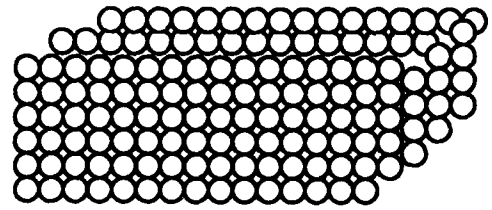

FIG. 7–Simple model of particles of matter in solid state.

Liquids—In a liquid as depicted in Fig. 8, the particles are molecular or atomic in scale. Distances between particles are not constant. Kinetic energy is greater than in solids. External pressure can shorten the distance between particles. Each material has a characteristic compressibility factor. All liquids behave elastically, flowing back and filling in. The population of particles has a distribution of kinetic energy values, with some being greater than the surface energy. The portion of the population which has a kinetic energy greater than the surface energy escapes and is called *vapor.*

For ideal conditions and "conceptual" materials, no interactions occur between the materials, the testing containers, and the surrounding environment. The material investigated is well behaved. When such materials are mixed together, the weight of each material times the individual material's density will add together as a linear sum.

Gases—In a gas, as depicted in Fig. 9, the particles are molecular or atomic in scale but more widely separated. Distance between particles is irregular. Kinetic energy is even higher than in liquids. External pressure can shorten the distance between particles. Each material has a characteristic compressibility factor.

Weighing solid or liquid material in a container or as a solid object is an easy task. Instruments for this task keep improving in accuracy, precision, ease of use, and lower cost.

For gas-phase material, vessels of accurately determined volume can be purchased and used. Materials of construction for durability and reuse are of concern. If the temperature of testing is controlled within the tolerance of the calibration of these vessels, expansion is not a concern. Since gases are seldom incorporated into a paint system, this topic will be passed over.

Further Discussion of Liquids and Solids

For liquids, containers can be constructed to hold a known volume. These vessels can be mass produced with adequate

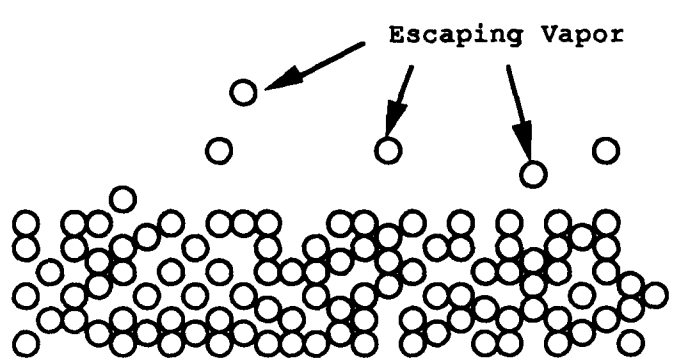

FIG. 8–Simple model of particles of matter in liquid state.

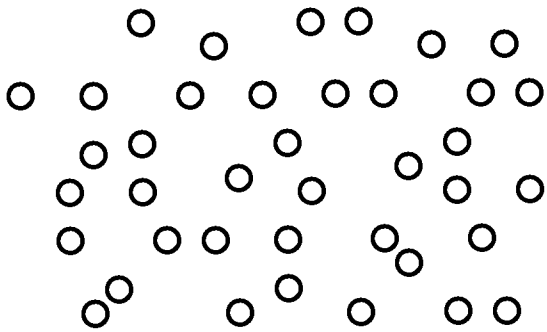

FIG. 9–Simple model of particles of matter in gas state.

accuracy to allow large numbers of users to have access. These are called *liquid pycnometers*. Some are also called *gallon weight cups*. Within the temperature range of 1°C and 99°C, the density of water can be determined. More detail will be given in the section entitled "Liquids." Devices that can float in water can be calibrated to show a scale calibrated directly in density. When these floats are used along with a scale for weighing, the volume of material can be determined [*6,7*].

Figure 10 contains drawings of several pycnometers as seen in a commercial scientific supplies catalog. The catalog text descriptions for two pycnometers have been included to inform you as to sizes, capacities, materials of construction, etc. The features discussed identify attributes of importance to the end user.

Liquids have other properties that can be used to test for density. One of these is sound transmission. Replacement of air with a liquid in a container will cause that container to shift a tone impulse to higher frequencies. The extent of the shift is related to the liquid's density and can provide a direct measurement with different degrees of accuracy depending on the sophistication of the instrument.

For solids, the task is more complex. Two paths are available. Either shape the solid into a known geometric figure and calculate the volume or use the solid to displace a material such as a liquid or a gas which has a known density. The solid can be shaped by mechanical, thermal, or chemical means. Mechanical means can be employed to cut, carve, and shape, then weigh. Thermal shaping is changing the solid into a liquid using heat to melt the solid, pouring the liquid into a mold, cooling to form a solid, and then weighing. Chemical shaping is dissolving the solid in a "carrier" liquid (solvent), pouring the solution into an open mold, and evaporating the solvent, leaving behind a solid property shaped to accommodate testing. The drawbacks of this technique are:

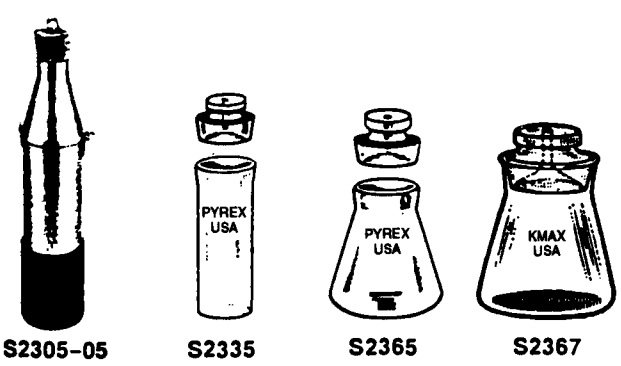
1. Complete solvent removal is often difficult.
2. Chemical reshaping of solids can cause problems if the original solid had small air pockets or if the solvent used is trapped in these voids, thus actually changing the solid and affecting its apparent density. Solids which demonstrate the latter behavior have a bulk density different than their skeletal density.

The principle of buoyancy, discovered in the third century by Archimedes, provides a means to determine volume [*5*]. Determination of volume by displacement requires acquiring a weight in air and a weight in a liquid of known density at the testing temperature. Complete submersion of the solid object or a representative portion of the material in a liquid of known density is required while determining the material's apparent weight. See Fig. 11. The weight difference is equal to the weight of the volume of liquid displaced. Knowing the liquid's density and the weight difference, the volume for the tested portion can be calculated by the following formula:

$$g_{\text{Distance from Earth}} = 1.0 \times 10^6\,\text{km} = g_E \frac{(6370\,\text{km})^2}{(1.0064 \times 10^6)^2} = 0.004\,g_E \quad (5)$$

Solids, Liquids, and Gases as Concrete Materials in a Physical World

A vast variety of materials exist, and interactions are possible between any of the different types of materials. When an



ASTM Crude and Fuel Oil Sampler

As specified in ASTM D270 for sampling light lubricating and crude oils, nontransparent gas oils, and fuel oils in sewage tanks. Copper with 19 mm (0.75 in.) diam neck opening and 430 cm (17 in.) brass handle; body ODxH, 95x356 mm (3.75x14 in.); capacity, 950 mL (1 qt).

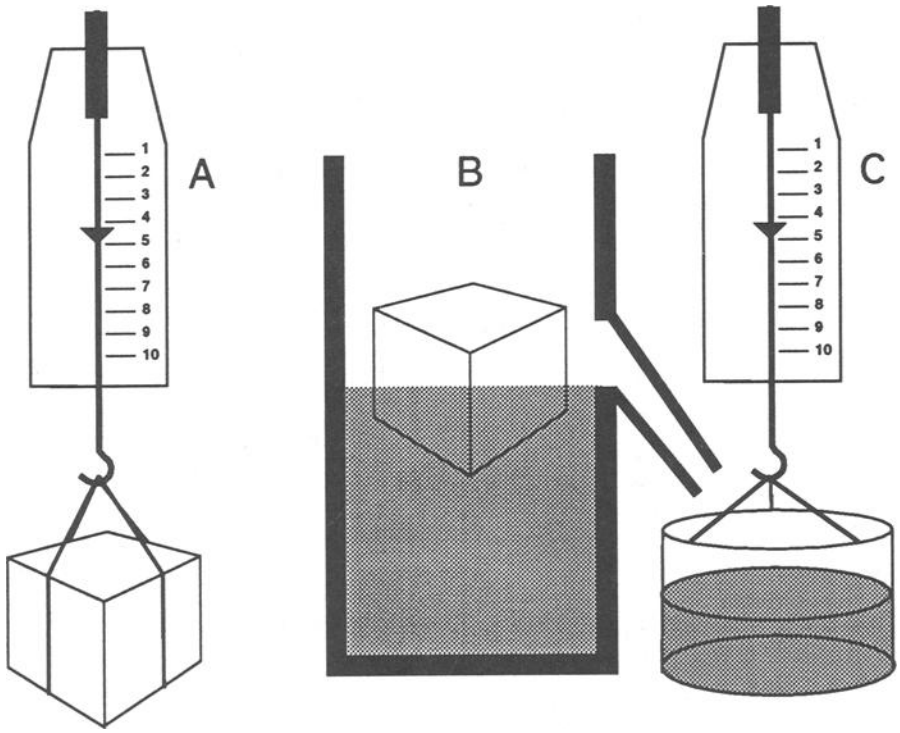

FIG. 11—*Displacement technique*—A block of wood weighs 5 oz (*A*). The wood block is placed in an overflow can filled with water up to the spout (*B*). The displaced water flows into the container at the side of the can (*C*). The weight of the displaced water equals the weight of the block if the block's density is less than or equal to the water. If the density of the block is greater than water, the entire volume of the block is displaced and the weight of the *water* equals the volume of the block (if temperature = 0°C) [*5*]. attribute, like density, can be directly measured, it is possible to identify two types of these interactions. The first is *ideal* behavior with respect to the attribute under investigation and the amount of mass used. These interactions are well behaved and produce predictable attribute changes. The second type is *nonideal* and means that other interactions are taking place than just that of mass-to-mass attraction. Materials are ideal if when mixed together the sum of the weight fraction of each material times the material's density equals the density determined for the entire mixture. Materials are nonideal if when mixed together the sum of the weight fraction of each material times the material's density does not equal the density determined for the entire mixture.

Some solids can exist with varying degrees of crystallinity incorporated into their solid form. As temperatures cycle up and down in the surrounding environment of these solids, the solids will change density as their degree of crystallinity changes and they move toward a thermodynamically stable form of the solid.

Finally, materials can chemically interact when mixed, producing or absorbing heat and generating an entirely new material with its own unique attributes.

These actions are not bad or good, but they basically exist and must be taken into consideration when dealing with mixtures such as liquid paints and solid coatings.

When a material (A) is homogeneous, the density is a fixed value for a fixed temperature. When a material (B) is heterogeneous, the density is also a fixed value for a fixed temperature. When two different materials, homogenous or heterogeneous, are mixed together, they become a new, heterogeneous material, and the resultant density is a new fixed value for a fixed temperature. Depending on whether the interactions are ideal or nonideal, the density can be predicted by calculation or a deviation in the density will result. Paints are formulated as ideal mixtures, but they don't always follow this assumption. The relationships between these values are given below [*8*].

$$A + A \text{ has A's density which is } \frac{W_A\rho_A + W_A\rho_A}{W_A + W_A} \quad (6)$$

$$B + B \text{ has B's density which is } \frac{W_B\rho_B + W_B\rho_B}{W_B + W_B} \quad (7)$$

$$A + B \text{ has a new density which may be } =, >, \text{ or } < \text{ that of } A \text{ or } B \text{ and is } \frac{W_A\rho_A + W_B\rho_B}{W_A + W_B} \quad (8)$$

where

W = weight of component,
ρ = density of the component.

Many important materials are available as complex mixtures in today's world. These mixtures can be heterogeneous in terms of phase. Gasoline for the car and lawn mower can contain butane dissolved into the heavier hydrocarbons. Paints, inks, and cements contain liquids and solids, with the liquid phase either neutral or reactive. If the liquid's role is

neutral, it can be a solvent or carrier or plasticizer. If the liquid's role is reactive, it is called a binder, reactive diluent, or catalyst.

Modern paints contain chemically reactive, low-molecular-weight polymers that, when heated, produce a crossed-linked solid and usually volatile by-products. When chemical changes occur, the linear density addition model is correct only by chance. Usually the volume is reduced from chemical bonds forming, and as a result, the density goes up.

Theoretical volume solids have been calculated for years in the coating industry using the linear model. This worked well for lacquers, varnishes, and other systems where chemical reactions took place at low levels and were of the oxygen uptake type, making the final film heavier from oxygen addition. Modern paints react internally, generate by-products of low molecular weight, and actually lose weight during cross-linking and film formation. But, because there has been no good way to determine the volume of paint films that is repeatable and reproducible, the practice of calculating volume solids is still used in the 1990s. (*Repeatable* means in the same lab, with the same instrument, time after time, and *reproducible* means between different sites or labs using similar but physically different instruments like balances, ovens, etc.)

Definitions Related to Density and Specific Gravity

$$\text{Bulk Density} = \frac{\text{Total weight of object including air or water}}{\text{Total volume occupied including air or water}} \quad (9)$$

$$\text{Skeletal Density} = \frac{\text{Total weight of object less air or water}}{\text{Total volume of actual material less air or water}} \quad (10)$$

Surface interactions—These interactions involve wetting of solid surfaces by liquids during liquid displacement testing. In determining the volume of a material due to displacement of a liquid, the liquid must come in close contact with the material surface. When the liquid meets or wets the surface without penetration into the bulk of the material, the volume of liquid displaced is equal to the bulk volume of the material being tested. When the liquid does not contact and wet the surface, a thin layer of air exists between solid and liquid. This also displaces liquid, making the apparent volume of the material larger. In tests like ASTM D 2965, where the volume of paint film being tested is very low, this error can be significant. Materials called surfactants can be added to increase wetting, but they affect the density of the liquid. Where surfactants cannot be used, another liquid must be used.

Permeation—When the liquid meets or wets the surface with total penetration into the bulk of the material, the volume of liquid displaced is equal to the skeletal volume of the material being tested. If there are small molecular weight molecules left inside the bulk of the solid, these can migrate out, leaving the testing liquid in its place. These will change the bulk testing liquid's density as they accumulate.

MEASUREMENT SYSTEM UNITS, CONVERSIONS, DENSITY, AND RELATIVE DENSITY

Today's world uses three systems of measurement [*4*].

1. International System of Units (SI), previously referred to as the metric system, based upon powers of ten. This was called the MKS system, standing for meters (distance), kilograms (force), and seconds (time). A common form of this system uses millimetres, grams, and seconds as the units. By universally accepted definition, 1.0000 g of distilled water occupies 1.0000 cm^3 (or 1.0000 mL) at 4.00°C.
2. The British system uses the British yard (distance), pound (force), and second (time).
3. The United States (U.S.) system uses the U.S. yard (distance), pound (force), and second (time).

The British and U.S. systems use the same basic linear distance and force units, but, when measuring volumes, the systems do not have equivalency. A British gallon of water (volume) weighs 9.993 lb at 77°F (25°C), while a U.S. gallon of water weighs 8.321 lb at 77°F (25°C) [*7*].

Conversion between the three systems can be accomplished using the following relationships:

$$\begin{aligned} 2.54\ \text{cm} &= 1.00\ \text{in.} \\ 231\ \text{in.}^3 &= 1.00\ \text{U.S./gal} \\ 453.6\ \text{g} &= 1.00\ \text{lb} \\ &\text{or} \\ 277.4\ \text{in.}^3 &= 1.00\ \text{British (Imperial) gallon} \end{aligned}$$

From SI to U.S.:

$$(2.54\ \text{cm/in.})^3(231\ \text{in.}^3/\text{U.S. gal})/453.6\ \text{g/lb} = 8.345\ \text{cm}^3\cdot\text{lb/U.S. gal}\cdot\text{g} \quad (11)$$

$$(2.54\ \text{cm/in.})^3(277.4\ \text{in.}^3/\text{British gal})/453.6\ \text{g/lb} = 10.02\ \text{cm}^3\cdot\text{lb/British gal}\cdot\text{g} \quad (12)$$

These are conversion factors, which carry particular units. They are used to convert density values for a material at any temperature into a second set of units at that same temperature. The 8.345 factor for conversion to U.S. pounds per gallon is sometimes confused with the 8.320 value for a U.S. gallon of water at 25°C (77°F) [*2*].

Density (in the SI system) at any temperature = density (in the U.S. system) × 8.345 at the same temperature.

Example for pure water at $°C (39.2°F):

$$\frac{1.000\ \text{g}}{1.000\ \text{cm}^3}(\text{SI}) = 1.000 \times 8.345\ (\text{conversion}) = 8.345\frac{\text{lb}}{\text{U.S. gallon}}\ \text{at 4°C}$$

for pure water at 25°C (77°F):

$$\frac{0.997\ 04\ \text{g}}{1.000\ \text{cm}^3}(\text{SI}) = 0.997\ 04 \times 8.345\ (\text{conversion}) = 8.321\frac{\text{lb}}{\text{U.S. gallon}}\ \text{at 25°C}$$

Note in these examples that the volume of space (container internal volume) has not changed with temperature. But, the amount of material which can fit into that volume has

changed with temperature! Using known volume devices provides *only* density values. Temperature must be stated as a significant variable.

LIQUIDS

Densities of Liquids—Methods of Determination

Buoyancy-Hydrometers

Hydrometers are flotation devices that are calibrated using water at various temperatures. When placed in clear liquids, the relative density is read directly from the scale on the hydrometer. The hydrometers range from low-cost, low-precision, to expensive, high-precision devices. Better-grade hydrometers also have incorporated thermometers for temperature corrections and greater independence of reading liquids in an as-is condition. A balance or a known volume device is not needed with this technique. Simplicity is the advantage of this technique. Shown in Figs. 12 and 13 are two types of hydrometers. The catalog text has been included to explain ranges and features unique to these devices.

ASTM methods using hydrometers are [*9,10*]

Test Method for Apparent Density of Industrial Aromatic Hydrocarbons (D 2935)

Test Method for Calculation of Volume and Weight of Industrial Aromatic Hydrocarbons (D 1555)

Displacement—Submersion—Specific Gravity Balances

A specific gravity balance is similar to the hydrometer. It is actually a balance which measures the counter weight applied to balance a plummet submerged in the liquid sample. The weight and volume of a mercury-filled elongated glass bulb (plummet) is determined by comparison with standards established by regulatory agencies and traceable back to well-characterized standards, referred to as primary standards, established by national scientific bureaus. The plummet is attached to a balance and submerged into a liquid to displace some of the liquid's volume. The change in weight is attributed to the weight of the displaced liquid. The plummet's volume is known, and it is related to displacement of water. These are related back to water as a calibration liquid, so they provide a relative density rather than a true density. With this device, the sample does not need to be clear because there are no markings on the plummet. The devices also allow the liquid to be at temperatures other than 4.0°C. This type of device is good for solvents and low-volatility materials. Two balances are shown in Fig. 14 and are from recent scientific lab supplier catalogs [*11*]. The catalog descriptions have been included because they are concise statements about the devices, their operating principles, ranges, and other relevant information.

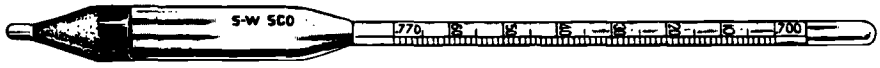
ASTM method using submersion:

Test Method for Specific Gravity (Relative Density) and Density of Plastics by Displacement (D 792)

Displacement—Fluid External Media

This is a device where the sample-holding chamber is not of a known, calibrated volume. A helium gas pycnometer can be used to determine the volume of a liquid in a metal or glass container. The pycnometer's test chamber volume is first established by determination of gas pressure differences in a sample chamber and after expansion into a connecting expansion chamber. Then an independent, empty sample container is introduced into the gas pycnometer test chamber and tested. The reduction in volume is allocated to the empty sample container. The independent sample container's weight is measured on an analytical balance. The sample is added to the sample container and weighed. The container and sample are tested again to establish a new volume.

The sample volume is (sample + container volume) − container volume. The sample weight is (sample + container weight) − container weight. Density is (sample weight/sample volume). The test is fairly fast. Containers of predeter-



Precision Hydrometers for Light and Heavy Liquids—175 mm

A series of short range hydrometers with an accuracy of 0.001, calibrated 60° /60°F. Design corresponds with ASTM specification E100 for plain hydrometers. With smooth, easily cleaned shapes, solid metal ballist, and cemented paper scales. Subdivisions, 0.001.

Chain Balance

For liquid densities from 0.0001 to 2.110

Chain gravitometer balance determines specific gravity of liquid with high degree of accuracy. Uses both plummet displacement principle and chain weight system for weighings. No calculations or riders are needed.

Instrument is prebalanced at zero reading by adjusting counterbalance weights. Plummet is immersed in liquid sample. Balance is zeroed again. Single roller-type weight is moved to notch on beam where equilibrium is approached; final adjustment is accomplished by raising or lowering one end of rhodium-plated bronze chain. Specific gravity is determined by adding rider and chain-support readings.

FIG. 14–Specific gravity balances—chain balance and Mohr Westphal balance with catalog text instruction and comments [*11*]. (Courtesy of Fisher Scientific)

mined volume can be kept available to help shorten testing time. Precision and accuracy are good. No ASTM test exists as yet for this technique [*12*].

Displacement—Known Volume Devices—Fluid Internal Media

These are devices of known, internal volume. They have many names such as liquid pycnometers, U.S. standard weight per gallon cups, U.S. mini weight per gallon cups, British standard weight per gallon cups, "featherweight" type weight cups, and Monk cup [*7,13*]. Liquid pycnometers come in a variety of sizes, shapes, volumes, and materials of construction. For precision, glass (inert, light weight, and transparent) is usually used. For testing demanding repeated use, other materials with reasonable inertness or resistance to chemical attack, such as stainless steel, are used. To combine both the light weight of glass and the ruggedness of metal, a "featherweight" construction of anodized, high-tensile aircraft alloy is employed at a cost consistent with the use of specialized materials of construction. The Monk cup is a special design (Fig. 15) and discussed under the topic of handling entrapped air in samples.

Liquid pycnometers or gallon weight cup vessels are built with a main body or container volume, a cap or lid with a vent hole, and sometimes a tare weight object. The tare weight is used as a counter weight for dual pan balances. The weight read after correcting for the tare weight is attributed to the material contained in the vessel at a level which reaches the top of the vent hole in the cap (see Fig. 16).

Both the vessel and a sample of the material to be tested are equilibrated to room temperature or a constant temperature bath temperature by immersion in the bath. Common temperatures for paint and solvent testing are 20°C (68°F) and 25°C (77°F) because these are temperatures in the human comfort range. Temperatures greater than these would drive off solvents. Moisture is not likely to condense out on surfaces from being too cool (weight gain drift during weighing), and volatile materials will not evaporate at a rate that significantly affects the weight readings taken (weight loss drift during weighing). Temperatures colder than these are easily obtained, but are less comfortable for the tester. However, any temperature can be used if the temperature is noted and the vessel volume is corrected for that temperature. If the bath is used, the vessel exterior must be dried off. This has to be done with minimum handling to prevent temperature changes from heat exchange by hands or drying materials.

Next, a portion of the tempered sample is poured into the vessel up to the top rim. The lid is carefully placed on the vessel so that the excess liquid is forced up through the vent hole in the lid *without* coming out around the lid lip. The excess is carefully cleaned off the surface of the lid and from around the lid lip. This is a cleaning, not merely a wiping off. Wiping leaves residues, which affect the results obtained. The sample-containing vessel is then carefully weighed.

Afterwards, the vessel and lid are cleaned as soon as possible and as well as possible to prevent buildup of residues, which will change the vessel's volume. A verification should be performed at frequent intervals with distilled water to catch inaccuracies from poor cleaning or damage to the vessel surfaces. For improved accuracy, the vessel can be calibrated using pure water at normal reading temperatures. Divide the gram weight of distilled water by the weight determined by direct testing. This produces a correction factor. This factor number is multiplied by the weight of the gallon weight found for an unknown liquid or mixture. If the determined density of water was less than expected, a factor greater than 1.000 is generated. As a result, the vessel's volume is less than expected. Tracking the factor value will alert the tester to problems arising from poor cleaning or rough handling that can damage and alter the testing vessel.

Sample sizes range from 10 to 84 mL. The combined weight of the vessel, lid, and sample affect the type of balance which can be used to provide good repeatability and reproducibility. The larger the size, the easier to get a sample representative of the bulk material. But the larger the size, the harder to remove entrapped air bubbles from the sample introduced during sample collection or preparation. For very

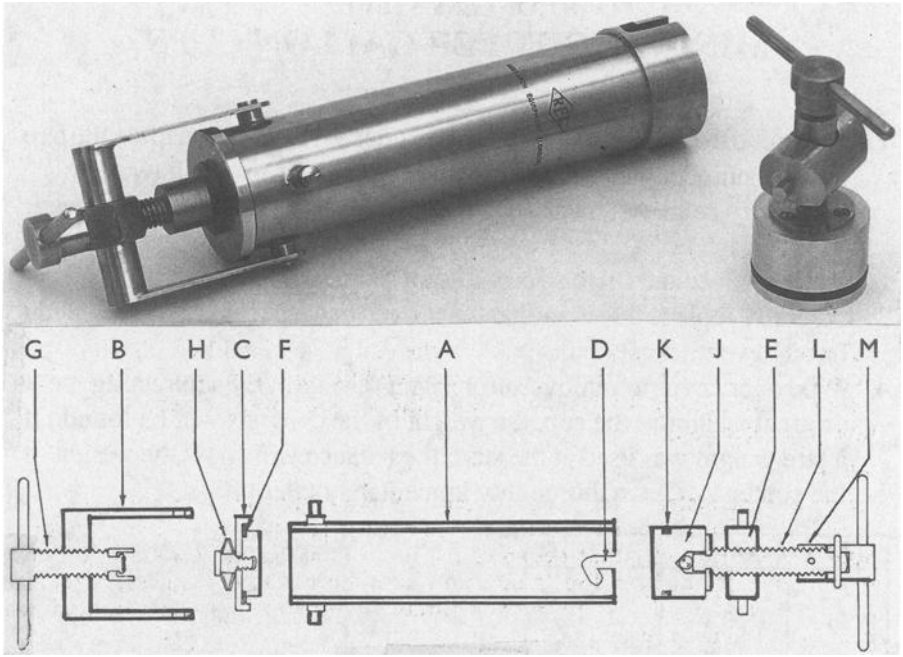

FIG. 15–Monk cup (weight per gallon cup) (courtesy of C. J. Monk and Journal of Oil and Color Chemists' Association) [2]. See Ref 2 for a discussion of Parts A to M.

volatile solvents, use of larger size vessels offsets the weight drift seen during weighing.

The problem of entrapped air can be countered in two ways:

1. The Monk cup is designed to pressurize the sample to 150 lb/in.^{2} in a known volume of space. This pressure compresses the entrapped air in the sample to such an extent that occluded air bubbles are reduced to a negligible volume. Entrapped air of up to 10 vol% can be dealt with by this technique. The volume produced is still larger than the true volume, and a density error is still present. Entrapped air should not be accounted for if the air escapes before use or the air is an artifact of sample mixing before testing. The Monk cup is large and heavy and requires use of nonanalytical balances [2]. Figure 15 is a schematic diagram and picture of a Monk pressure weight-per-gallon cup.
2. An alternative technique is to mix a measured weight of the unknown density material with the weight of a known diluent from a full weight per gallon cup. The blend is then placed back into the cup and then weighed. The following, enclosed in quotes, is copied directly from the GARDCO minicatalog Number 9, including the diagrams, with permission from GARDCO [7].

$$X = \frac{W_{\text{unknown}} B_{\text{lend wt per gallon}}}{(W_{\text{unknown}} + W_{\text{diluent cup weight}} - 10\, B_{\text{lend wt per gallon}})} = \frac{WB}{(W + A - 10B)} \quad (13)$$

where $A = W_{\text{diluent cup weight}}$

"Heavy-bodied materials which entrap air present a problem in true weight per gallon (density) measurements. Air entrapment causes the apparent volume of a material to be greater than actual and density or weight per gallon calculations are low and erroneous. The practice of measurement under pressure does reduce the error but the error is far from eliminated as the entrapped air is normally not removed, but only compressed as shown in Figs. 17 and 18."

"Most materials that are difficult to evaluate can be simply and accurately measured by the following depicted procedure."

"A measured weight of the unknown material is thoroughly blended with the weight of a known diluent from a full weight per gallon cup. The blend is then placed in the cup and the weight per gallon is determined. The value of the unknown material is calculated from the formula given above. The diluent liquid must be compatible with the material containing the entrapped air and it must be thin enough in viscosity to allow entrapped air to rise to the blend's surface and escape. In the case of particulate, such as pigment, the liquid must be able to wet the particle surfaces and displace air in pockets or depressions on the surface."

ASTM methods using known volume devices are [*13,14*]:

Test Method for Density or Relative Density of Pure Liquid Chemicals (D 3505)

Test Method for Density of Paint, Varnish, Lacquer, and Related Products (D 1475)

Sonic Frequency Shifts

Waves of air reaching a human ear are recognized as sound. The pitch of a sound is related to how many waves reach our ear per unit of time. This unit of time is referred to as *frequency*. Waves are made by an object moving in the media: air or liquids or even solids. The media touched by the wave can pass this movement through itself. When a boundary between two media of different densities is encountered by the wave, two actions occur: (1) some waves are reflected back; (2) a portion of the waves are passed into the new media but with their frequency changed.

STAINLESS STEEL

MINI WEIGHT PER GALLON CUPS

METHOD OF USE

1. Determine the weight of a clean cup in grams. As an alternative, the cup may be supplied with an accurate tare weight for use with two-pan laboratory balances. Note: Do not interchange tare weights between cups as each cup and tare weight is matched.
2. Remove cover and fill to within 1.7mm of rim with material to be tested.
3. Carefully replace cover so that the air and excess material is expelled through vent.
4. Wipe over cover to remove surplus and reweigh. By subtracting the original weight of the cup, the weight of the contents will be found. If a tare weight was used at the start, the balance will show the weight of the contents. Clean thoroughly immediately after use.

TEMPERATURE		WEIGHT
C.	F.	Grams
21	69.8	8.329
22	71.6	8.327
23	73.4	8.325
24	75.2	8.323
25	77.0	8.321
26	78.8	8.319
27	80.6	8.316

DETERMINING ACCURATE CUP FACTOR

Comparative results on different materials measured in the same cup are accurate to within the limits of sensitivity of the balances used. Comparative results between cups may be improved by determining a cup factor as follows: Divide 99.925 by the gram weight of distilled water held by the cup at 25°C to determine the cup factor. For example, if the weight of water held by the cup is 99.800 grams, divide 99.925 by 99.800 which is 1.0013. Multiply all cup readings by this factor. In the same manner, if the cup holds 100.200 grams, divide 99.925 by 100.200 which is 0.9973 and all cup readings should be multiplied by this factor.

FIG. 16–Mini-weight per gallon cups [7].

Changes in density also lead to changes in frequency. This can be demonstrated by filling a matched set of water glasses to different levels with water, then striking each glass lightly to produce a sound. The higher the water level, the higher the tone. Just as the frequency changes from an empty glass (air, less dense) to a high frequency tone when filled with water (more dense), the replacement of liquids of differing densities also shifts the frequency for glasses filled to the same level. This is the principle for several digital density meters commercially available today.

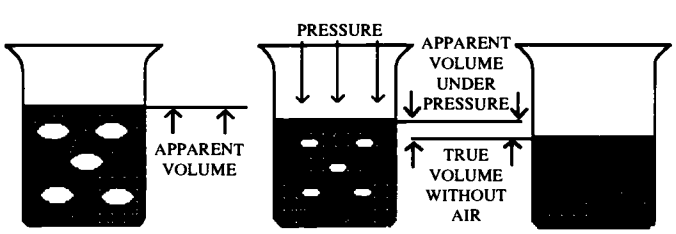

FIG. 17–Liquid with entrapped air [7]. Figure provided by Paul N. Gardner Co., Inc.

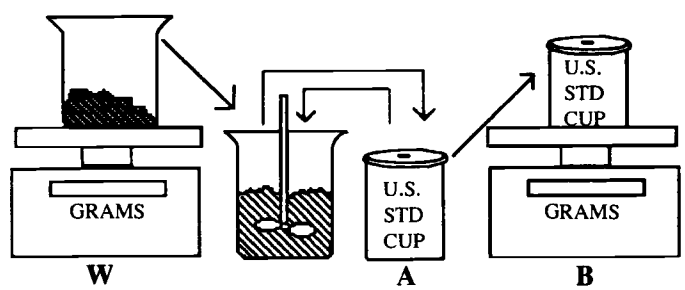

FIG. 18–Diagram for mixing known and unknown density materials [7]. Figure provided by Paul N. Gardner Co., Inc.

Measuring devices have been devised using a glass tube, an oscillator, and a sensor. The oscillating frequency of the tube changes when air is replaced with a liquid. The instrument can use air and water to establish a set of constants, called A and B, for the following relationships [15]

$$A = (T_w^2 - T_a^2) \div (d_w - d_a) \tag{14}$$

$$B = T_a^2 - (A \cdot d_a) \tag{15}$$

where

T_w = observed period of oscillation for cell containing water,
T_a = observed period of oscillation for cell containing air,
d_w = density of water at test temperature,
d_a = density of air at test temperature,
t = test temperature expressed in degrees Kelvin,
p = test barometric pressure expressed in torr,
d_a (g/mL) = $0.001\,293 \times (273 \div t) \times (p \div 760)$
d_w (g/mL) = 0.997 04 at 25°C (273 + 25 = 298°K)

Constant A is used by the instrument's computer to calculate constants K_c and K_{cr}. Constant B is used by the instrument's computer to return the reading for air density.

Modern digital density instruments are equipped with heating and cooling devices internal to the instrument, such that the sample can be equilibrated within the instrument in a matter of seconds. This leaves the pressure term, P, as a visible variable. Pressure changes can occur over a period of time due to weather changes.

The sample tube must be cleaned after each use. The tube's condition needs monitoring to verify that it is at original condition. Frequent calculation of the instrument cell constant K_c overcomes both of these problems.

For density values

$$K_c = \frac{1}{A} = \frac{d_w - d_a}{T_w^2 - T_a^2} \tag{16}$$

$$d_{\text{material}} = d_w + K_c \cdot (T_a^2 - T_w^2) \tag{17}$$

For relative density values

$$K_{cr} = \frac{1.0000 - d_a}{T_w^2 - T_a^2} \tag{18}$$

$$d_{\text{material}} = 1.0000 + K_{cr} \cdot (T_s^2 - T_w^2) \tag{19}$$

where

T_w = observed period of oscillation for cell containing water,
T_s = observed period of oscillation for cell containing sample,
K_c = instrument constant for density,
K_{cr} = instrument constant for density,
d_w (g/mL) = 0.997 04 at 25°C (273 + 25 = 298 K) density of water at test temperature, and
t = test temperature expressed in degrees Kelvin.

Small process computer chips built into commercially available instruments handle all the necessary calculations. Small sample volumes (1.0 to 2.0 mL) are used so heterogeneous samples like paint must be well mixed. The samples must be free of entrapped air. Small amounts of air cause fluctuations in the readings. Use of dilution with a compatible solvent (of known density) to thin the sample can be used if the thinning does not cause pigment dropout. The contribution of the thinner solvent can be calculated and backed out.

The ASTM method using the digital density meter is [*15*]:

Test Method for Density and Relative Density of Liquids By Digital Density Meter (D 4052)

SOLIDS

Densities of Solids—Methods of Determination

With solids, determining the volume for a known weight of the material is a challenge for several reasons. First, the form is fixed and direct, accurately known volumes are the exception rather than the rule. Second, solids are seldom homogeneous in their density. Processing often introduces voids or regions of differing degrees of crystallinity, both of which effect density. For large objects, displacement techniques as well as sonic shifts are useful. For powders and small particles, displacement and density by mixing with liquid diluent are the most common techniques. For thin films, only displacement techniques are useful.

Direct Volume Measurement by Pycnometer

Pigments are insoluble, solid particles used to impart color or light reflectance in paints. To provide more than an apparent density, special steps must be taken. ASTM Method for Specific Gravity of Pigments (D 153) is a set of three variations on the diluent pycnometer technique described in Fig. 18. It uses a vacuum pump and vacuum desiccator or bell jar to reduce the pressure on a sample of solid pigment. Variation A places a weighed sample of pigment in a dry, weighed glass pycnometer. White kerosene is then added to cover the pigment. The pycnometer and sample is then placed in the dessicator or bell jar and slowly evacuated to remove air entrapped on the irregular surfaces of the pigment. This is a method to wet the pigment surface and remove the contribution of entrapped air in the pigment. After all bubbling stops, air is let back into the jar and the pycnometer is filled to the top with kerosene and weighed. Variation B evacuates the pycnometer before the kerosene is added. Most of the kerosene is added to the pycnometer while it is under vacuum. The pycnometer is topped off with kerosene after returning to normal pressure. Variation C uses a measuring burette to add the kerosene so that volume of kerosene added is known [*2*].

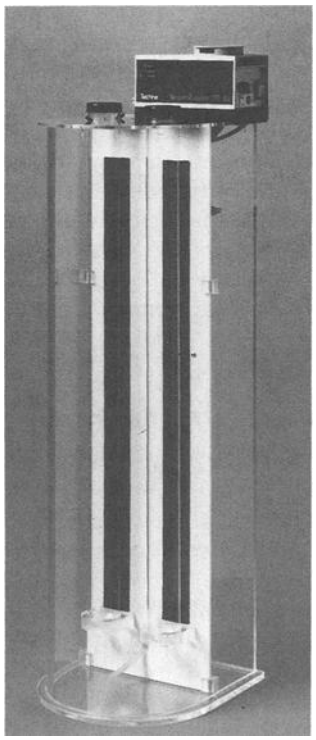
ASTM methods using pycnometer are [*2,16*]:

Test Methods for Specific Gravity of Pigments (D 153)
Test Method for Density (Specific Gravity) of Solid Pitch (D 2320)

Displacement of Liquids

This was discussed in the section on Solids, Liquids, and Gases as concepts and under ideal conditions.

Density gradient column systems (Fig. 19) are another form of submersion test methodology, inverted from the plummets of the density balances. Here the fluid is the calibrated, known test media, and the solid is the unknown. A vertical column tank with black background is carefully filled with a mixture of liquids in a very strict order to establish a heavy-to-light liquid density gradient. Measurements are made by adding in both unknown solid materials such as fibers, film pieces, powders, and glass particles and reference materials of known density. The particles will sink to the level of their own density. Using the proper reference materials, exact matches can be established within 0.0001 g/mL. There is a problem when the sample interacts with the fluids and



For accurate density determination of small solid samples to 0.001g/mL. Conform to ASTM D1505-68 for testing plastics. Measurements are made with reference to standard glass floats calibrated within ±0.0001g/mL. Fibers, irregular fragments, pieces of film, powders and glass are suitable. Several determinations can be made at same time.

In wide use for testing polyolefins, fluorocarbon polymers, nylons, PVC. Can separate natural and synthetic fibers. Can assay factors affecting density such as degree of crystallinity of plastics, concentration of isotopic content, presence of trace amounts of boron in silicon.

FIG. 19–Density gradient column systems with text from supplier catalog [*6*]. (Courtesy of Fisher Scientific)

absorbs them or interacts in other chemical ways which perturb the normal test action as with inert materials such as glass or plastics. Powders with irregular surfaces can also experience surface wetting problems and air pocket entrapment. Densities can be determined from 0.79 to 2.89 g/mL with this technique [*24*].

The test is of long duration, requiring a settling time of usually several hours. Several caution notes are included concerning thin film samples and their handling which could change the density. Potential users should review ASTM D 1505 to assess the applicability of this technique to their own personal needs and use.

ASTM methods using displacement of liquid and gases are [*17–19*]:

Standard Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D 2697)

Test for Specific Gravity (Relative Density) and Density of Plastics by Displacement (D 792)

Standard Test Method for Density of Plastics by the Density-Gradient Technique (D 1505)

Displacement—Gases

Helium pycnometers have been available for a number of years with many people expressing interest in using these devices to determine the volume of solids of known weight. These instruments are usually relatively expensive and only recently have become sufficiently automated to reduce the intense manual labor required to do a good job. Test method activities are being pursued with ASTM paint committee D 01.21 for thin film (ASTM D 2697) volume solids [*1,12*]. The main problem is to provide a sufficient amount of free paint film to test at a valid film thickness. Films that are too thick can retain solvents. Films that are too thin are very hard to handle. Free films develop static charge buildups which further complicate the testing procedure.

Dry powders are a second candidate for this technique. Helium gas displacement eliminates the need for the vacuum pump and the kerosene used in ASTM Method D 153, Test Methods for Specific Gravity of Pigments, to replace the air in the voids and available surface cavities. The drawback is that the fine powder is easily blown around. The instrument must be designed to eliminate powder travel and to keep the fine particles from the valves and seals. Helium pycnometery may become the method of choice as methods are developed and exchanged in the standard testing methods arena [*2*].

ASTM methods using Helium Pycnometery [*21*]:

Test Method for Density of Solid Pitch (Helium Pycnometer Method) (D 4892)

Sonic Frequency Shifts

The sonic frequency shift, principle and equations, has been discussed previously. Use of the sonic technique is limited to continuous objects which can be cut and shaped. Powders and small particles can be suspended in liquids and tested using the equipment discussed previously and using the equations noted earlier under **Sonic Frequency Shifts.** When the instrument uses solids instead of liquids, several considerations change. A glass tube is no longer used. The solid specimen must be cut into a rectangle with a smooth surface. Surface flaws will introduce errors in the readings.

A sonic sensing head is attached to the solid specimen (approximately 75 mm in thickness), and measures the velocity of sound transmitted through the specimen. Solid specimens require a minimum conditioning time period under controlled temperature and humidity conditions before testing. A calibration curve can be established using materials of known density. The published use is limited to polyethylene plastics. Alternative methods are probably cheaper or less time/labor consuming.

ASTM method using Ultrasound [*20*]:

Standard Method for Density of Polyethylene by The Ultrasound Technique (D 4883)

Apparent Density

Many pigments or powders are tested without regard to the air entrapment on the particle surfaces or in the voids between where the particles touch. These materials are placed in a graduated transparent container, and a vibrator is touched to the container wall. The particles pack down, and a weight is taken. This is referred to as *apparent density.*

ASTM methods based on apparent density include [*22–24*]:

Test Methods for Methylcellulose (D 1347)

Test Methods for Sodium Carboxy Methylcellulose (D 1439)

Test Methods for Hydroxypropyl Methylcellulose (D 2363)

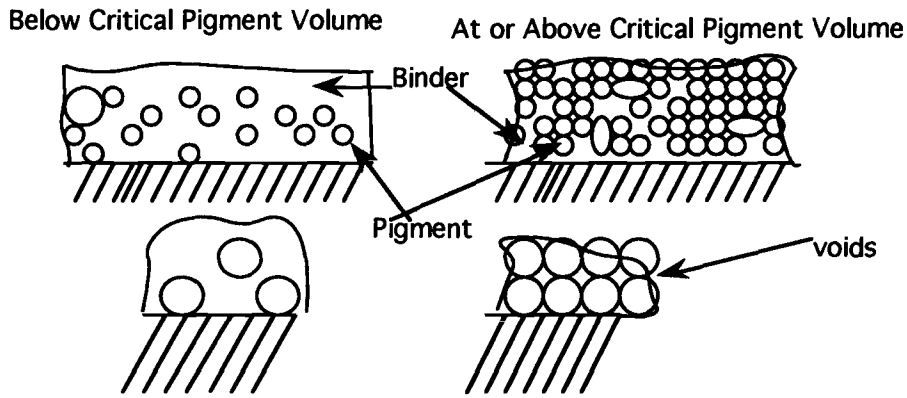


FIG. 20–Pigment volume relationships.

PAINT VOLUME SOLIDS

Paint is a mixture of materials that is designed to protect and beautify a substrate. When paint is sold, it is sold by volume as gallons or liters. What the consumer wants is the most coverage for the money. Commercial painters and original equipment manufacturers paint surfaces to a minimum thickness called "hiding." They know the square footage or square meter surface area they need to cover. With the thickness for hiding known, a volume of solids needed for painting a house or an automobile can be calculated. Government regulators would like to know the volume of volatile organic material included in a gallon of paint. A ratio of volume volatiles to volume solids would be a measure to compare paint products in terms of pollution contribution.

Theoretical Calculations of Paint Volume Solids

For many paint systems in commercial use today, a straight calculation of solids content can be performed with good results using the densities and weight percent content of materials which contribute solids to the final product. For many other systems, however, this calculated answer does not account for additional reaction by-products or provide information about how the density of the material has changed when cross-linking occurs. For these systems an analytically tested answer is needed. The answer would relate to the present U.S. Environmental Protection Agency's (EPA) Reference Method 24: Guidelines of Testing for VOC at 110°C for 1.00 Hour Bake [*1*].

Analytical Determination of Paint Volume Solids

Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D 2697) is the latest version of this test. The test is based on displacement of liquids, usually water or kerosene. Complications by cured paint surfaces cause this test method to be suspect and is not accepted by EPA for their regulatory purposes. A new method based on volume determination by gas (helium) displacement is under development and evaluation [*1*]. The helium is a pervasive gas that behaves closely to an ideal gas. Where paint surfaces are hard to wet with water, the helium has no problem getting very close to the paint surface and displacing air residing at the surface. The test chambers are usually from 5.0 to 30 cm^3 in volume. The paint sample is introduced as a free film or attached to a carrier such as a metal disk or aluminum foil. When the film is a free film, static charges can build up and cause sample loading and handling problems. The test instrument is not inexpensive, but it is highly automated and minimizes the human labor required to about 5 min per test.

CRITICAL PIGMENT VOLUMES

Definition

A condition when a paint has too much pigment and too little polymer such that internal voids are created which trap air or solvent in the vapor state [*1*].

Effect

A solid is created which has a higher apparent volume than really exists. See Fig. 20.

Relationship to Volume Solids

The present volume solids test uses liquids which are unable to penetrate into the void areas. A larger volume of water will be displaced, and the apparent weight loss will be greater in water. The resin is spread out over the pigment surfaces and will experience less opportunities to cross-link or tangle. The binder will not cure well, and the durability will be poor.

Particle-Size Measurements

by George D. Mills[1]

PARTICLE-SIZE MEASUREMENT ASSOCIATED WITH the paint and coatings industry has broadened in scope considerably over the past few decades. Not only must we evaluate the size, shape, and size distribution of the pigments, fillers, and emulsified resin particles used in the formulation of the coating system, but major efforts are now put forth to address environmental and applicator's health problems that are specific to particle size and nature. Environmental and economic concerns have been a substantial driving force in the development of powder coating technology, which requires monitoring finished powder size and size distribution to ensure consistent application parameters.

We have learned that the size, shape, and nature of dust particles in the air we breathe during the manufacture, application, and abrasive removal of paints are of utmost concern to our health. Airborne dusts of silica, asbestos, as well as lead- and chromium-laden paint debris generated during abrasive blasting are serious health threats. In an effort to protect the general public, government regulations now address the monitoring of small respirable dust particles of less than 10 μm ("R10" particles) during the abrasive removal of certain coatings.

In the production of electronic microcircuits, chips, and semiconductors, photo-resist coatings are applied to silicon wafers with line-to-line resolution of fractions of a micron. Dust particles, which are a fraction of this size, if allowed to contaminate the coated surface, will cause the production of defective chips. Dust has forced the development of more sophisticated clean-room technology in recent years. The reject rate of produced microchips caused by defects in the coating as a result of ultra-small particles of dust is a major problem.

As technology advances in the evaluation of smaller-size particle systems, materials used to standardize and calibrate the measuring/monitoring equipment must be developed. The necessity for standard traceable test materials, i.e., from the National Institute of Standards and Technology (NIST), formerly NBS, which are required to ensure the reliability of the measurements, has led to secondary industries that produce these standards from various materials.

Due to pressing global concerns with solvents emissions as well as the associated economic benefits, powder coatings as a class have grown at a very fast rate over the past 20 years. Many properties impacting the production, delivery, application, and film-forming characteristics are related to the average particle size of the manufactured powder. Often, of equal importance, is the amount of very small particles present. These "fines" affect fluidization and electrostatic application characteristics of the powder. Although an understanding of the relationships of powder properties to product application characteristics and performance is important, quality assurance/quality control (QA/QC) requirements demand high-speed, on-line (real-time) monitoring. This demand for rapid, accurate analysis of particle characteristics has been a driving force in the development of current instrumentation. The availability of low-cost computers and pertinent software as well as highly reliable and stable energy power sources and detectors have allowed the development of fast, accurate, broad spectrum, and "in-process" instrumentation. The development of robust solid-state laser diodes has allowed the replacement of bulky gas lasers, which required optical table stability. Further, the development of fiber optics, as well as the technology associated with its ease of alignment, has assisted in downsizing the footprint of some current generation instrumentation.

A major objective of this chapter is to provide an understanding of the various methodologies available for evaluating particle size, shape, and distribution. The hiding power and light transmission characteristics of coatings are greatly affected by the particle size of included pigments and fillers. Tensile strength of the cured system, water and gas vapor transmission coefficients, chemical resistance, and interface anticorrosive activity are only a few areas impacted by the size, shape, nature, and size distribution of the pigments and fillers formulated into the coating.

This chapter will allow an educated choice of technologies based on the size-dependent measurement most related to the desired property of importance. An appreciation of the mathematics involved will aid in determining and understanding the limitations and potential errors inherent in the measurement.

History of Particle-Size Analysis

The earliest reported particle sizing was about 150 B.C. in Greek and Roman mining manuals using sieves made of leather, woven hair, and planks. The Germans introduced wire-woven screens in the 15th Century. Microscopes were reportedly used in the 1700s for size analysis. Automated machinery was developed in the 1800s for weaving metal-wire sieve fabric. In the late 1800s to early 1900s, standards were developed defining sieve sizes. The first apparatus of record used for classification of pigment particles into different sizes

[1]President, George Mills & Associates International, Inc., P.O. Box 847, Humble, TX 77347-0847.

Copyright© 1995 by ASTM International

was reported by Thompson [*1*] in 1910. Oden proposed the use of gravity sedimentation as early as 1916 [*2,3*].

Energy sources of various wavelengths, employing many different configurations, have been used to measure particle size. Visible light photometry was reported by Stutz and Pfund [*4*] in 1927. Gamble and Barnett [*5*] employed radiation in the near-infrared region. Atherton and Peters reported using light-scattering techniques in 1953 [*6*]. The electron microscope found use in the 1940s for characterizing very small particles as well as to define the corresponding surface topography. The invention of the laser and diode array detectors opened the way for developing the fast light-scattering and blocking instruments widely used in the 1990s.

Importance of Particle-Size Analysis

As the physical properties of paints, coatings, and polymers in general are impacted by the size, shape, and size distribution of the fillers included in the formulation, it is imperative that characterization of the pigment and filler system be correlated with the physical properties of the coating.

Because of the early importance of zinc oxide as a pigment in oil-based paints and its existence in multi forms and shapes, this material was studied in the 1920s and 1930s. Bunce [*7*] found that as the average diameter of zinc oxide in a paint increased from 0.19 to 0.31 μm, the elongation of the film increased and the load at the breaking point decreased (Fig. 1). Eide [*8*] showed that coarse acicular zinc oxide imparted greater durability to a paint than did "round" zinc oxide. In related studies, Morris [*9*] and Nelson [*10*] found evidence that acicular asbestine of a wide distribution of sizes favorably influenced the durability of paints, and a review by Jacobsen [*11*] cites many examples of the significance of particle size and shape of pigments and extenders on the optical and physio-chemical properties of coating systems.

Many surface properties are impacted by the pigment's and filler's particle size and nature of which gloss is one of the most prevalent. While the larger-size particles can "protrude" through the surface of the coating, causing a surface roughness related to the size of included particles, extremely fine particles can affect gloss by adsorbing binder to a point that the gloss is decreased due to a lack of available binder at the coating surface. The "oil adsorption" of the pigment is a function of its surface area and increases as the average particle size decreases. The "critical pigment volume concentration" (CPVC) exists at a pigment loading at which there is insufficient binder solids to completely wet out the included filler and pigment particles. Coatings formulated above the CPVC cannot be glossy. Abrasion resistance of the coating may be increased by the addition of hard fillers such as silica. The relationship between particle dimensions and film properties is depicted in Fig. 2. The National Paint, Varnish, and Lacquer Association has published a Pigment Index that gives information on the particle size of many of the pigments available on the American market [*12*].

Other coating properties impacted by variations in particle size and shape include the efficiency of contained UV blockers and absorbers such as carbon black pigments. The use of acicular pigments such as Wollastonite (asbestos free) are popular in many types of coatings. The tensile and compressive strength of coatings also can be modified by judicial choice of particle size and shape, and gas vapor and molecular water transmission of a coating can be altered with the proper choice of pigment loading and size.

The coalescent and film-forming characteristics of emulsion binders are impacted by the particle size of the dispersed resin particles. Cold touch up, brushability, and mechanical

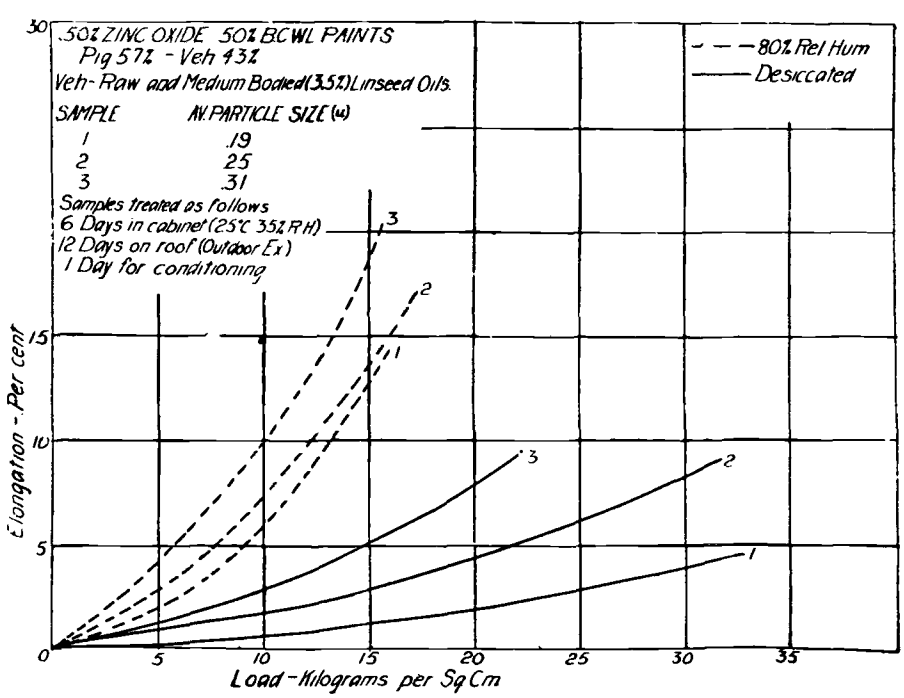

FIG. 1–Stress-strain curves of some paint films. These illustrate the effect of the particle size of zinc oxide on the strength of paint films.

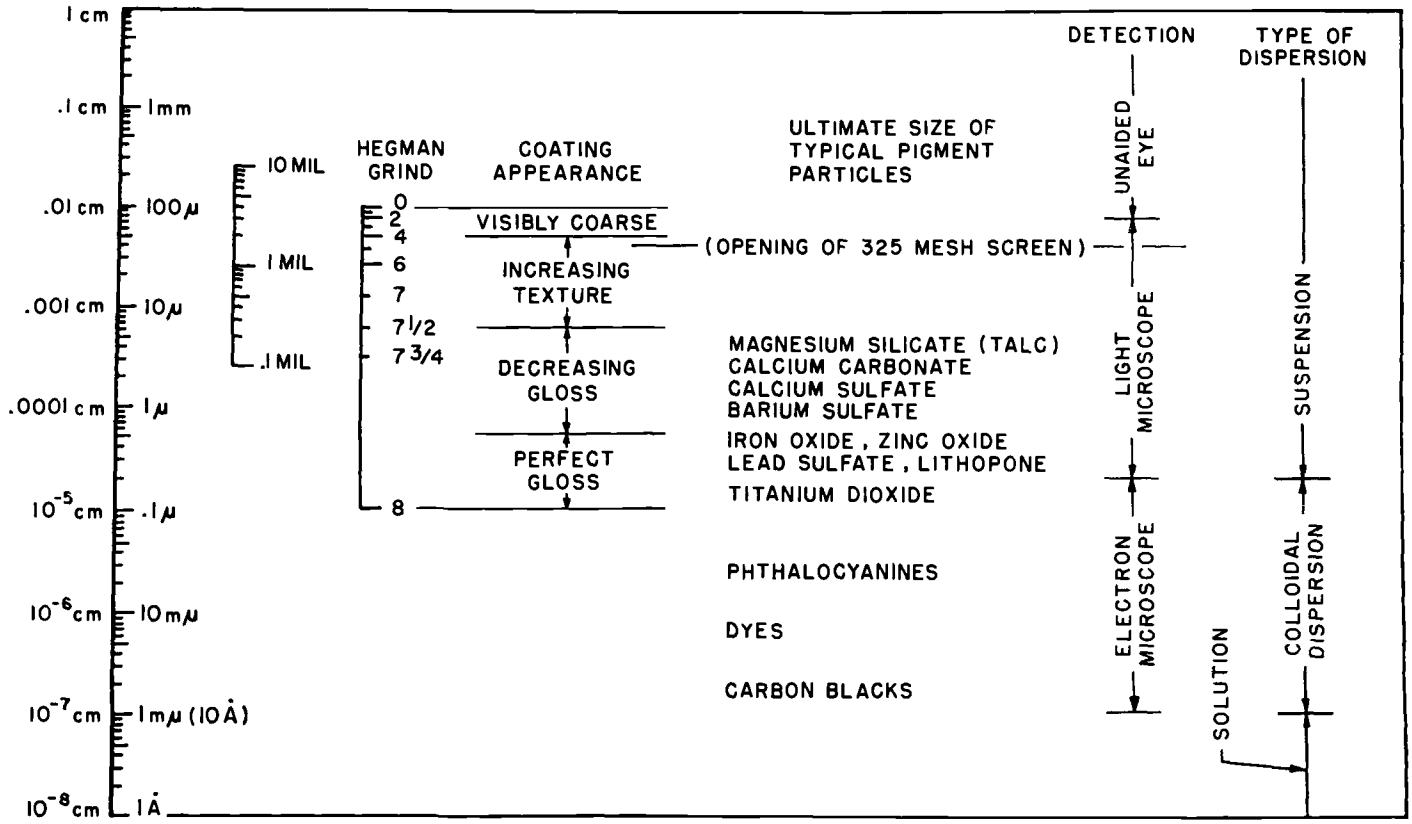

FIG. 2–Dimensions of granular pigments and their relation to surface properties (from Ref *12*). (Courtesy of the *Journal of Paint Technology*.)

stability during pigment dispersion are a function of properties that are related, in part, to polymer particle size. Surfactant demand and effectiveness are a function of polymer particle size (as well as other binder variables). Because of the importance (dependence) of many coating properties on the small finite size of the pigment, fillers, catalysts, and polymers formulated into the coating, the demand for rapid, accurate analysis of particle characteristics has lead to the refinement of many techniques.

CONSIDERATIONS IN SAMPLING TECHNIQUES

Normally, when a particle-size determination is made, one will not work with the total collection of particles comprising the bulk sample. A "representative" collection of particles is usually chosen. This sample is then reduced in size a few more times until only a few milligrams remain for the actual instrumental testing. The assumption is usually made that the fraction actually evaluated is, in fact, "identical" in particle size, size distribution, shape, and nature to the total of the bulk material. This sample test fraction, which usually does not exactly represent the bulk, can be a major source of error, introducing considerable bias and distortion to the results. The reliability of any measurement depends on the degree of representitiveness of the test sample. Thus, the sampling technique is as important (if not more so) than the actual particle-size measurement, though in reality there is little chance that the sample selected will be identical to the bulk material.

Theoretical Considerations of Variance in Sampling

To obtain a representative sample, the sampling process is usually divided into several steps during which a conscious effort is made to reduce bias. The bulk material is usually obtained in huge, ton lots. The first sample reduction provides the "gross" sample, which is on the order of kilograms. This sample is then reduced to the "laboratory" sample, which is on the order of grams. The actual evaluation sample introduced to the instrument is on the order of milligrams. The reduction process will almost always introduce some bias, depending on the actual spread in the distribution. This bias will diminish as the consistency approaches unity, i.e., all particles approach being identical. The bias exists because the physical forces acting on the particles in a collection are not the same, but are, in fact, size dependent. The "fines" act differently in a pile than will the course particles. Their angle of repose is different, often resulting in particle stratification and some segregation.

There are some established rules that must be followed to minimize this bias. The "perfect" sample is one in which the differences seen between the evaluated characteristics and those that actually exist in the bulk can be ascribed to the expected number variations described by statistics. For a sand (A) and sugar (B) mix, the probability that the number fraction, p, of (A) in the bulk actually is represented by the

number fraction (p_i) in the sample is computed from the number of actual particles in the bulk (N) and the reduced sample (n) [13]. The equation is as follow

$$\mathrm{Var}(p_i) = \frac{p(1-p)}{n}\left(1 - \frac{n}{N}\right) \quad (1)$$

Theoretically, the expected deviation (i.e., standard deviation), σ_i, is the square root of the variation. Since the use of the weight fraction is often more convenient, the equation for variance is given by

$$\mathrm{Var}(P_i) = \frac{P(1-P)}{w}[Pw_B + (1-P)w_A]\left(1 - \frac{w}{W}\right) \quad (2)$$

where the weight fraction in the sample and bulk are P_i and P, respectively, W and w are the bulk weight and sample weight, respectively, and w_A and w_B are the weights of individual grains of A and B, respectively.

Even with the "perfect" sample, there is a finite probability that the measured sample will deviate from the actual bulk by some predictable value. To minimize this "guaranteed" deviation, a minimum sample size is required. One may calculate the minimum sample size required to yield values within preset statistical limits [13]. The equation relating the minimum sample weight of a gross sample is given by

$$M_s = \tfrac{1}{2}[\rho/\theta^2][1/w_\lambda - 2]d_\lambda^3 \times 10^3 \quad (3)$$

where

M_s = the limiting weight in grams,
ρ = the powder density in g/cm^3,
θ^2 = the variance of the tolerated sampling error,
w_λ = the fractional mass of the coarsest size class being sampled,
d_λ^3 = the arithmetic mean of the cubes of the extreme diameter in the size class in cm^3.

The collection methods used in obtaining the sample are important. Depending on the nature of the material being tested, samples should be gathered so as to minimize the introduction of bias. There are two "golden rules" of sampling that should be followed when possible [14]. These are:

- The sample should be collected while in motion.
- All of the stream should be collected for a short period of time rather than a portion of the stream for a longer period of time.

This procedure will assist in minimizing the probability of error generated by stratification and segregation due to differing weights of the particles within the stream and of the way they act within the collective mass of the sample during transport. Special collection devices are available for affecting the sample collection.

Sampling Techniques and Equipment

Sampling techniques have been developed to minimize the systematic errors introduced both in collecting the gross sample and in reducing its size to the analytical sample. In the work done by Allen and Khan [15] using sand-sugar and sand-sand, mixtures were evaluated utilizing different collection techniques. These techniques included; (1) cone and quartering; (2) scoop sampling; (3) table sampling; (4) chute riffling; and (5) spinning riffling. The data presented in Table 1 show the values obtained via each method as well as the expected standard deviation from the known sample.

Cone and quartering is a procedure in which the powders are piled into a cone. The cone heap is then carefully pushed down flat and divided into four equal sections. The assumption is that the cone will be symmetrical about its central axis and the flattened sections will all be representative of the bulk mixture. A problem exists as it is very difficult to produce perfect symmetry, which results in some size segregation from the center out. The technique is also operator dependent, and tests showed this technique to give the largest standard deviation of the five techniques evaluated (see Table 1).

Scoop sampling entails randomly dipping into and pulling a scoopful of powder from a pile of the material to be evaluated. Because the pile is usually not totally symmetrical and evenly distributed throughout, the technique is prone to errors. Since in this procedure the powder is not caught while moving, it will not be typical of the bulk lot of material.

Table sampling (Fig. 3) utilizes a tilted surface over which a powder sample is allowed to slide. A series of splitting wedges cut the sample into numerous sections where some portions fall through openings and are discarded. Ultimately, a decreased quantity of sample is collected, although it is necessary that the incoming powder be uniform and consistent.

Chute splitting utilizes a funneling or channeling device capable of alternately placing the powder sampling stream into one of two collection hoppers. The technique is subject to error and operator bias if segregation is allowed to occur in loading the bulk sampling trough. Such error is present when the two collected portions are not the same size.

Spinning rifflers (Fig. 4) utilize a series of smaller collection tubes or holders mounted in a way to collect a flowing powder stream over a very short time period. This technique was found to be the most reliable method for sampling and, when tested with different operators, showed little operator bias. Such was not the case for the other techniques investigated.

PARTICLE CHARACTERIZATION METHODOLOGY

Particles that are perfect spheres can be described by a single value representing the sphere's diameter. Calibrated microscopes are useful in reading such values directly from the reticule. They have some utility with spherical resin parti-

TABLE 1—Standard deviation in particle size determination of a sugar-sand mixture as a function of sampling techniques.

	Standard Deviation (σ)[1]	
	Sugar-Sand	Sand-Sand
Cone and quarter (worst)	5.762	6.812
Scoop sampling	6.312	5.142
Table sampling	2.11%	2.09%
Chute riffler	1.10%	1.01%
Spinning riffler (best)	0.27%	0.132
Random variation	0.09%	0.08%

[1]Binary mixtures of sand-sand and sand-sugar were used, and all particles of one component and none of the other would pass through a designated sieve. Density of sand and sugar, respectively, is 2.65 and 1.64 g/mL. From Allen, T. and Khan, A.A., 1970, *Chemical Engineering*, Vol. 238, pp. 108–112.

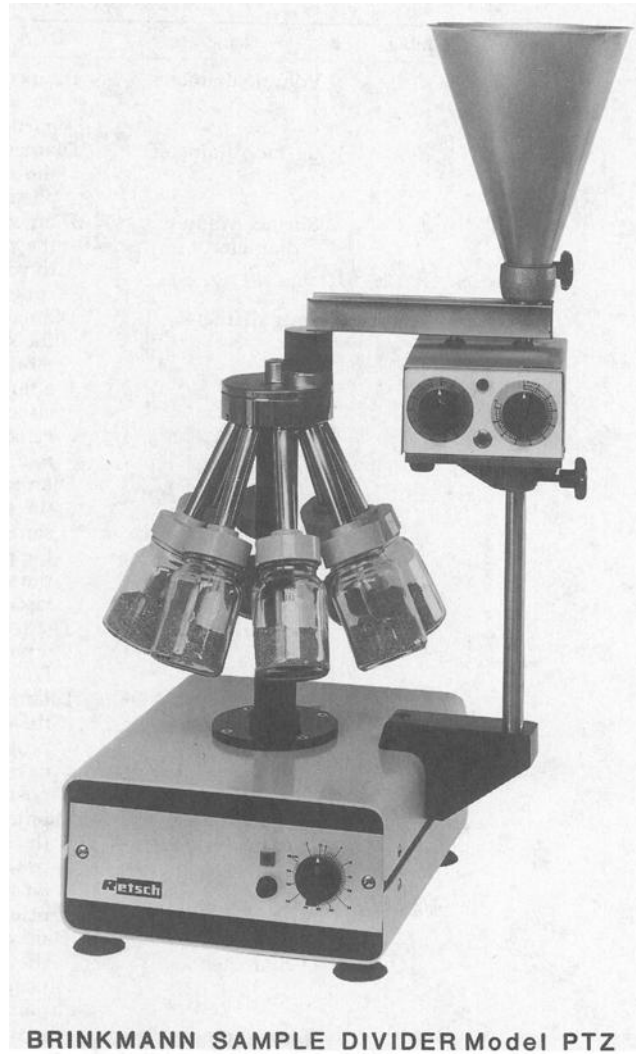

FIG. 4–The spinning riffler. (Courtesy of Brinkman Instruments, Inc.)

cles and with visual measurement of standardized test materials. Classification of most powders, on the other hand, must address particles of various shapes and sizes.

A particle-size determination utilizes some size-dependent property that can be measured and then relates this property to a linear dimension. The measurement derives either from individual particles or as a property of the collection of particles that is often expressed as a diameter of sorts. Measurement of a single individual particle can have many different "diameters" depending on the direction and method of view. Particle characterization, therefore, may involve determining the rate of a particle's travel through a fluid (either under the influence of gravity or while being subjected to angular acceleration due to rotation), its actual surface area, its ability to pass through a screen of square or round holes, or its ability to scatter light of various wavelengths in various directions.

It is convenient to use the term "equivalent diameters" when comparing sizes. The value so determined for a given collection of irregular particles will vary somewhat depending on the technique used (i.e., the size-dependent variable being measured). The definition of some of these "diameters" are presented in Table 2 along with their mathematical representation. Table 3 lists some of the methods, the nominal particle-size range, and the size measured. The methods available for determining particle size take advantage of many different characteristics of the powder particle.

Definitions of Particle Size and Shape

Particle shapes are everything but spherical for pigments and fillers, which are produced, essentially, by crushing and shattering. As the sizes get smaller, the actual particle shape plays an increasingly important role in its use in a coating as well as on the physical laws employed for its characterization. From the diagram in Fig. 5, the same particle may be defined in a number of ways [*16*]. Some of these include the following:

Martin's Diameter—the distance between opposite sides of a particle measured on a line bisecting the projected area. To ensure statistical significance, all measurements are made in the same direction regardless of particle orientation.

Feret's Diameter—the distance between parallel tangents on opposite sides of the particle profile. Again, to ensure statistical significance, all measurements are made in the same direction regardless of particle orientation. Note: Both

TABLE 2—Definitions of particle size.

Symbol	Name	Definition	Formula
d_v	Volume diameter	Diameter of a sphere having the same volume as the particle	$V = \frac{\pi}{6} d_v^3$
d_s	Surface diameter	Diameter of a sphere having the same surface as the particle	$S = \pi d_s^2$
d_{sv}	Surface volume diameter	Diameter of a sphere having the same external surface to volume ratio as a sphere	$d_{sv} = \frac{d_v^3}{d_s^2}$
d_d	Drag diameter	Diameter of a sphere having the same resistance to motion as the particle in a fluid of the same viscosity and at the same velocity (d_d approximates to d_s when Re is small)	$F_D = C_D A \rho_f \frac{v^2}{2}$ where $C_D A = f(d_d)$ $F_D = 3\pi d_d \eta v$ $Re < 0.2$
d_f	Free-falling diameter	Diameter of a sphere having the same density and the same free-falling speed as the particle in a fluid of the same density and viscosity	
d_{St}	Stokes' diameter	The free-falling diameter of a particle in the laminar flow region ($Re < 0.2$)	$d_{St}^2 = \frac{d_v^3}{d_d}$
d_a	Projected area diameter	Diameter of a circle having the same area as the projected area of the particle resting in a stable position	$A = \frac{\pi}{4} d_a^2$
d_p	Projected area diameter	Diameter of a circle having the same area as the projected area of the particle in random orientation	Mean value for all possible orientations $d_p = d_s$ for convex particles
d_c	Perimeter diameter	Diameter of a circle having the same perimeter as the projected outline of the particle	
d_A	Sieve diameter	The width of the minimum square aperture through which the particle will pass	
d_F	Feret's diameter	The mean value of the distance between pairs of parallel tangents to the projected outline of the particle	
d_M	Martin's diameter	The mean chord length of the projected outline of the particle	
d_R	Unrolled diameter	The mean chord length through the center of gravity of the particle	$E(d_R) = \frac{1}{\pi} \int_0^{2\pi} d_R d\theta_R$

Martin's and Feret's diameters are generally used for particle-size analysis by optical and electron microscopy.

Equivalent Circle Diameter—the diameter of the circle having an area equal to the projected area of the particle in random orientation. This diameter is usually determined subjectively and measured by ocular micrometers called graticules.

Equivalent Spherical Diameter (E.S.D.): This often affords a more useful measure, particularly where industrial processing is involved. This diameter is determined, in effect, by measuring the behavior of the irregular particle in a certain circumstance and relating that to the behavior of a sphere of otherwise identical properties.

Sedimentation (Stokes') E.S.D.—the diameter of a sphere of the same density as the particle and having the identical free-fall velocity of the particle.

Volume E.S.D.—the diameter of a sphere having the same volume as the particle.

TABLE 3—Comparison of particle-sizing methods.

	Nominal Range, μm	Size Determined
Gas Permeability	0.1–40	Mean
Gas Adsorption	0.005–50	Mean
Brownian Motion	0.01–3	Mean

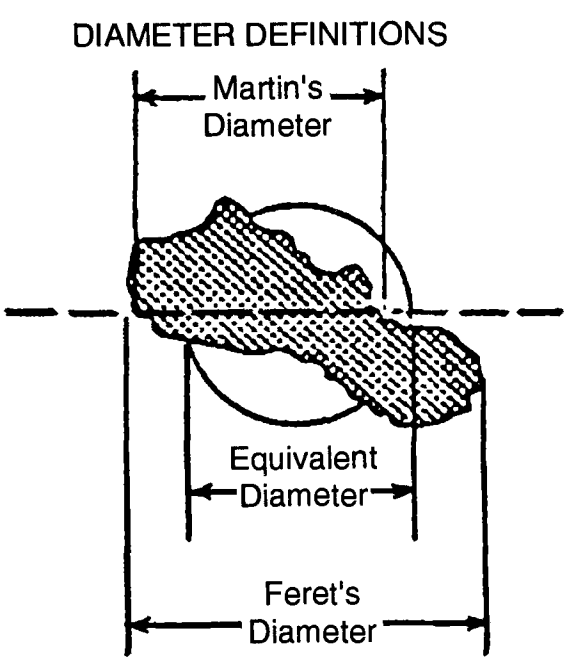

FIG. 5—The relationship of some stated diameters and the physical size of the particle.

Particle Size From Surface Area

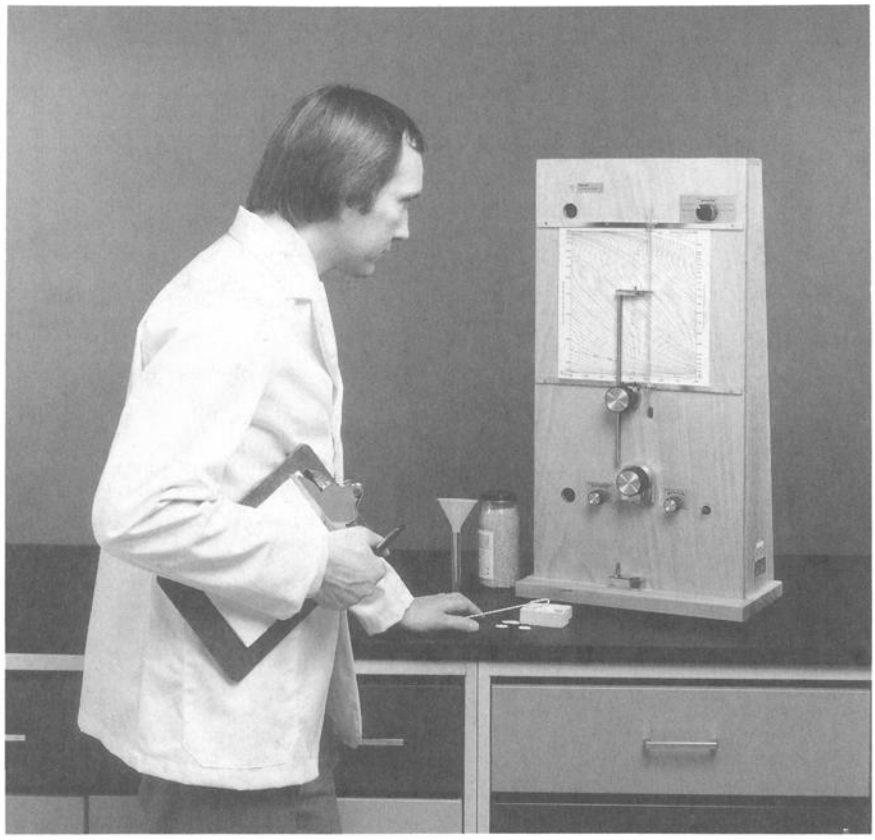
It is often useful to use the approximation of size from surfaces to evaluate other parameters derivable from the volume function, such as specific surface area and density. The basic equations that describe a sphere's surface area and volume are given by

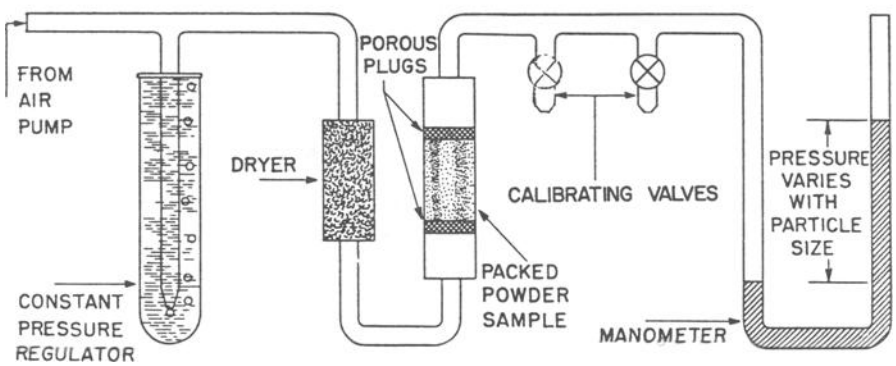
$$\text{Area of a sphere} = \pi D^2 \quad (4)$$

$$\text{Volume of a sphere} = \pi D^3/6 \quad (5)$$

These relationships allow determination of the mean particle diameter if the specific surface (area) is known. Particle-size characterizations that employ surface area techniques in the size determination yield average diameters. The surface area of a powder may be determined from gas adsorption experiments. By assuming uniform-size nonporous and spherical particles, the mean particle size may be determined from the surface area data. The Fisher subsieve sizer is an example of an instrument of this type (Fig. 6). The "specific surface" obtained equals the determined surface area divided by the product of the particle volume and density. With appropriate units conversion,

$$D = 6/[\rho A] \quad (6)$$





1. Perspective of Operating Principles

FIG. 6–The Fisher subsieve sizer. (Compliments of Fisher Scientific.)

where

D = particle diameter, μm,
ρ = particle density, g/cm^3, and
A = specific surface area, m^2/g.

Any shape other than a sphere, either regular or irregular, has a greater ratio of surface to volume, and consequently the particles will be smaller than calculated. Cracks, crevices, and pores are other factors leading to an increase in specific surface area and to a corresponding decrease in calculated particle size.

Perfectly spherical particles are seldom encountered in mineral pigments and fillers used in paint and coating applications since these particles result from shattering by crushers and high-speed pulverizers. Crystalline materials fracture along crystal planes, while some pigments are acicular (like needles). With the many shapes of particles to be evaluated and characterized, instruments that operate on different principles "see" different values of the size-dependent variable being monitored. As a result, a sample characterized by one machine may yield a somewhat different value when

evaluated using a different technique. For this reason, the practitioner must be aware of the size-dependent variable to which his machine is sensitive.

Methods [*17*] for determining specific surface include adsorption of gases by the pigment, adsorption of solutes from solutions by the pigment, and permeability of pressed pigment particles to gases or liquids.

Adsorption of Gases

This method is based on determining the number of gas molecules that will adsorb as a monomolecular layer on the surface of the particles. Knowing the area occupied by one molecule and the number of molecules, the specific surface area of a specimen of pigment may be calculated from

$$\Sigma = nNA \tag{7}$$

where

Σ = specific surface area in cm^2,
n = number of moles of gas per gram of pigment,
N = Avogadro's number, 6.02×10^{23}, and
A = area covered by each molecule.

Knowing the specific surface, the surface mean diameter may be calculated.

Brunauer-Emmett-Teller (BET) Method—The general procedure for this method [*18,19*] includes introducing the specimen into an enclosed space of known volume followed by degassing with heat and evacuation. A known amount of gas is admitted to the system, and its pressure is determined. The gas is then compressed to a new volume, and the corresponding pressure is determined. The procedure is repeated until enough data for the preparation are obtained. By means of the BET equations, the surface area is found, and from it the average particle size may be calculated.

Continuous Flow Method—This method makes use of the BET equation, but the adsorbed gas is determined by concentration measurements in a continuous flow system [*20*]. Nitrogen gas is adsorbed by the specimen at liquid nitrogen temperature from a stream of nitrogen and helium gas and is later eluted by warming the specimen. The amount of nitrogen liberated is estimated by thermal conductivity. For detecting changes in the amount of adsorbed nitrogen, Beresford et al. [*21*] used the Perkin-Elmer-Shell sorptometer with conductivity bridge and potentiometric recorder.

Gravimetric Method—In addition to the volumetric methods, a gravimetric method using balances patterned after that of McBain and Bahr [*22*] can be used. The procedure is much simpler but requires care as the apparatus is very fragile and the changes in weight are very small.

An essential part (Fig. 7) of the gravimetric method is a fused silica spring balance from which a small glass "bucket" for the specimen is hung. The balance assembly is located in a glass housing connected to a source of gas and to a manometer for determining the pressure. The bucket is hung on the balance, the housing is closed, and the specimen is degassed by evacuation. The zero point of the balance is recorded. Gas is admitted to the housing, and the change in weight of the specimen is determined by noting the change in the elongation of the balance with a traveling microscope. Details are set forth in Ref *17*.

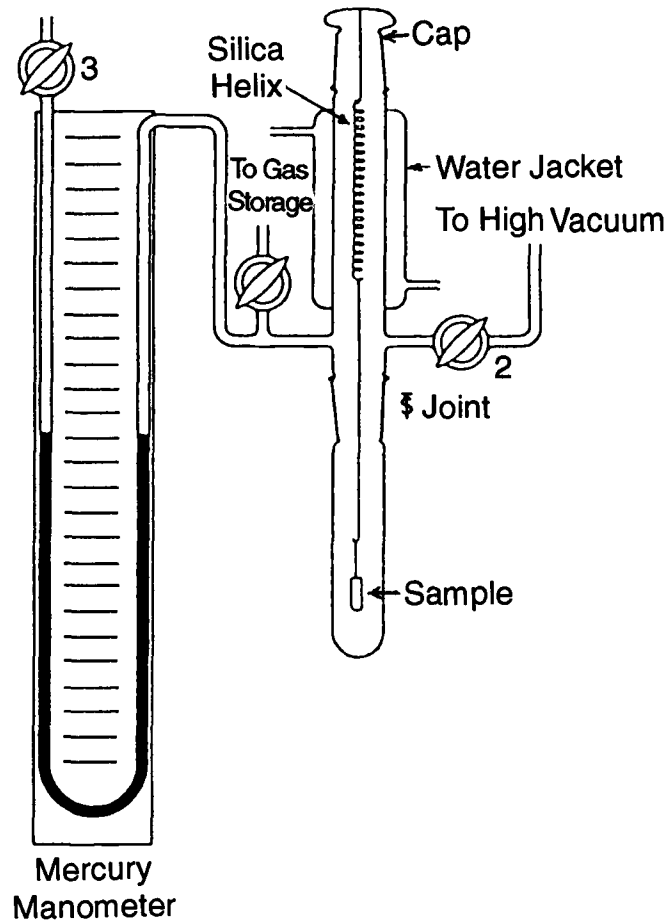


FIG. 7–The Components of a basic gravimetric adsorption apparatus.

Adsorption of Nongaseous Molecules

Adsorption of molecular species other than typical gaseous molecules is possible also. These include the adsorption of solvents and surfactants in special cases.

Adsorption of Solutes onto Pigments—This method depends on the adsorption of solute molecules onto a particle when it is wet out by a solution containing the dissolved surface active solute [*23*]. The process requires that the adsorbent be thermodynamically more active than the solvent and the kinetics be such that wet-out times be reasonable. Typical systems used are stearic acid in benzene, dyes in benzene, and wetting agents in water. The amount adsorbed will asymptotically approach a constant value with time. At this value it is assumed that the surface of the particles is covered with a mono-molecular layer of solute. The area occupied by a single molecule of solute may be obtained from tests made with solids of known areas. The amount adsorbed is obtained by analysis of the solution before and after adsorption.

A disadvantage of the method is uncertainty about the size and orientation of certain types of molecules. On the other hand, the method is rapid and easy to perform. For this reason it is suited to routine tests where its reliability has been established.

Soap Titration of Emulsion Particles—Maron et al. [*24*] determined surface area and particle size of a synthetic latex by

titrating with a soap until the critical micelle concentration of the soap in the solution was attained. From the effective molecular surface area of the adsorbed soap and the amount adsorbed, surface area and particle size are calculated. The method is calibrated with electron micrographs. Brodnyan and Brown [*25*] also studied the technique.

Permeation Through Packed Powders

In this method, a gas, usually air, is forced through a compacted bed of the pigment. The rate of flow is a function of voids (pore space), pressure drop through the bed, specific surface of the pigment, and viscosity of the gas. A knowledge of all the other factors allows calculation of the specific surface area and, from it, the mean surface diameter. The method is fairly simple and is suitable for routine determinations of spherical or near-spherical particles.

Gooden-Smith Method—Using air as the gas, Gooden and Smith [*26*] designed a permeation method with two special features: (1) the weight of specimen used in grams is numerically equal to its density and (2) every specimen is packed to the same volume (Fig. 8). Together with a graphic calculator, these features greatly simplify the test and make it attractive for routine testing or research in the particle-size range 0.2 to 50 μm.

Hutto-Davis Method

The principle differences between this and the preceding method are: (1) the weight of the powder used to make the compacted pellet is calculated to give a definite porosity, and (2) the volume of air is kept constant for all plugs.

Hutto and Davis [*27*] modified the apparatus of Carman and Malherbe [*28*] by providing an improved manometer, better control of the volume of air, and an improved press for preparing the specimen. They also designed a nomograph for calculating specific surface and surface area. The apparatus consists of: (1) a U-tube with legs of unequal length and closed at each end with a sintered glass disk, (2) a manometer, (3) a capillary specimen tube, and (4) a leveling bulb containing mercury.

To provide the constant volume of air, the U-tube is inverted and filled through the stopcock at the bend. Then, with a capillary eyedropper, a weight of mercury equivalent to 1 mL is removed, leaving an equal volume of air after which the stopcock is closed and sealed. The mercury does not pass through the sintered glass disk at the pressure used in the test. To make a test, a plug of pigment is formed inside the specimen tube using the special press. The weight of the specimen is a function of its density and the desired porosity of the plug (usually about 0.5). With the leveling bulb in the lower position, the specimen tube is attached to the side arm of the apparatus, and a vacuum is applied by opening the stopcock at the upper right-hand corner. The vacuum is adjusted, and simultaneously the stopcock is closed, timing is started, and the leveling bulb is raised to its upper position, which forces the 1 mL of air into the system. The timing is stopped when the manometer returns to zero. The stopcock is then opened, and the bulb is returned to its lower position for another run.

Separation and Collection: Particle Size by Elutriation

This approach is primarily a means for separating or fractionating a quantity of pigment into portions according to particle size rather than providing a value of the sizes separated. Size determinations may then be made on the separated fractions. The technique has utility in evaluating the influence of pigment and filler particle size on the properties of the formulated product. After standardizing operating conditions for a material and measuring sizes by an independent method, approximate size distribution may be estimated for additional material.

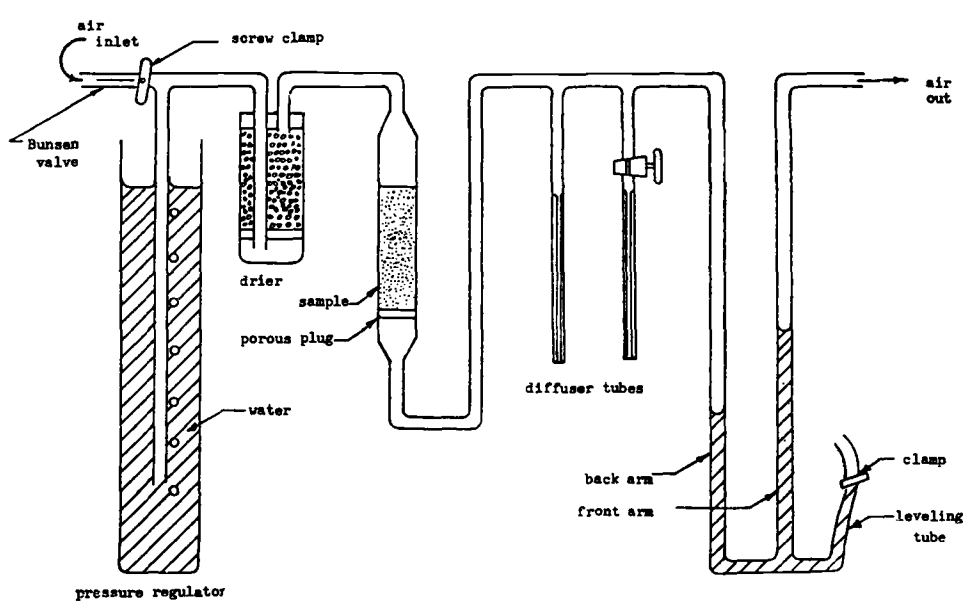

FIG. 8–Gooden-Smith apparatus for surface area. (Courtesy of *Official Digest.*)

Roller Particle-Size Analyzer

This device [*29*] uses elutriation by air to separate pigments into sizes. The glass U-tube at the bottom of Fig. 9 is charged with the specimen of pigment. Air under pressure is admitted through a nozzle that extends to the bottom of the tube. The other arm of the tube is connected to the metal settling tube. By proper selection of size of nozzle, size of settling tube, and velocity of the air, separation into desired fractions is obtained. The fractions are collected in paper extraction thimbles connected with a gooseneck to the settling tube. During the separating, the U-tube and the settling tube are vibrated vigorously. Using 25-g charges, the average time required for separations ranges from 62 min for particles up to 5 μm in diameter to 11 min for particles from 40 to 80 μm in diameter.

Felvation

This method [*30*] combines elutriating and sieving for fractionating fine powders. The basic apparatus (Fig. 10) consists of a column about 4 in. (10 cm) in diameter and 24 in. (61 cm) in height. The specimen is placed in the narrow tube at the right. Fluid is introduced and allowed to pass through at a relatively low rate. The powder soon becomes fluidized in the conical base of the column. The flow of the liquid is increased gradually. The smaller particles reach the sieve and pass through it. The throttling action of the sieve increases the flow through it. Hence, particles that have passed through do not fall back and clog the screen. Eventually, particles just larger than the sieve openings reach the sieve, but they do not block the screen as they reduce the flow around them and then tend to fall from the sieve.

The sieve functions only as a gage. It does not support the powder. Highly accurate electroformed sieves are used, but, because of their small size (1 in. (2.5 cm) in diameter), their cost is reasonable. Beside being economical, the method is rapid. Complete fractionations can be run in a period as short as 10 min.

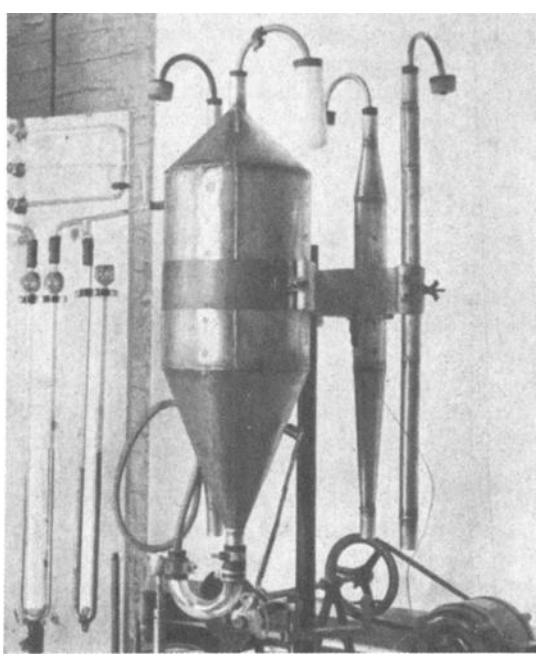

FIG. 9–The roller particle-size analyzer.

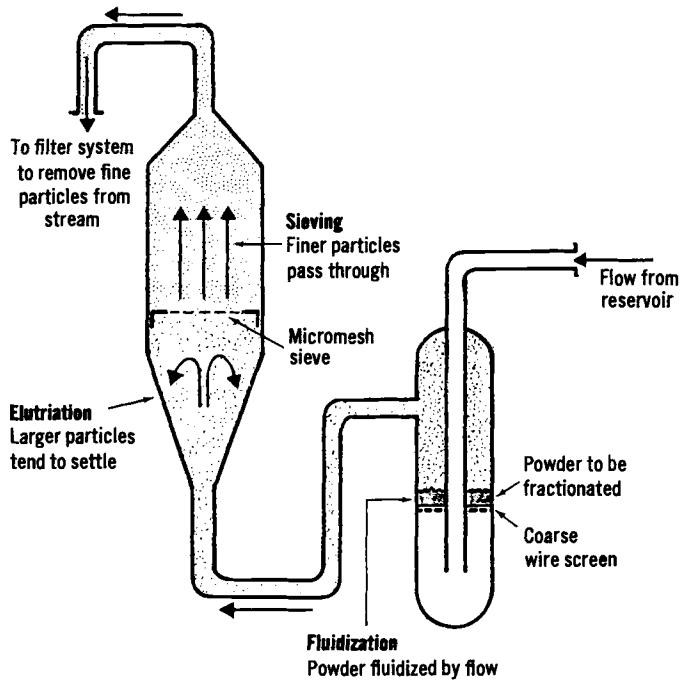

FIG. 10–Felvation. Fractionating powders into different sizes by a combination of fluidization, elutriation, and sieving. (Courtesy of *Chemical and Engineering News*.)

Individual Particle Sensing

In this technology, individual particles are separated from each other by a diluted suspension in either air (by fluidization followed by entrainment in a flowing stream) or a constantly stirred conductive solution. The particles are then forced to pass through the sensing zone. In one air-fluidized instrument, the time of flight between two precisely placed laser light sources and detectors is used to calculate size. In another, the attenuated light as detected by a photodiode is used to calculate a size. In the liquid suspension instrument, a change in the established electrical resistivity through an electrolyte circuit is measured as a particle passes through a small orifice.

Time of Flight from Light Blockage

An instrument based on aerodynamic time-of-flight technology was developed by Dahneke [*31*]. The measurement range is reported to be from 0.2 to 200 μm, with 150 channels per decade and a count rate of up to 100 000 particles per second. Output may be reported in either geometric or aerodynamic diameter. In this instrument, a gas (usually air for pigment particles) is used to break down agglomerate material and entrain them in a controlled flow; a specially designed "pulse-jet dispenser" is used where a controlled flow of air is directed down onto a sample placed into a small cup (Fig. 11). Depending on the nature of the sample, the operator sets the computer values for particle count rate, flow pressure, and pulse pressure. The disperser flow pressure controlling the carrier gas usually remains constant. The disperser

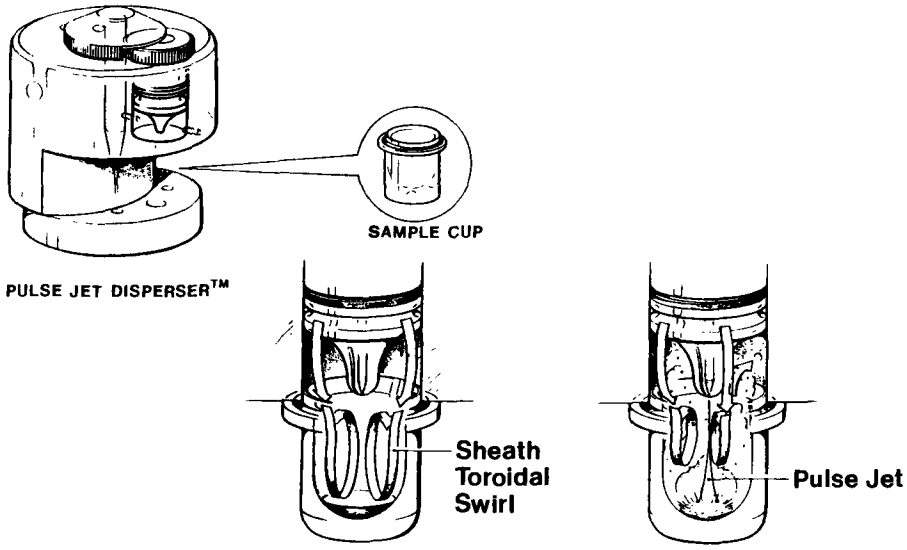

FIG. 11–A diagram of the operation of the dry-powder pulse jet disperser. (Courtesy of Amherst Process Instruments, Inc.)

pulse pressure determines the number of particles fed through the analyzer.

Measurements are made over 2-s intervals to ensure that the minimum count rate is met. Should the count rate fall below the predetermined count rate, the pressure is increased. Should the count rate exceed the maximum allowed, the pressure is dropped by a factor of 2, thus maintaining the number of counts between the allowed maximum and minimum.

The particles are deaggregated to primary size and fed into the injection tube of the sonic nozzle suspended as single particles in the air stream moving at about 6 L per minute. There is no operator involvement during the 1 to 5-min determination. Two laser beams set at a discrete distance apart and directed onto two photomultipliers make up the "sensing zone" (Fig. 12). As the particle passes through the set of laser beams, light that is attenuated and scattered is monitored by the detectors. Signal analysis using cross-correlation techniques give the particle's time-of-flight (TOF) with a resolution of 25 ns. The technique is reported to be able to discriminate between particles with only a 10% size difference. Attachments to the instrument also allow the investigation of sprayed aerosol droplets as well.

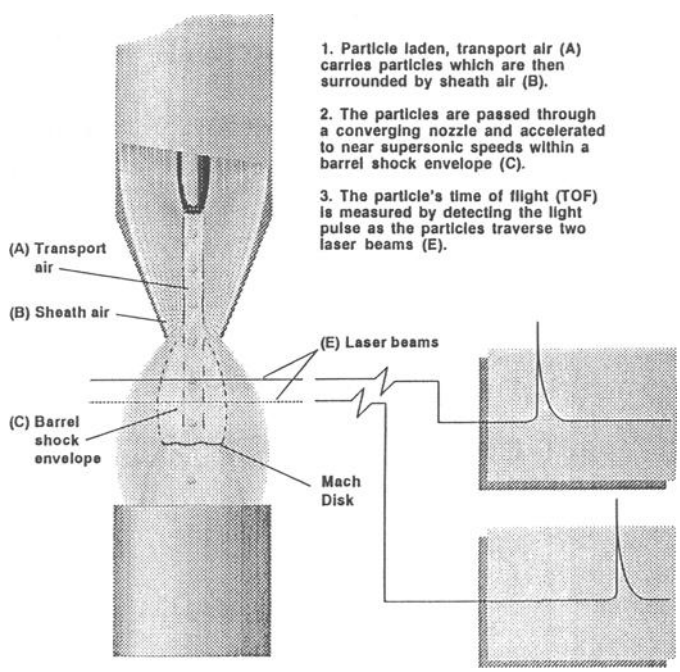

FIG. 12–Schematic of the aerosol beam generator and detection mechanism. (Courtesy of Amherst Process Instruments, Inc.)

Electrical Resistance

According to the Coulter principle [*32-34*], when a particle suspended in an electrically conductive liquid enters a constricted path between electrodes, it changes the pathway electrical resistance between the electrodes. This change produces a fluctuation in the applied voltage that, under proper conditions, is inversely proportional to the volume of the particle. When the dispersion is made to pass through a hole small enough to pass the particles one by one, the resultant series of voltage fluctuations may be electronically amplified, scaled, and counted.

A functional diagram is shown in Fig. 13. The beaker and tube contain the suspension. When the stopcock is opened, a controlled vacuum starts flow of the suspension from the beaker into the tube and also unbalances the mercury in the manometer. The stopcock is then closed, and the mercury siphon continues the flow of the suspension. Electrical contacts in the manometer start and stop the counting of the particles. The volume of the manometer tube between the contacts determines the volume of the specimen. This ranges from 0.02 to 5 mL. A fresh volume is drawn for each count. A typical count requires from 3 to 30 s, depending on the size of the hole and the volume between the contacts in the manometer. The Coulter counter was found to be useful by Princen et al. [*35*] for particle-size determination of emulsified oil systems.

COULTER PRINCIPLE

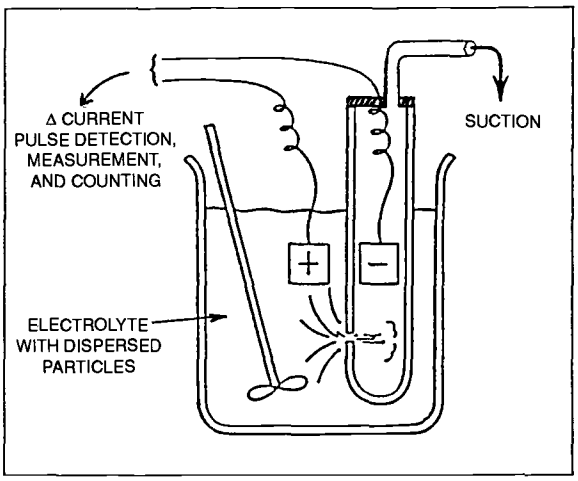

FIG. 13–The Coulter principle: A fluctuation in current flow occurs when a particle paretically blocks the small opening between the electrodes. The size of the particle is related to the amount of change in current flow.

The principle utilized to determine individual particle size is the electrical resistance of the particle as it is forced to pass through a small hole in a glass envelope through which an electrical potential exists.

Particle Size by Sieving

Sieving appears to be a simple means for separating pigments into fractions according to size. A significant addition to the physical laws governing the process has been made by Whitby [*36*], who investigated variables such as size distribution, mesh size, sieve loading, sieve motion, sieve material, and relative humidity. A comprehensive manual on sieving methods has been published by ASTM [*37*] and the W. S. Tyler Company [*38*].

For routine testing, sieves conforming to ASTM Specification for Wire-Cloth Sieves for Testing Purposes (E-11) are useful. These sieves are made of woven wire cloth, supported in frames of up to 12 in. (30 cm) in diameter. A skirt protrudes slightly below the sieve, allowing it to nest into the frame of the next size sieve. The openings in successive sieves progress from a base of 1.00 mm in the ratio of the square root of 2 to 1 (i.e., 1.414:1). When selecting a range of sieves from the series, it is recommended that each sieve, each alternate sieve, or each fourth sieve be taken. In this way, the basic ratio between successive sieves remains constant.

The U.S. Series of sieves is patterned after the Tyler Series that was introduced in 1910 [*38*]. In fact, the two are now interchangeable, the only difference between them being the designations of the individual sieves. Those in the U.S. Series are identified preferably by the sizes of the openings in millimeters or micrometers, while an alternate means is by a number approximately equal to the mesh. Tyler sieves are identified by mesh. Equivalent sieves are available in both series. The sieves proposed as standard by the International Standards Organization (ISO) correspond to many of the sieves in the U.S. Series. Especially useful for sizes under 100 μm is a sieve made by a photoengraving and electroplating process [*39*]. Such sieves are intended to serve mainly as primary reference standards [see ASTM Specification for Precision Electroformed Sieves (Square-Opening Series) (E-161)].

Hand Sieving

If the sieves are used singly, the following directions that appear in several ASTM test methods, among them D 546, Sieve Analysis of Mineral Filler for Road and Paving Materials, may be used.

> After transferring the specimen to the sieve, "Hold the sieve, with pan and cover attached, in one hand in a slightly inclined position so that the specimen will be well distributed over the sieve, and at the same time gently strike the side about 150 times per minute against the palm of the hand on the upstroke. Turn the sieve every 25 strokes about one sixth of a revolution in the same direction each time. Continue the operation until not more than 0.05 g passes through the sieve in 1 minute of continuous sieving."

Sources of error in hand sieving are operator fatigue and casual attention to directions. While machine sieving eliminates these errors, some specifications still require hand sieving unless it can be shown that machine sieving gives the same results.

Machine Sieving

Machine sieving has the advantages of uniformity of treatment and saving time since the operator is free to perform other tasks while the machine is working. Several types of machines are available. The conventional ones impart an oscillating or rotating motion (or both) to the sieve, with regular tapping. None appear to reproduce the motions of hand sieving.

Ro-Tap Sieve Shaker—This machine [*37*] (Fig. 14) manipulates a series of sieves, graduated with respect to mesh size, so as to permit separation of a specimen into sizes. As the name implies, the sieves are given a special rotary motion accompanied at regular intervals by a tap. The nature of the specimen dictates the size of the sieve openings and the timing cycle. This type of machine is recommended in ASTM Test Method for Particle Size or Screen Analysis at No. 4 Sieve (4.75-mm) and Finer for Metal Bearing Ores and Related Materials (E-276).

Sonic Sifter—In the Allen-Bradley sonic sifter [*40*] (Fig. 15), the sieves are stationary, and agitation is imparted to the particles by an oscillating column of air. Sieve wear and particle attrition are said to be minimal. The sonic sifter consists of a sieving chamber, a diaphragm at the top vibrating at 60 Hz, and a motor with the necessary controls. The amplitude of vibration is adjustable to the nature of the specimen. A determination may require no more than 60-s operation of the machine.

To make an analysis, the sieves, in descending order from top to bottom, are assembled in the holder, and the specimen (not more than 30 g or 10 mL) is transferred to the top sieve. The cone, coupling unit, and the diaphragm are added, and the stack is latched within the chamber. The complete assembly is positioned in the machine, the power level and the time interval are set, and the operation is started. After the sift

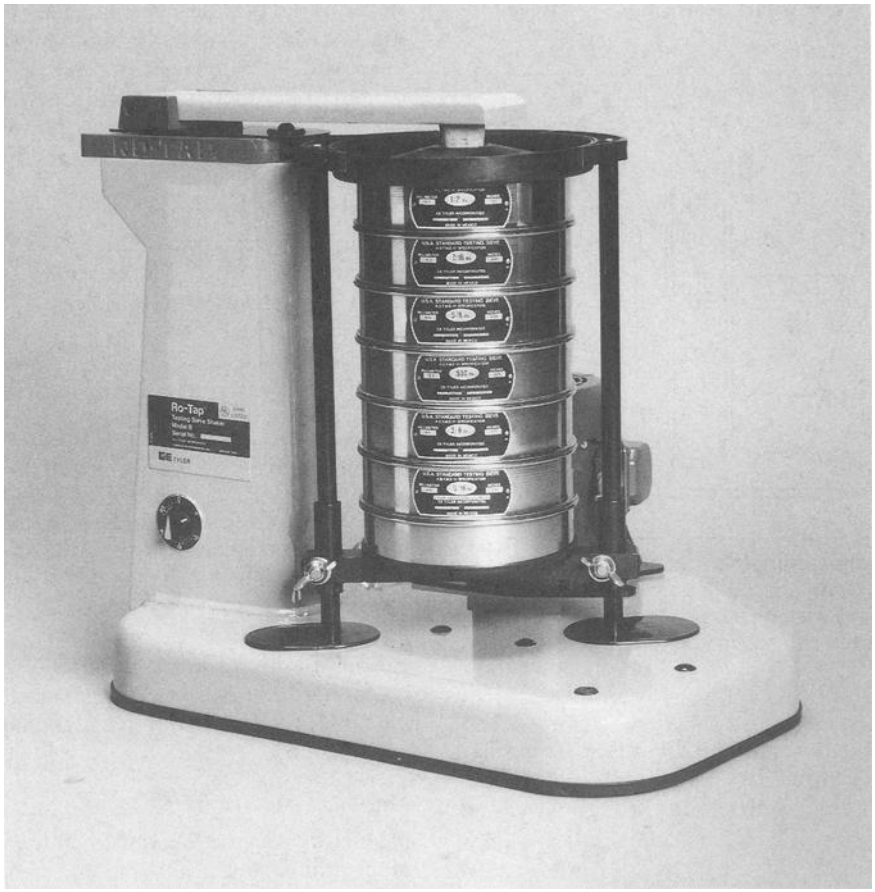

FIG. 14–Ro-tap resting sieve shaker. (Courtesy of W. S. Tyler Co.)

interval, the stack is removed and opened, and the fractions are weighed and computed in the usual manner.

Air-Jet Sieve—A cross section of the air-jet sieve [*41*] is shown in Fig. 16. A specimen is seen being processed through the component parts. The complete operational unit includes a vacuum cleaner. The hose of the vacuum cleaner is fastened to the outlet at the lower left. The specimen is placed on the sieve, and the air, which comes from the rotating split nozzle on its way to the vacuum cleaner, agitates the specimen. The finer particles pass the sieve and are collected in a tared filter bag; the coarse particles are retained on the sieve. Sieves with different meshes are used for additional fractionations, and the procedure is repeated. New tared filter bags are used for each fractionation if retention of the fractions is desired. Air velocity must be regulated, and a manometer is used to indicate the vacuum in the housing.

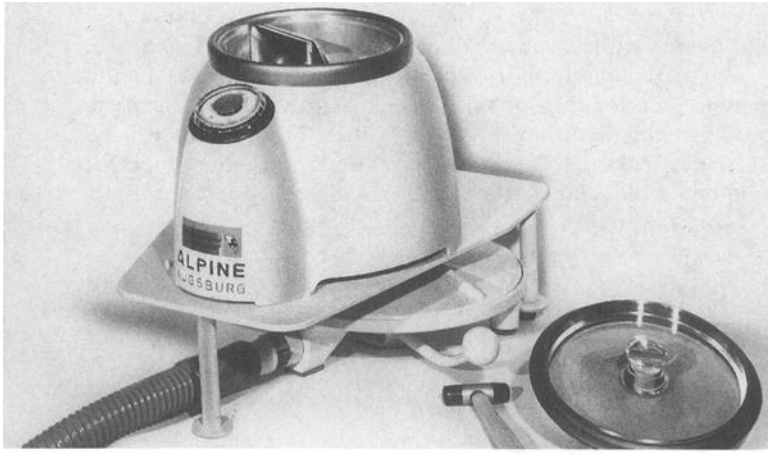
Direct Microscopic Measurement

Microscopes, both optical and electron as well as automated image analyzers, are used to measure particle size directly. Optical techniques suffer somewhat from an inability to focus on the "edge" of a particle at very high magnifications due to a depth of field problem. The lower limit is set by its resolving power and the upper limit by its depth of focus. The microscope is especially useful for measurement of plate-like and needle-shape particles that do not obey Stokes' law, on which the sedimentation methods are based. Disadvantages of the method are that it is slow and laborious. Hence, it is used chiefly for the calibration of the more rapid relative methods. ASTM Practice for Particle-Size Analysis of Particu-



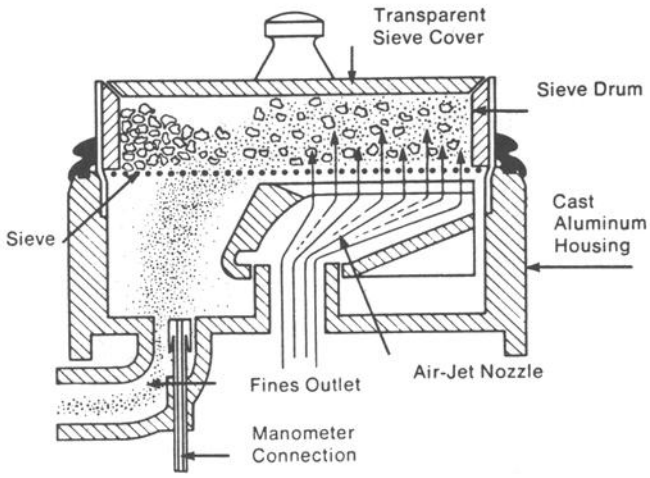


FIG. 16–Alpine air-jet sieve. (Courtesy of Gilson, Inc.)

late Substances in the Range of 0.2 to 75 μm by Optical Microscopy (E 20) and a paper by Loveland [*42*] are good references. Dark field illumination can use the detecting power of the microscope rather than the resolving power for sizes below the resolving power of the optical microscope.

Green [*43*] was the first investigator to systematize the use of the microscope for direct measurement. He dispersed the pigment in a medium on a microscope slide, photographed the dispersion at a known magnification, and projected the image on a screen to increase the magnification for measurement. Dunn [*44*] bypassed the photomicrograph by projecting the image of the particles directly from the slide on the screen.

Ideally, the pigment should be dispersed in the medium in which it is used, but this is rarely done. Green used turpentine, Allen [*45*] recommended a viscous vehicle, and Eide [*46*] used fused resins. Gehman and Morris [*47*] milled the pigment in rubber, dissolved the mix in a solvent, and applied the suspension to the slide.

Microscopes equipped with view-through linear scales, circles or ellipses in graduated sizes, may be used as a direct measurement method [*42*]. The comparison scale may be a micrometer eyepiece, an eyepiece reticle, or a scale engraved on the microscope side.

The use of the electron microscope for particle characterization is now a routine practice. The resolving power is many times that of the light microscope and may be used in scanning as well as transmission mode. With state-of-the-art surface analysis tools such as energy dispersive X-ray (EDX) built into the scanning electron microscope (SEM) equipment, elemental analysis of a single-pigment particle within the coating matrix can be done conveniently while the coating sample is in the instrument.

Array Method Using Optical Microscope

The array method of particle sizing lends itself to systems of monodispersed spheres, as in Fig. 17 (from Duke [*48*]). These are highly uniform with respect to diameter. When placed on a flat plate, the spheres tend to align themselves into hexagonal arrays. These are characterized by straight rows of the particles. Because of this, the rows can be measured, and the diameter of the particles may be derived by dividing by the number in the row.

Transmission Electron Microscopy (TEM)

TEM is useful for the measurement of latex microspheres of 200 nm and larger [*49,50*]. The procedure usually utilizes the magnification factor of the microscope in the size determination from photomicrographs. Because this factor is not always dependable, photographs are sometimes made against a replica diffraction grating of known spacing. Figure 18 shows 100-nm latex microspheres on a 2160-line/mm grating. Sources of error include uncertainty in the accuracy of the line spacing, the roughness of the lines, and the line thickness relative to the size of the particles. Duke [*51*] has used an internal standard of NIST traceable materials, as shown in Fig. 19, and reports accurate sizing to as small as 50 nm.

Particle Size by Sedimentation

The use of the principle that a particle will "fall" through a liquid medium at a rate dependent on its diameter (as well as other variables) is a popular sizing technique. By this

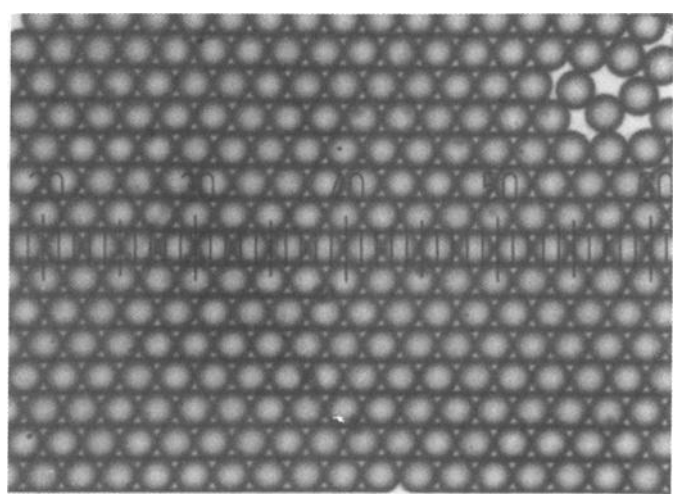

FIG. 17–Microphotograph of 9.87-μm spheres in arrays. (Courtesy of Stan Duke.)

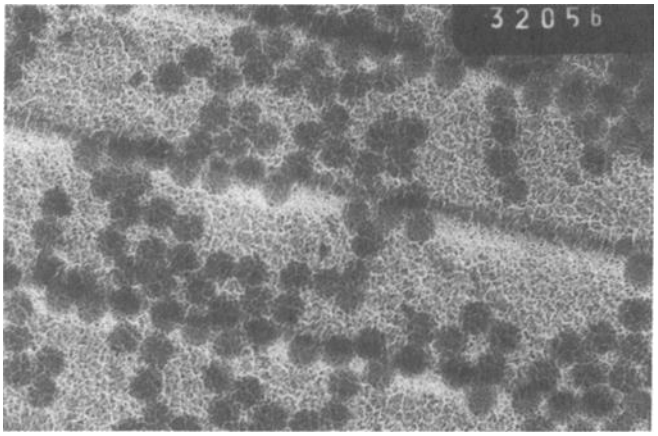

FIG. 18–Microphotograph of 100-nm latex spheres against a 2160-line/mm grating. (Courtesy of Stan Duke.)

method, the pigment particles are dispersed in a liquid and then allowed to settle under the influence of gravity or centrifugal force. The rate of particle movement through the liquid then gives the particle diameter. Among the methods for measuring the rate of particle movement in a fluid are: (1) collecting the particles on a balance pan suspended in the dispersion, (2) analyzing specimens withdrawn with a pipet from different levels, (3) determining density with hydrometers or "divers," and (4) measuring attenuated light transmission through the dispersion. With low-cost computers and extremely stable rotational control provided by advanced electronic feedback circuits, the sedimentation methods using centrifugal acceleration have become popular.

A prerequisite to analysis by the sedimentation process is that the particles must be at their primary size. Vigorous stirring, usually with a dispersant agent or surfactant, both with and without ultrasonics, is often necessary. Agents to prevent flocculation may be required, and adjustments in solution pH may be necessary to stabilize the system. These additives must be evaluated at different levels to determine impact on the derived values.

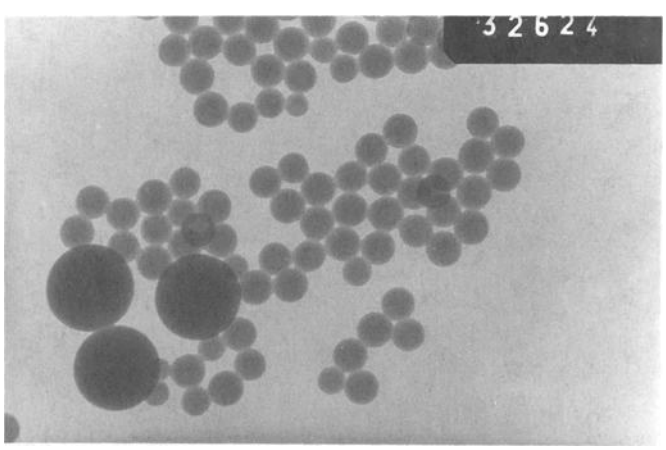

FIG. 19–The use of an internal standard of known size. (Courtesy of Stan Duke.)

Stokes' Law

For essentially spherical particles, one assumes that Stokes' law will be followed when particles are falling in a fluid under some accelerating potential such as gravity or centrifugal force. This assumption requires that the particles will fall freely under laminar flow conditions [*52*]. For a perfect sphere, the diameter can be calculated simply from the Stokes' equation.

$$D = \left[\frac{18\,\mu v}{g(\rho_p - \rho)}\right]^{1/2} \tag{8}$$

where

D = diameter of sphere,
μ = medium viscosity,
v = velocity of fall under influence of gravity,
g = gravitational constant,
ρ_p = sphere density, and
ρ = medium density.

Most often, the particles are not exactly spherical. Because of this, it is difficult to relate a particle's dimensions directly to the observed settling rate. The usual procedure is to use Stokes' equation to determine the values for d from the sedimentation distance and its corresponding time. The value so determined is then the "Stokes' diameter" of the particle. The definition then becomes "the diameter of a sphere that has the same density and free falling velocity (in a given fluid) as the particle being investigated (within the range of Stokes' law)."

This practice avoids the problem of variations in free fall velocities caused by shapes which differ from being a sphere. The assumption holds and permits useful comparisons of the size distributions when similar types of materials are evaluated. The size distribution of particles of different shapes may be compared provided that the phenomenon being studied is dependent on its behavior in the fluid.

While the concept of the Stokes' diameter is useful, it is necessary to appreciate its limitations. One should not equate the Stokes' diameter to a sphere of equal volume or other related quantity. Two types of errors may be introduced. In the first case, errors arise when the particle's movements depart from Stokes' law and, in the second case, errors are introduced by the experimental technique itself.

Departure from Stokes' law can occur when flow conditions are not met. Stokes' equation is valid under laminar flow only. Consequently, there is an upper limit to the size of a particle that can be evaluated in a given liquid. Large particles can experience too high a velocity in the liquid and create turbulent flow. Vortexes in the liquid in the vicinity of other particles also introduce errors. Laminar flow is determined by the Reynolds number experienced by the particle/fluid system at the fall rate. The Reynolds number, Re, is defined as

$$Re = \frac{vd\rho}{\eta} \tag{9}$$

where v is the velocity in the fluid, d is the diameter in centimeters, ρ is density of the particle in grams per milliliter, and η is the viscosity in poise. According to B.S. 3406 [*53*], the value of Re cannot exceed 0.2 if the introduced error from Stokes' law deviation is to be less than 5%. This would imply

that the upper limit of particle size would depend on both the viscosity and density of the fluid. For water, this value would place an upper limit of about 60 μm. However, as might be anticipated from the Reynolds equation, this limit may be stretched somewhat when using either more dense or more viscous liquid media than water.

Another problem arises when the concentration of particles is too great. The Stokes' equation assumes single particles having no influence from the wall of the vessel or other particles in close proximity. Wall effects are minimized by employing properly sized vessels. While some investigators have recommended that the volume concentration should be kept less than 0.05%, others recommend concentrations of up to about 0.5 to 1% by volume. Certain investigators feel that this compromise introduces systematic errors and renders the method inappropriate as an absolute measure, although it is suitable as a routine control method. The flocculating nature of the powder in the test fluid will impact the maximum concentration that can be used. B.S. 3406 recommends a concentration of 1% by volume, although it cautions that, under certain circumstances, a small interference may occur. Because of the potential introduction of systematic errors at higher concentrations, efforts to refine the technique so that reduced concentrations are used are underway. Precision with differentials no more than 4% are usually expected.

Another problem that must be addressed is the temperature stability of the liquid. Not only is there a change in the liquid viscosity, but thermally produced convection currents grossly impact the sedimentation process. Because of the difficulty in maintaining thermostatic control over the long periods required for gravitational settling, there is usually a lower particle-size limit of about 2 μm when water is used as the suspending liquid.

Gravity Sedimentation

The analysis of particles by sedimentation is possible because of Stokes' law, which states that the time of fall of a particle through a viscous medium is proportional to the particle's density (the difference between it and the medium) and its diameter. Of course, if the density of the medium were greater than the particle, the particle would float. Another requirement is that all of the particles must have a common density. This rules out mixtures of different minerals and pigments having different densities since they cannot be determined together.

Because of the time required for sedimentation to occur, the simple gravimetric method and the photometric method appear to be limited to pigments of sizes above 0.5 to 1.0 μm. Cadle [*53.1*] and Orr and Dallavalle [*54*] have reviewed the many variations of the method. Gravity settling was first proposed by Oden [*55,56*]. Calbeck and Harner [*57*] were among the first to use the technique for paint pigments; Jacobsen and Sullivan [*58*] brought the method to a higher degree of refinement by using an analytical balance with one of the pans replaced with a cup submerged in the suspension.

Hydrometer Method—The density of a dispersion is proportional to the concentration of the dispersed material, and methods for particle-size analysis based on the use of the hydrometer have been developed. One such method is ASTM Method for Particle-Size Analysis of Soils (D 422). Another, developed in large part by Bauer [*59*], is TAPPI Method T649sm, Determination of Particle Size of Clay. Included in the method is a nomograph by Casagrande [*60*] to aid in the calculations. The same nomograph is found in Test Method for Particle Size Distribution by Hydrometer of the Common White Extender Pigments (D 3360) [*61*].

Radioactivity Method—Connor and Hardwick [*62*] report on this method for determining the height of the sedimentation. The radioactivity is either induced in the specimen or is used as an external probe. The technique avoids disturbing the suspension by periodic sampling and can be used with both gravity and centrifugal sedimentation.

Centrifugal Sedimentation

The centrifuge is used to provide an accelerating force for sedimentation analysis. Configurations exist using rotating disks with "see-through" ports as well as holders of small see-through cells.

Disk Centrifuge—The technique for the disk centrifuge was developed by Atherton et al. [*63*]. The apparatus might be considered to be a direct descendant of the single cell centrifuge of Donoghue [*64*] and the scratch start technique of Marshall [*65*]. The range is from 0.01 to 0.5 μm.

The apparatus consists of a centrifuge unit, a sampling unit, and an electronic control unit [*66*]. The rotor of the centrifuge is a cell (hollow disk) of plastic or glass that rotates on a horizontal axis (Fig. 20). The back wall is attached to the shaft of the rotor. The front wall has a hole in the middle that serves as an access port. The inside diameter of the standard cell is 10 cm, and the width is 1 cm. In operation, the cell takes liquid up to a minimum radius of 2.3 cm. The speed ranges from 500 to 8000 rpm.

The sampling unit (Fig. 21) consists of a probe connected to collection flask and a clock motor. The probe is an L-shape thin-wall steel tube arranged to rotate about the axis of one arm. The other arm terminates in a sharp bevel for scooping up the contents of the cell in a manner analogous to that of an inside cutter in a lathe. The center of rotation of the probe lies below the center of the rotor.

To make a test, an appropriate volume of "spin fluid," typically a 4% sucrose solution, is transferred to the rotating cell. After swirling stops (20 to 30 s), the specimen—usually 0.5 mL of a 0.5% dispersion—is expelled from a syringe against the back wall near the center of rotation. The specimen flows outward over the wall unit it reaches the free surface of the spin fluid, where it forms a band about 1 mm thick. The spin fluid and the dispersion do not mix because of the higher density of the former. Thus, zero time for the measurement is defined rather accurately.

After the desired time, spin fluid is withdrawn from the cell with the probe, which is driven by a clock motor at 1 rpm. With the pickup end of the probe in the 12 o'clock position, the motor is started automatically. All but 5 mL of the spin fluid is removed for measurement of the undersized fraction of the dispersed powder.

The development of detector systems must consider the action on a transmitted light beam. Light-scattering theory dictates that when light of intensity I_0 attempts to pass through a dilute suspension (i.e., no multiple scattering) of particles, it is lost or extinguished to an extent that I_t makes it

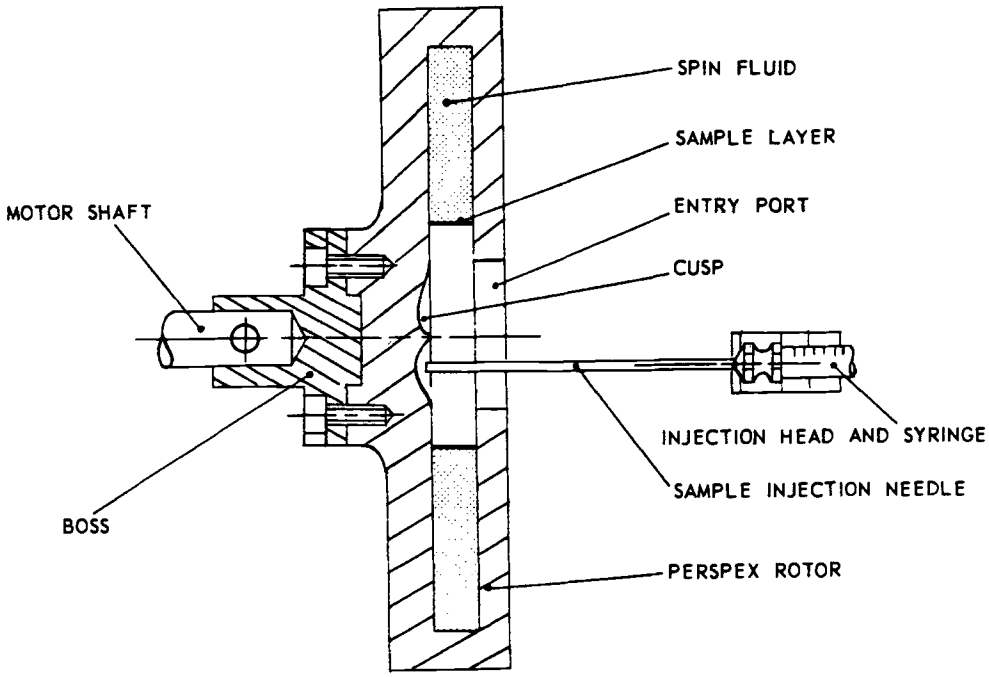

FIG. 20–Diagram illustrating the principle of the disk centrifuge. (Courtesy of Joyce, Loebl & Company, Ltd.)

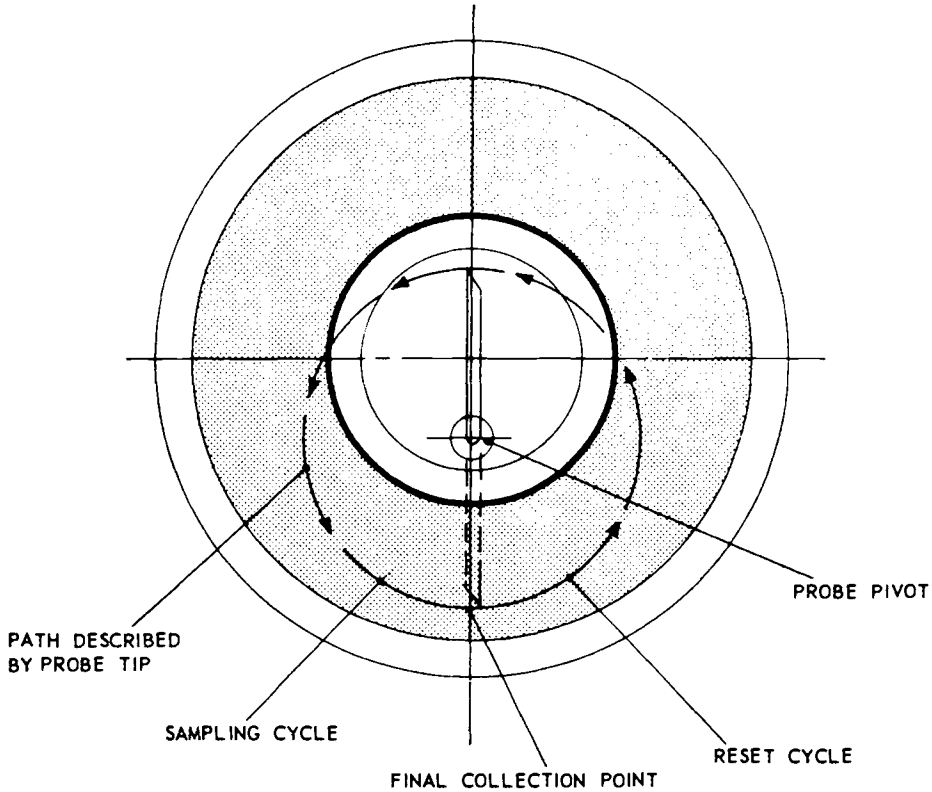

FIG. 21–Relationship of disk and probe of disk centrifuge sampling. (Courtesy of Joyce, Loebl & Company, Ltd.)

through. Mathematically [67,68], the transmitted light is given by

$$I_t = I_0 \exp(-\alpha_{ext} L) \quad (10)$$

where L is the length through the suspension, and α_{ext} is the attenuation coefficient (turbidity). The value of α_{ext} is related to the number concentration of particles, N per unit volume, by

$$\alpha_{ext} = NC_{ext} \quad (11)$$

where C_{ext} is the extinction cross section of the particles. The extinction efficiency of a particle of cross-sectional Area A is conveniently expressed as

$$A = C_{ext}/Q_{ext} \quad (12)$$

This yields the relationship

$$\alpha_{ext} = \frac{N\pi d^2 Q_{ext}}{4} \quad (13)$$

Photo extinction detectors on modern turbidity instruments essentially determine α_{ext}. The internal calculation of Q_{ext} requires knowledge of the particle refractive index, size, shape, orientation, state of polarization, and wavelength of the scattered light as well as the refractive index of the suspending liquid. Using Mie theory [67–69], size may be deduced. Oppenheimer [70] has pointed out that a source of potential error is that the refractive index of the suspending liquid and particles must be known for each wavelength.

Rotating Cell Holder Centrifuge—Real time monitoring is provided on some instruments and is advantageous when irregular measurements force an abort. One such instrument can perform centrifugal as well as gravity analysis using the same on-board computers. With ten different rotor speeds switchable from 300 to 10 000 rpm, an accelerating potential of up to 9000 g is available. Particles as small as 0.01 μm are reported to be measurable.

The instrument uses two small, transparent rectangular cells (Fig. 22) mounted opposite each other on the balanced rotor. While they counterbalance each other, one serves as a reference for the suspension liquid, and the other holds the particle suspension system under analysis. Three photocells in the top monitor three opposite light-emitting diodes (LED) on the back side of the rotor. This allows real-time monitoring of the reference cell, the sample cell, and the rotor speed (Fig. 23). Data are displayed in real time on a built-in CRT as well as printed out on tape after the analysis for a permanent record. Graphs are presented indicating the absorbance versus time, frequency distribution, and cumulative distribution (either percent undersize or percent oversize).

Light Attenuation and Scattering Techniques

Spectrophotometric Techniques

Gamble and Barnett [71] developed a method for measuring particle-size distribution by the scattering of light in the near infrared. The pigment is dispersed in low concentration and placed in a transmission cell for spectrophotometric measurement. From the shape of the spectrophotometric curve, the relative size and size distribution characteristics of an unknown pigment are obtained in terms of calibrated samples (Fig. 24).

Bailey [72] also developed a spectral transmission method using infrared wavelengths from 0.4 to 2 μm. The spectrophotometric curve was related to size by graphic comparison with specimens of known sizes.

Atherton and Peters [73] measured light scattering by polydispersed system of spherical particles. The size distribution curves for the materials compared favorably with direct measurement with the electron microscope.

Leobel [74] used a spectrophotometer to obtain the effect of wavelength on turbidity in the determination of the size of latex particles. The sizes of particles used for calibration were determined from electron micrographs.

Light-Scattering Techniques

When solid particles pass through a light beam, the light will interact with the particles in one or more ways. It can either be reflected, refracted, diffracted, or adsorbed and reradiated. This is shown schematically in Fig. 25. The scattered radiation will present a pattern that is dependent on the shape and size distribution of the particles. By evaluating the scattered radiation detected at different locations relative to the beam direction and in different positions, much can be learned about the scattering media. Figure 26 depicts some of the angular intensities of scattered light produced by particles of various size. With low-cost computers and stable de-

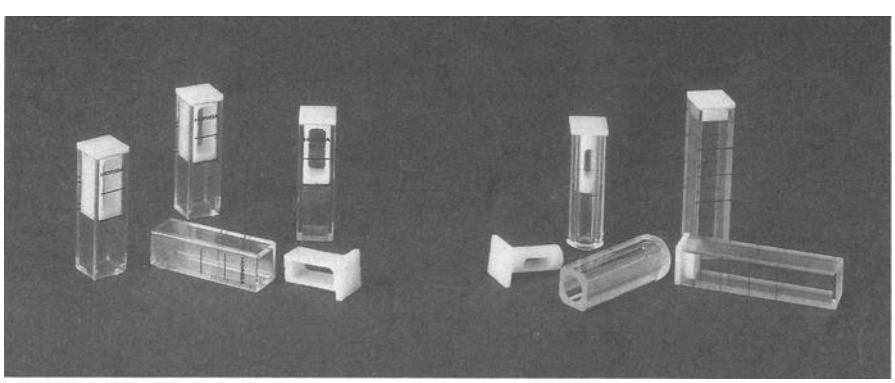

FIG. 22–Reference cells used in a centrifuge. (Courtesy of Horbia Instruments, Inc.)

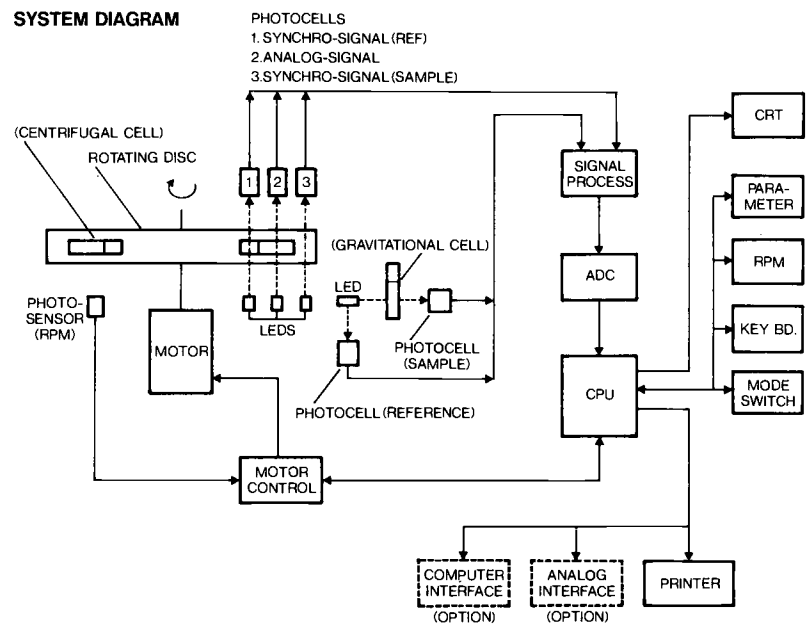

The CAPA-700 system is comprised of an optical system, a centrifuge, computation circuitry and input/output functions. The rotating disc in the horizontally mounted centrifuge is connected directly to the motor to minimize gravitational effects, and electronic control keeps the rotational speed stable at the set value. The CPU monitors and controls automatic checking for fluctuations in rotational speed, computation formulae and deterioration of the light source and detector, assuring precision data at all times. In the optical system, a reference cell guarantees both optical and mechanical balance for each revolution, which, after CPU processing, gives even higher precision particle size distribution analysis.

FIG. 23–A modern instrument for determining particle size in real time.

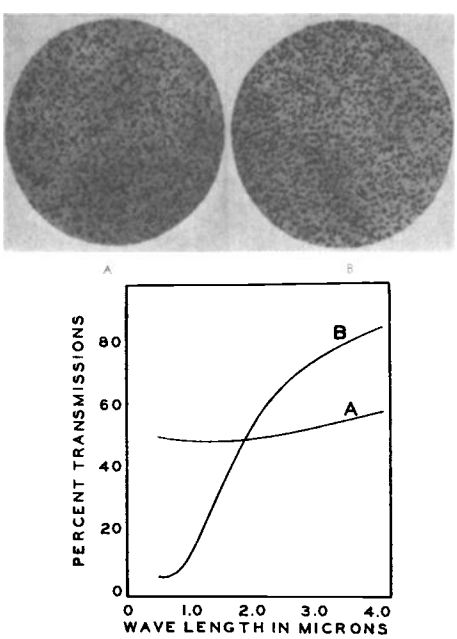

FIG. 24–Particle size may be determined from the scattering of radiation in the near infrared region of the spectrum.

tectors, instruments have been developed that can monitor this scattered radiation, giving fast and reliable data.

Angular dependence techniques, which include detection and manipulation of signals from front (reflection) as well as side and rear (diffraction), have been integrated into a single instrument. Angular-dependence, light-scattering techniques have been widely studied for information concerning the sizes of both pigmentary and nonpigmentary particles. In the latter class, polymeric organic materials from molecular to latex sizes have been included. Debye and Bueche [*75*] described how to characterize the optical inhomogeneities related to size from information concerning the way a system scatters light.

Angular-dependence techniques include the work of Brice et al. [*76*], who designed a photoelectric photometer for measurement of molecular weight by applying the Debye theory.

Aughey and Baum [*77*] note that particles in the size range of large molecules produce variations in the intensity of light scattered at large angles to the illuminating beam. Progressively larger particles produce significant variation in the light scattered at small angles. The light source is a well-defined monochromatic beam. The cell containing the dispersion is stationary, and the photoelectric tube travels around the cell in an arc that covered a useful range from 0.05 to 140°. Scattered light reaches the tube through a small aper-

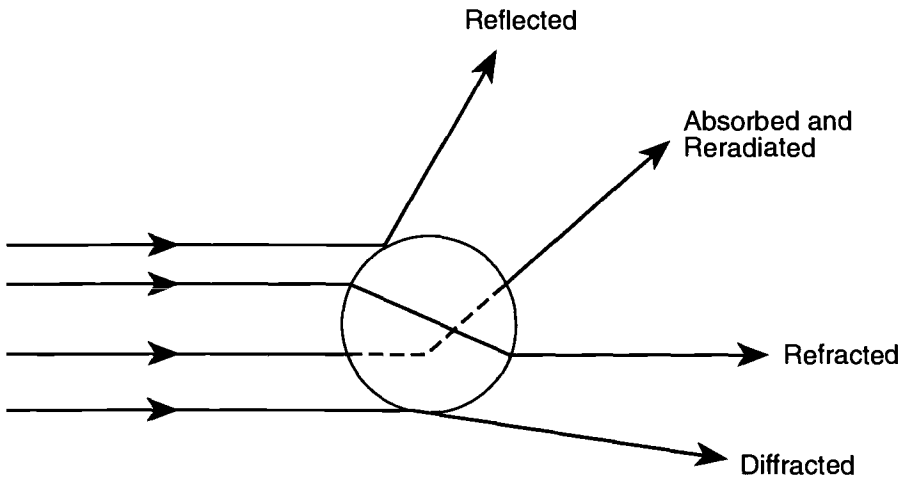

FIG. 25–Possible interactions when light strikes a particle.

ture in the housing for the tube. The radii of the optical inhomogeneities range from 0.1 to 100 μm. Modern diode array detectors are now available to do similar tasks without the movement.

Diffraction of Laser Light—Instruments using diffraction of single-wave-length laser light have been made possible by the development of low-cost, highly stable lasers and diode array detector technology. By fluidizing the particles in a stream of air, they are directed through a cell being illuminated by a laser source. The He-Ne laser, emitting a coherent beam of 632.8-nm wavelength is often used. To increase the cross-sectional area of the beam, expanders are often employed (Fig. 27).

The diffraction pattern that is seen by the detector is a pattern of rings varying in darkness depending on the size distribution of the passing particles. On-board computers use both the Fraunhofer diffraction and Mie scattering theories to calculate the particle-size distribution of the sample. These methods allow the determination of size distribution based on the intensity distribution of the diffracted laser beam. Since the intensity pattern is a function of the actual particle size, mixtures of particles having different densities may be measured together, unlike those relying on Stokes' law. The instrument is reported to address 0.1 to 200-μm particles.

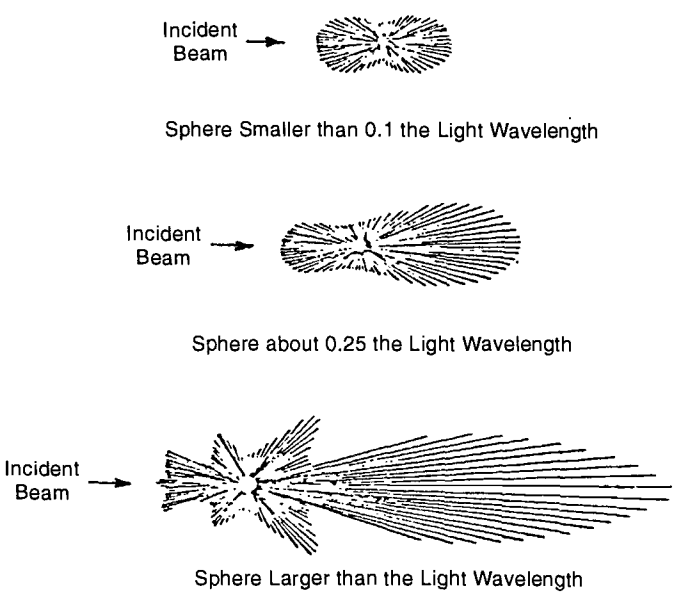

FIG. 26–Angular intensity of scattered light after striking a particle.

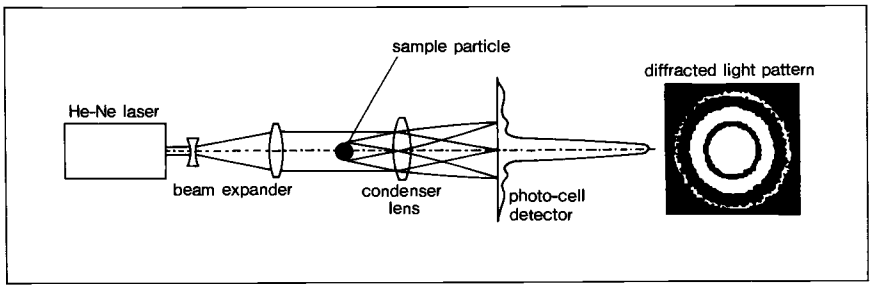
Total Light Scattering—Instruments capable of monitoring light from all sides can effectively measure particles even smaller than the usual limit of 0.1 μm. This limit is imposed because of the physics relating the wavelength of the incident radiation and the interacting particles. By taking advantage of a set of detectors located strategically around the scattering cell, data relating to even very small particles less than 0.1 μm are determined. As the size of the particle decreases, the intensity of the scattered light obscures critical differences in the angular distribution. In practice, this difficulty in treatment of data leads to the so-called laser-diffraction measurement barrier.

Since there is an increase in both the side and rear scattering with very small particles, it is possible to take advantage of the phenomenon. Figure 28 is an instrument diagram with an arrangement of detectors that allow a single instrument to measure a broad range of sizes. Light irradiating the particles is scattered at various angles. For relatively large particles, light is scattered in the forward direction, while, for smaller particles, the light tends to be scattered in all directions. By arranging a lens system and manipulating data from the detectors, the particle-size distribution is calculated from the Mie theory. Since the size of the particles measured is a function of the wavelength of the impinging radiation, the instrument uses a beam of filtered blue light to expand the range.

X-Ray Scattering

The Debye-Scherrer small angle X-ray scattering technique for observing interference effects related to particle size is well known [*78*]. Some generalizations on the use of the technique were addressed by Debye [*79*].

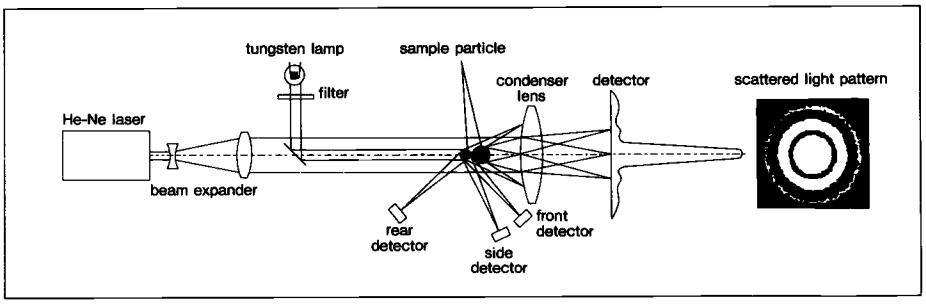
Yudowitch [*80*] and Danielson et al. [*81*] both employed the "diffraction peak" procedure for the determination of latex particle size. For control they used a latex whose size had been determined under the electron microscope.



Principle of Operation

The He-Ne laser emits a beam of 632.8 nm whose flux is enlarged by a beam expander and radiated upon the particles suspended in the liquid. After it has been diffracted and dispersed by the particles, the laser beam passes through the condenser lens and its image is formed at the photo-cell detector located at the focal point of the lens.

The diffraction pattern that appears at the detector is a pattern of light and dark concentric rings that corresponds to the particle size distribution of the sample. Now, using both of the Fraunhofer diffraction and Mie scattering theories, the intensity values are used to calculate the particle size distribution of the sample.



Here is how the LA-900 works.

Light irradiating the particles is scattered at various angles. If the particles are comparatively large, this scattering tends to be concentrated in a forward direction. As the size of the particles decreases, the light is scattered in all directions. Therefore, to measure larger particles, data from a small angle of scatter is required; to measure smaller particles, a larger angle of scatter is required.

On the LA-900, to measure the distribution of low angle scattered light, a condenser lens is used with an array detector at the focal point of the lens. To measure large angle scattered light, detectors are used at the front and rear of the sample chamber. From angular measurement of the scattered light by all of these detectors, the particle distribution is calculated from Mie theory.

It is also true that as the wavelength of the light becomes shorter, so does the measurement size of the particles. Therefore the LA-900 uses a He-Ne laser beam and a red light beam and a blue light beam obtained by filtering a tungsten lamp to expand the measurable range.

FIG. 27–Schematic layout for the large-particle system. (Courtesy of Horbia Instruments, Inc.)

Drawdown Techniques for Texture and Oversize

During the manufacturing of paints and coatings, there is a need for rapid, "on-the-floor" testing to determine whether a dispersion has reached its maximum grind. The "grind" gages were developed to provide quick, on-the-spot answers. Some of the tests could be done in the factory at the disperser during the grinding stage of production. Actually, during the production of paints and pigmented coatings, the pigments are not ground but are only wet out and dispersed to their "primary" size. This primary size is the smallest possible size supplied from the producer.

Thin-Film Drawdown for Oversize Particles

This test [*82*] is suited particularly for detecting oversize particles that adversely affect the gloss of high-gloss industrial enamels. A 2-mL wet film of the enamel is spread on a

Flow Schematics

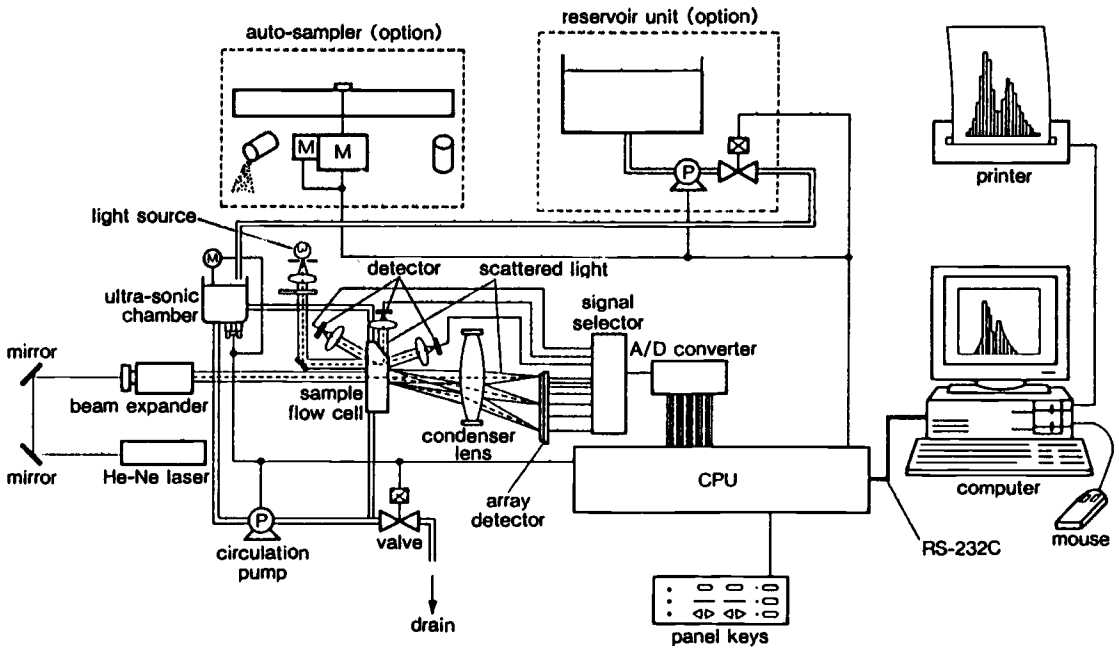


FIG. 28–Schematic layout for a system measuring both large and small particles. (Courtesy of Horbia Instruments, Inc.)

glass plate with a Bird applicator blade. Inspection of the film is best made in a dimly lit room with the operator facing a light source such as a window or under a florescent light with a grid that can be reflected from the wet paint sample. With the eye focused on the silhouetted image of the window sash or the reflected pattern from the light or ceiling, extremely fine particles may be detected and compared with a visual standard. They appear as a roughness to the wet surface.

A variation of this approach is to illuminate the specimen at grazing incidence with a spotlight and view the film through a magnifier parallel to the specimen. Still another version is the use of wedge-shape or step-wise multithickness films.

Fineness-of-Dispersion Gages

Drawdown tests for the detection of oversize particles led to development of fineness-of-dispersion gages, or, as first called, fineness-of-grind gages. The gage is a steel block in which is cut a wedge-shape channel, tapering usually from 4 mils at the deep end to zero at the other end, though other depths and different widths and lengths of the channel are available. Some gages have twin channels. An excess of the sample is placed in the deep end of the channel, and the excess is drawn to the shallow end with a scraper. At some point along the channel, coarse particles or agglomerates become visible. The results are interpreted by reference to standard reference patterns. The addition of slow-evaporating solvents may be required to thin down the system to allow more time for reading the gage without experiencing volume loss by evaporation.

St. Louis Gage—This [*83*], the first of the dispersion gages, was designed to facilitate the use of the North Standards. The channel is 2 in. (51 cm) long and 0.005 in. (0.13 mm) deep at the deep end. The sample and the selected North Standard are placed side by side in the deep end, drawn by a scraper toward the shallow end, and compared.

Hegman Gage—The Hegman gage [*84,85*] (Fig. 29) made the North standards and the St. Louis gage obsolete. It is essentially a St. Louis gage with the addition of a scale to show the depth of the channel or the distance from the deep end. Instead of evaluating the dispersion in terms of the North standards, the distance from the deep end is reported. The finer the dispersion, the greater the distance. This is the reverse of the North standards, where the finer the dispersion, the lower is the number of the standard.

ASTM Gage—The gage specified in ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems (D 1210) is almost identical to the Hegman. The steel block (Fig. 30) is about 180 mm long, 63.35 mm wide, and 12.7 mm thick. The channel is 100 μm deep at the heel. The gage is calibrated according to depth in steps of 10 μm along one edge and to the corresponding nearest 0.1 mil along the other. The dimensions of the scraper are shown in the diagram.

Experience has shown that the speed of drawdowns and the angle at which the scraper is held have no important effect on the results. However, the time lapse between the drawdown and reading, as well as operator technique, are important [*86*]. Readings should be made within 10 s after completion of the drawdown, especially for dispersions with a rating of seven or better due to the volume loss from solvent evaporation. Good practice suggests three drawdowns using

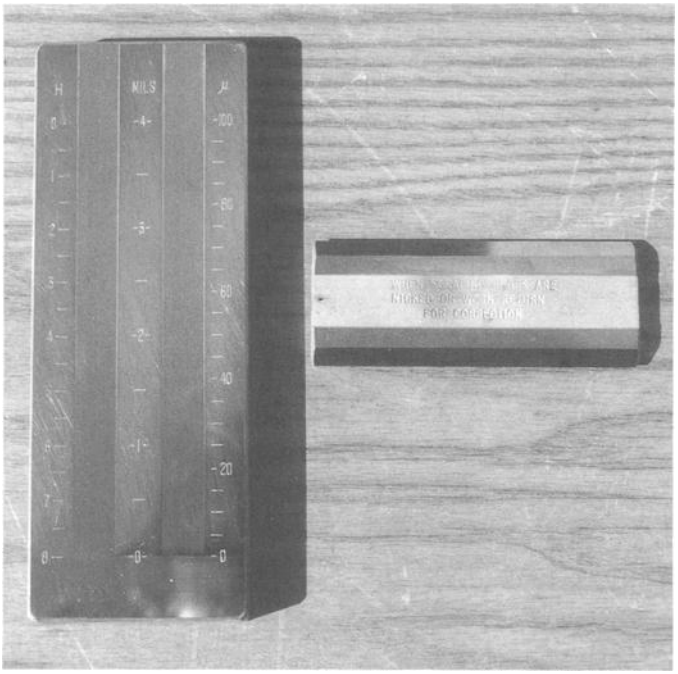

FIG. 29–Hegman fineness-of-dispersion gage. (Compliments of Lynn Shirey.)

fresh material each time. The first drawdown allows accommodation to the light source and a rough estimate of the dispersion pattern and the end point. Subsequent readings may then be made within 3 or 4 s. ASTM directs viewing the drawdown with the line of vision at a right angle to the long dimension of the channel and at an angle between 20 and 30° with the face of the gage in a light that renders the pattern readily visible. Diffuse subdued light is preferred.

Elimination of operator variance is aided by the use of six standard patterns. Figure 31 illustrates reading of the end points, and the scales show the depth of the channel. This scale appears to have some advantage over both the North and the Hegman scales as it is related directly to the dimensions of the oversize particles. Other scales in use include the FSCT (Federation of Societies for Coatings Technology) scale, which divides the distance into ten parts.

Constant Depth Gage—The channels in this gage are of constant depth rather than tapered as in the gages previously described. The gage most often used has four channels, 1/2 in. (1.3 cm) wide and 6 in. (15 cm) long, having depths of 0.002 (0.005 cm), 0.0015 (0.0038 cm), 0.0010 (0.0025 cm), and 0.0005 in. (0.004 cm) equivalent to Hegman values of 4, 5, 6, and 7, respectively. Other depths can be supplied. The advantage of this type of gage is the long path available for inspection, a condition that should minimize the influence of bubbles and foreign matter on the ratings.

NPIRI Grindometer—Printing ink films are much thinner than those of paints or coatings. Relatively fine particles in the latter would be considered relatively coarse in the ink. Because of this, the printing ink range is addressed with a gage designed by the National Printing Ink Research Institute (NPIRI) called the Grindometer [*87,88*]. The channel of this gage is only 0.001 in. deep at the deep end, is 1 in. (2.54 cm) wide, and the scale is graduated in steps of 0.0001 in. (0.000 25 cm).

X-Ray Microradiography Technique

This technique detects undispersed clumps of pigment (inorganic types only) in paint. It uses low-energy X-rays [*89*] to resolve oversize material in the range of 1 μM or less, which is below the range detectable with fineness-of-dispersion gages.

A thin film of paint is spread over the surface of photographic-sensitized, fine-grain film. The specimen is exposed

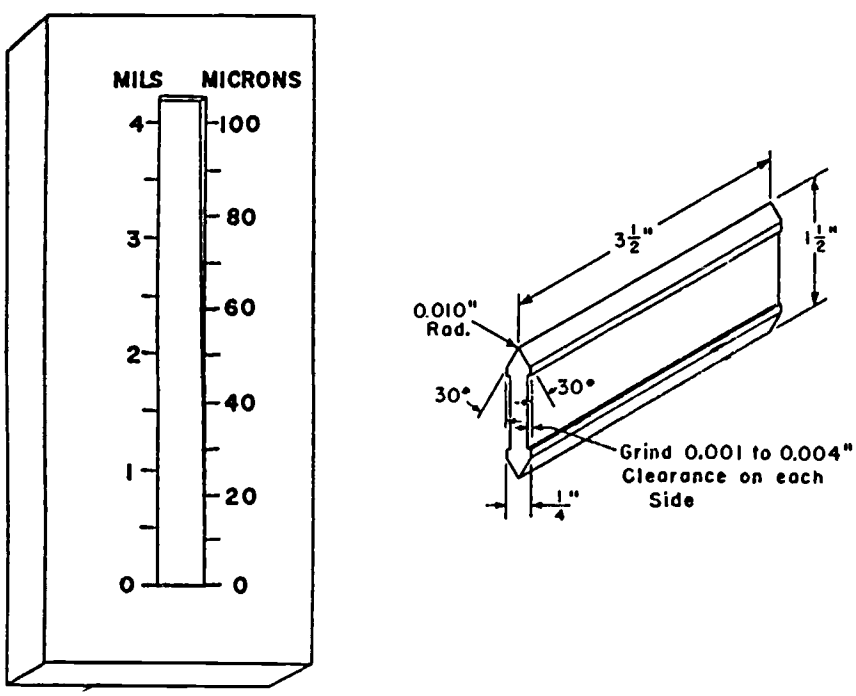

FIG. 30–ASTM dispersion gage and scraper.

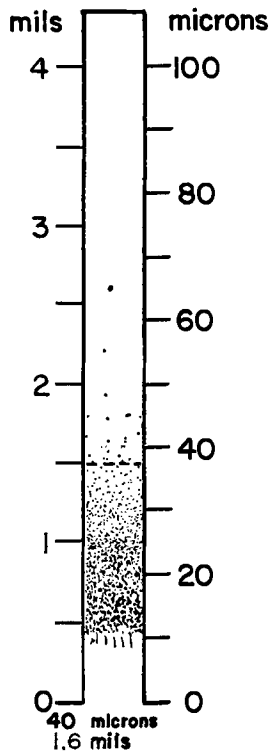

FIG. 31–Typical pattern produced by a dispersion gage.

to X-rays and the film developed after removal of the paint. The film is enlarged optically to reveal silhouettes of the oversize materials on a photographic negative. Determination of size may be made following the methods used for light and electron microscopy.

Hydrodynamic Chromatography: Angstrom Particle Sizing

The separation of angstrom-sized particles may be affected by the use of hydrodynamic chromatography. In this technique, the mixture of very small particles is allowed to transgress a long capillary tube in which the liquid medium is flowing in laminar flow. It is well known that fluids, both gasses and liquids, will experience a pressure drop as a function of distance traveled and of the diameter of the tubing that occurs because the fluid in actual contact with the wall of the tube does not flow and is stationary. For noncompressible fluids, (i.e., liquids), this variation in flow velocity from wall to center of tube may be used to separate particles of differing size.

For laminar flow, the velocity of flow through the cross section of the tube increases from the wall to the center, essentially in concentric "layers" [*90*]. This may be represented by the vectorial diagram in Fig. 32 of the flow velocity profile. The actual velocity of flow of one of the "concentric circular layers" will be a function of its distance from the wall of the tube. The flow velocity gradient is given by

$$V_r = \frac{(P_0 - P_L)R^2}{4\eta L}[1 - (r/R)^2] \qquad (14)$$

where

V_r = liquid velocity at radius, r,
$(P_0 - P_L)$ = pressure drop for the distance, L,
R = inside radius of capillary,
r = effective radius of liquid at V_r,
η = viscosity of fluid in flow, and
L = length of capillary.

Because the larger particles tend to have statistically more volume in the fluid away from the wall, the larger particles are under a greater influence of the faster-moving fluid away from the wall more so than the smaller particles, which can physically fit in the slower-moving layer nearer the wall. Thus, the larger particles advance faster than the smaller ones affecting the separation.

THE ROLE OF PARTICLE-SIZE REFERENCE TEST MATERIAL

Carefully prepared particles of known size and composition have become an important part of testing for emulsions, powders, film, and processes. When properly used, reference particles are an important factor in demonstrating compliance with standards such as ISO-9000, FDA Good Manufacturing Practices and various military specifications [*91*]. In the past two decades, the need for instrument calibration has prompted the establishment of several businesses specializing in the production and supply of reference particles, which are available in assortment of materials of various sizes, densities, and grades.

A brief discussion of some typical applications will illustrate the usefulness of these test reference particles. They are used for instrument calibration, filter checking, flow tracing, and evaluation of processes such as blending, cleaning, and spraying, to name a few.

Instrument calibration and checking covers two broad classes: (1) particle-size analyzers and (2) particle contamination analyzers. Both types of instruments are calibrated or controlled by spherical particle-size standards, primarily polystyrene microspheres, which are normally measured and calibrated by methods traceable to the National Institute of

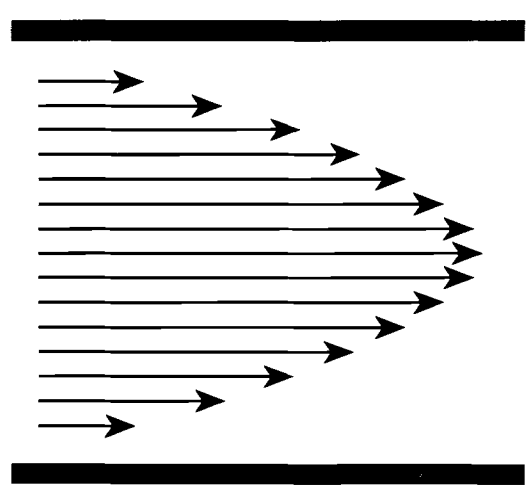

FIG. 32–Vectorial representation of the velocity of a fluid in laminar flow.

Standards and Technology (NIST). The spherical calibration particles have fairly predictable instrument responses and are available as aqueous suspensions of highly uniform particles in discrete sizes (diameters) from 0.02 to 2000 μm. In addition to polystyrene spheres, which may be nonfluorescent or may contain various fluorescent dyes, calibration spheres are composed of silica and glass. Nonspherical materials such as alumina, quartz, and various milled powders are available as experimental materials or controls.

Particle-size spectrometers are used to measure the particle-size distribution of powders, suspensions, emulsions, and aerosols. Other than composition, particle-size distribution is probably the most important variable in product quality and performance. The major class of instruments, particle counters, are used to measure trace amounts of particle contamination in air, water, chemicals, beverages, and medicines. A recent variation of the particle counter can measure particle contamination on flat surfaces, such as silicon wafers, and a variety of optical and electronic parts. All these instruments, as well as optical and electron microscopes, require calibration and reference particles to assure both the quality and traceability of measurements.

In addition to instrument evaluation and calibration, reference particles are used to verify retention ratings and pore-size distribution of air and liquid filter media. Using aerosol particle generators and precision particle counters up and down stream, high-efficiency particulate air (HEPA) filters can be certified for use in ultraclean manufacturing operations for rigorous contamination control. Polystyrene spheres with approximately a 0.25-μm diameter are frequently used for this purpose.

Another broad class of reference particle application is for validating processes, such as for cleaning, blending, dispersing, separation, and spraying. Fluorescent particles, which have bright and distinctive colors that can be contrasted with other background materials, are frequently used to follow the flow or direction of a process. Other materials such as pollens, ground walnut shells, refractory powders, or other materials of the desired particle size and specific gravity are available as model systems for evaluating processes.

In conclusion, reference particles are a key ingredient of modern testing methods, and their use should be considered at an early stage in any QA/QC program as quality management programs require the regular and timely evaluation and standardization of particle-sizing equipment.

Rheology and Viscometry

by Richard R. Eley[1]

Nomenclature

Φ Fluidity integral, Eq 64
α Rate of decay of roughness amplitude, s^{-1}
β Time constant characteristic of a critical shear rate, s
γ Dimensionless shear strain
$\dot{\gamma}$ Shear strain rate, s^{-1}
$\dot{\gamma}_w$ Wall shear rate in tube flow, s^{-1}
δ Phase shift; thickness of adsorbed polymer layer
ϵ Extensional (Hencky) strain, dimensionless
$\dot{\epsilon}$ Extensional (Hencky) strain rate, s^{-1}
η Coefficient of viscosity
η_0 Zero-shear viscosity
η_∞ High-shear limiting Newtonian viscosity
η_d Dispersion viscosity
η_e Extensional viscosity
η_l Liquid-phase viscosity
η_r Relative viscosity, η_d/η_l
η' Dynamic viscosity
$[\eta]$ Intrinsic viscosity (limiting viscosity number)
θ Angle of inclination with respect to the vertical
λ Wavelength of coating surface striations; elastic stress relaxation time constant
ν Kinematic viscosity
π Ratio of circumference of a circle to its diameter
ρ Density
σ Surface tension; generalized stress
σ_0 Initial imposed stress
σ_e Tensile stress
τ Shear stress; viscosity-kinetic time constant for drying, wicking, or thixotropy
τ_0 Yield stress
τ_s Tangential surface shear stress
τ_w Wall shear stress
ϕ Volume fraction of internal (dispersed) phase of a dispersion
ϕ_e Effective volume fraction for a dispersion
ϕ_m Maximum packing fraction of a dispersion, where $\eta_r \rightarrow \infty$
ω Angular frequency ($= 2\pi f$)(rad/s)
A Area of shear face
De Deborah number (λ/t)
F Force
F_g Force of gravity
G Shear modulus
G_∞ Plateau modulus
G^* Complex shear modulus
G' Storage modulus
G'' Loss modulus
K Consistency in power law model; constant in viscosity-molecular weight equation
L Capillary tube length
M_w Weight-average polymer molecular weight
M_c Critical (entanglement) polymer molecular weight
P Pressure
Q Volumetric flow rate
R Capillary tube radius; particle radius; air bubble radius
T Absolute temperature
T_g Glass transition temperature
a Curvature parameter in Eq 15; amplitude of coating surface striations
a_0 Time-zero amplitude of coating surface striations
e Base of the natural logarithmic scale = 2.718 28
f Frequency, Hertz
g Gravitational acceleration
h Film thickness
k Boltzmann's constant; general rate constant
l Length
m Kinetic energy correction term for capillary tube flow, Eqs 72 and 73
n Power law exponent
t Time
v Velocity
x Coordinate parallel to substrate
y Coordinate normal to substrate

INTRODUCTION

THE VALUE OF RHEOLOGICAL SCIENCE is increasingly being realized in the coatings laboratory. One reason is economic: As much as half the cost of new product development can be consumed in solving rheology-related problems of manufacture or performance. Moreover, the rheology of an established product can go awry due to reformulation or a raw material or process change, and such problems are generally in urgent need of solution. Rheological analysis can be a cost-effective aid to the coatings formulator in understanding and solving product and process difficulties.

Traditionally, measurement of the viscosity or "consistency" of paints and coatings had been based on a number of test methods having certain perceived virtues: They were

[1]The Glidden Company (member ICI Paints), Glidden Research Center, 16651 Sprague Road, Strongsville, OH 44136.

Copyright© 1995 by ASTM International

undemanding in operator skill, required inexpensive equipment, and the result was usually a single number requiring no interpretation. These tests proved useful enough, especially as tools of the experienced formulator or bench chemist. This was partly because, in the times when many industrial coatings were solvent-borne and relatively low in solids, the product rheology was seldom far from Newtonian. In the latter case, any test serves as well as any other. The advent of environmentally compliant technologies, such as waterborne, higher solids, and powder coatings, changed this situation. With the new formulations, non-Newtonian, time-dependent, and viscoelastic behaviors were encountered. Here, the traditional methods were inadequate for the reasons that many of the latter tests yield only a single-point measurement, use arbitrary (rather than absolute) viscosity units, or use a flow field which is "nonviscometric."[2] Any of these shortcomings render a method inappropriate for non-Newtonian materials.

A recurrent failing in product viscosity testing is the employment of methods not relevant to the performance property in question. This deprives the test of any analytical or predictive power relative to paint performance. Thus, for example, a low-shear viscosity measured using a spindle viscometer, paddle viscometer, or orifice cup bears no relation to the performance of a paint during application, generally a high-shear process. Part of the aim, therefore, is the development of tests which are related specifically to the critical processes paints must undergo.

Rheological factors play a key role in all stages of a coating's lifetime, from manufacture to the final career of a protective, decorative film. The many processes embodied in that history involve broad aspects of the science of rheology. Table 1 lists some coatings processes, each process having associated with it several distinct deformation characteristics. For each deformation type, a specific rheological test is required to measure its effect on the process. Many of these measurement quantities are independent, i.e., they cannot be inferred from another rheological property. Obviously, if one were to measure only steady-shear viscosity, and over a limited range of shear rate at that, the real cause of a performance problem may be missed. Thus, the characterization necessary for complete understanding of rheology-controlled behavior may require the use of more than one instrument and technique. Notwithstanding, many problems can be solved from shear viscosity and viscoelastic data alone provided the experiments performed are well designed and the results properly interpreted.

In order to take full advantage of the capabilities built into the sophisticated rheological instruments now being widely used in the coatings industry, more than a passing knowledge of the subject of rheology is required. This chapter is therefore somewhat tutorial in style, endeavoring to provide the novice an entry point to the discipline. Certain concepts are discussed at some length because of their importance or complexity. One of these is viscoelasticity. It is worth the time because (a) it is established that viscoelasticity exerts control over coating processes when present, and (b) a number of commercial instruments are capable of viscoelastic characterization of materials.

Finally, in the words of Professor Ken Walters, "Rheology is a difficult subject." This is certainly true, combining as it does several disciplines under one banner: mathematics, physics, physical chemistry, colloid and polymer science, continuum mechanics, etc. This is not to mention the special complexities of the experimental methods used. Furthermore, rheology requires mastery of concepts peculiar to the science with which most persons have had limited opportunity to become familiar in the normal course of a technical education. Nevertheless, it is quite possible for the nonspecialist to acquire a useful working knowledge of the principles and practice of rheology and to use this profitably in linking formulation and performance for coatings.

DEFINITIONS OF BASIC TERMS

Rheology

The derivation of the term *rheology* is from the Greek *rhein*, "to flow." The classical definition of the science of rheology is "the study of the deformation and flow of matter." Some have pointed out a redundancy in this definition since flow is a subset of deformation, as we shall see. An operational definition of rheology would be "the study of the response of certain materials to the stresses imposed on them."

In order to quantify the deformation and flow behavior of materials, three basic terms must be defined. The first two of these relate to the measurement of the deformation (strain and strain rate) and the third to the measurement of the force required to deform the material (stress).

Deformation (Strain)

A deformation is a change in shape and/or volume of a material in response to an applied stress. The equivalent engineering term is *strain*. During the lifetime of a coating, the deformation history may be complex (see Table 1), with the most important components being simple shear and extension. For purposes of definition, we will limit our discussion to simple shear. Simple shear deformation is exactly analogous to the spreading of a deck of playing cards, each card representing a thin volume element (or shear plane) displaced relative to its nearest neighbor (Fig. 1). If a force F is applied to the uppermost volume element (thickness dy), the material will deform by the displacement of adjacent volume elements by a distance dx. The total thickness is Δy, and the total displacement is Δx. The shear strain, γ, is the ratio of the net displacement, Δx, to the distance of separation of the confining surfaces, Δy.

$$\gamma = \frac{\Delta x}{\Delta y} \tag{1}$$

Strain Rate

In order to measure the viscosity, or resistance to flow, of a fluid, we must know not only the extent of deformation (strain), but also the rate of deformation (strain rate). The strain rate is the change in strain per unit time, or the time

[2]"Viscometric" shear flow requires that the flow be "everywhere indistinguishable from steady simple shear" [*1*].

TABLE 1—Rheological components of coatings processes.

Process	Deformation Type or Attribute	Rheological Property	Non-Rheological Effects
Roll Coating	Squeezing flow	Biaxial extensional viscosity	Drying
	Stretching flow	Uniaxial extensional viscosity	
	Shearing flow	Shear viscosity	
	High strain rate	High shear viscosity	
	Large accelerations	Elasticity (G')	
	Large decelerations	G' recovery	
	Surface area transients	Dynamic surface tension	
Spray	High shear rate	High shear viscosity	Flash-off
	Large accelerations	Elasticity (G')	
	High-strain-rate extensional flow	Extensional viscosity/elasticity	
	Surface area transients	Dynamic surface tension	
Brushing/rolling	Medium shear rate	Shear viscosity	
	Stretching flow	Extensional viscosity/elasticity	
	Surface area transients	Dynamic surface tension	
Leveling/sagging	Slow shear flow	Low shear stress viscosity	Wicking
	Surface-stress driven	Dynamic surface tension	Drying
	Transient	Structure recovery kinetics	
Curtain coating	Extensional flow	Extensional viscosity/elasticity	
	Surface area transients	Dynamic surface tension	
	Shear (pumping, extrusion)	Shear viscosity	

$$\text{Shear Stress } (\tau) = \frac{F}{A} \qquad \text{Shear Rate } (\dot{\gamma}) = \frac{dv}{dy}$$

$$\text{Shear Strain } (\gamma) = \frac{\Delta x}{\Delta y} \qquad \text{Viscosity } (\eta) = \frac{\tau}{\dot{\gamma}}$$

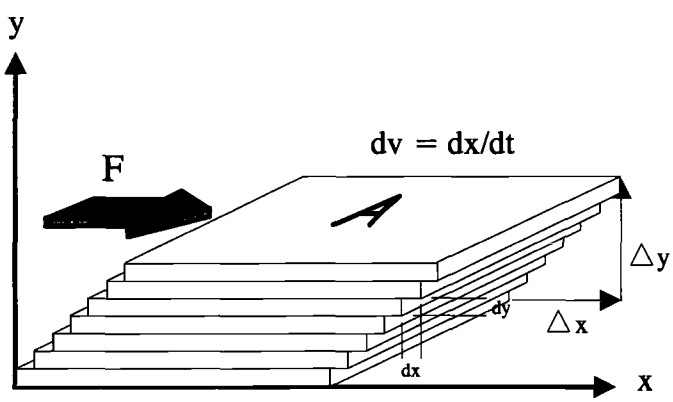

FIG. 1–Basic term definitions for simple shear.

derivative of the strain, symbolized $\dot{\gamma}$, where the "dot" signifies "time derivative of." Therefore, from Fig. 1

$$\dot{\gamma} = \frac{\Delta\gamma}{\Delta t} = \frac{\Delta(\Delta x/\Delta y)}{\Delta t} = \frac{\Delta(\Delta x/\Delta t)}{\Delta y} = \frac{\Delta v}{\Delta y} \tag{2}$$

If the deformation is simple shear, the strain rate is then called the shear rate. The dimensionality of $\dot{\gamma}$ is $LT^{-1}L^{-1}$ (e.g., cm/s per cm). Unit cancellation leaves reciprocal time (s^{-1}) as the unit of shear rate. It is conceptually helpful, however, to remember that, as shown by Eq 2, the shear rate is actually a velocity gradient (change in velocity per unit gap between shearing surfaces, $\Delta v/\Delta y$).

Stress

Force applied to a material creates a state of stress within the material. Stress can be expressed in units of force per unit area (e.g., dyne/cm^2), or, equivalently, energy per unit volume (e.g., erg/cm^3). In terms of Fig. 1, the shear stress, τ, is the force, F, necessary to maintain steady shearing motion against the resistance of the confined fluid divided by the area of the shear face, A.

$$\tau = \frac{F}{A} \tag{3}$$

Viscosity

The viscosity of a fluid characterizes its resistance to flow. The resistance to flow is, in turn, a measure of the friction between the flow units of the fluid (e.g., molecules) or may also be a measure of the attractive forces between the flow units. Thus, a "viscous" fluid (one reluctant to flow) may be so because of high molecular weight (as in motor oil) or be of relatively low molecular weight, but having strong intermolecular interactions (e.g., hydrogen bonds, as between sugar molecules in honey).

The separation of molecules in flow dissipates energy, chiefly as frictional heat. Flow, therefore, is a process which costs energy, of which the viscosity is a measure. For the case of shear deformation, the viscosity, η, is calculated as the ratio of shear stress to shear rate. The viscosity, therefore, is the energy per unit volume dissipated to attain a unit velocity gradient.

$$\eta = \frac{\tau}{\dot{\gamma}} \tag{4}$$

Modulus

Materials comply with an applied stress by deforming, or undergoing strain. For ideal Hookean materials, the strain will be proportional to the applied stress. The modulus is the proportionality constant between the stress and strain. For example

$$G = \frac{\tau}{\gamma} \tag{5}$$

where the shear modulus, G, is equal to the ratio of the shear stress and shear strain. Most polymeric materials and most coatings systems as well are non-Hookean, i.e., the modulus is not a material constant, but will depend on both rate and extent of deformation.

Units

Various systems of units for rheological variables are in use and may be encountered in the literature. Until recently, the most common system of units for rheological terms was the cgs (centimeter-gram-second), or "small metric" system. However, many technical publications and scientific journals now specify that *Systeme Internationale* (SI) units be adhered to. The SI system is based on the "large metric," or MKS (meter-kilogram-second) units, with some additional named units. The units associated with the above variables, according to the various systems, are given in Table 2.

CLASSES OF RHEOLOGICAL BEHAVIOR

Newtonian Fluids

Isaac Newton postulated that the force resisting motion of liquids is proportional to the rate at which one attempts to "separate the parts" of the liquid. In terms of our defined quantities, this would be expressed as

$$\tau \propto \dot{\gamma} \tag{6}$$

or

$$\tau = \eta\dot{\gamma} \tag{7}$$

where η is a constant of proportionality, called the coefficient of viscosity or simply the viscosity.

Equation 7 is the simplest example of a flow model, an expression which allows one to predict the flow properties of a material in response to an applied stress. Fluids which obey Eq 7 over a range of shear rate are said to be Newtonian over that range. The viscosity of Newtonian fluids is a material constant and depends only on the thermodynamic variables of temperature, pressure, and concentration. If the viscosity of such a material is measured at any shear rate or shear stress, the viscosity under all conditions of deformation is known.

Non-Newtonian Fluids

Of materials encountered in the coatings industry, only dilute or low-molecular-weight polymer solutions or stable dispersions of low concentration are likely to be Newtonian. In general, polymer solutions, colloids, dispersions, and suspensions of particulate solids will be non-Newtonian. For non-Newtonian materials, the viscosity is no longer a material constant, but is called a material function—in this case, a "function" of the shear rate (or shear stress). For non-Newtonian fluids, a viscosity measured at a single shear rate is not an adequate representation of the rheology of the system.

CLASSES OF NON-NEWTONIAN BEHAVIOR

In the following sections, the various types of non-Newtonian flow behavior will be outlined. At the same time, several mathematical expressions which can describe non-Newtonian flow will be introduced. Mathematical models are useful for summarizing flow behavior quantitatively. To be sure, materials may be evaluated by qualitative comparison of flow curves (e.g., by visual inspection), but the mathematical analysis of a flow curve has significant value. For one thing, the model constants may have physical significance. For example, some of the models contain a yield stress term (see **Plastic (Yield) Behavior**) as a fitted parameter. The magnitude of this parameter may be coupled to sag or leveling performance [*2*]. A later section of this chapter, **LEVELING,** gives examples of how sagging can be predicted for non-Newtonian fluids using constants from models discussed below. Furthermore, the values of model parameters may be associated with formulation variables, allowing one, in principle, to optimize rheology by adjusting composition in a rational way.

It should be understood that the models about to be discussed are actually idealizations and therefore limited in their ability to represent the behavior of real materials. The models can describe real behavior at least over a limited range of stress or strain rate. Thus, a second use of mathematical models of flow is to make predictions of flow behavior, bearing in mind that it is dangerous to extrapolate the models beyond their range of validity.

As mentioned above, the simplest flow model is the Newtonian expression, which has only one constant, the coeffi-

TABLE 2—Units.

Variable	CGS	MKS	SI
Strain	Dimensionless	...	...
Strain rate	s^{-1}	s^{-1}	s^{-1}
Stress	Dyne/cm^2	N/M^2	Pascal (Pa)(= 1 N/M^2)
Viscosity	Poise (P)(= 1 dyne · s/cm^2) or centipoise (cP) (1 cP = 0.01 P = 1 mPa · s)	...	Pa · s (= 10 P) or millipascal-second (mPa · s)(= 1 cP)
Modulus	dyne/cm^2	N/M^2	Pa

cient of viscosity, η. To describe more complicated behavior, we will have to add additional coefficients and terms, the physical significance of which will be given when possible.

Shear-Dependent Viscosity

Materials in which the viscosity falls with increasing shear rate[3] are designated *shear thinning*. Simple shear thinning behavior without either time dependence (see under **Time-Dependent Fluids**) or a yield stress (see under **Plastic (Yield) Behavior**) is termed *pseudoplastic*, a common type of non-Newtonian behavior in coatings systems. Viscosity rising with increasing rate of shear is called *shear thickening*. The term *dilatancy* (see under **Shear Thickening Fluids**) is often applied to shear thickening behavior, although this refers strictly to shear thickening accompanied by a volume increase, as the term implies. Figure 2 shows curves illustrating viscosity-shear rate relationships for Newtonian and non-Newtonian fluids.

As stated, Newtonian behavior is the simplest of all and is described by Eq 4. The viscosity, η, is a material constant independent of shear rate (Contour *N*, Fig. 2). More complicated viscosity-shear rate behavior requires a more complex expression to model it. The first level of complexity is to add yield behavior (see under **Plastic (Yield) Behavior**) to the Newtonian model, resulting in the Bingham equation [*3*]

$$\tau - \tau_0 = \eta_p \dot{\gamma} \tag{8}$$

Equation 8 says that, above the yield stress (τ_0), the shear stress (minus the yield stress) is directly proportional to shear rate.[4] It is a common misconception that this corresponds to Newtonian behavior above the yield stress. Figure 2, Curve B shows that the Bingham model displays power-law-like behavior, but deviates from the power law (Curve PL) at higher shear rate, approaching the plastic viscosity, η_p, as a limit. Casson [*4*] modified Bingham's equation by taking the square root of all terms

$$\tau^{1/2} - \tau_0^{1/2} = \eta_\infty^{1/2} \dot{\gamma}^{1/2} \tag{9}$$

The Casson model is not empirical, but was theoretically derived specifically for systems whose primary flow units are rigid rods. Casson's equation is reputed to hold for a variety of paint systems, particularly as modified by Asbeck [*5*]

$$\eta^{1/2} - \eta_\infty^{1/2} = \tau_0^{1/2} \dot{\gamma}^{-1/2} \tag{10}$$

which is somewhat surprising since few paints utilize rod-shaped particles as fillers or pigments. In fact, this author's experience is that frequently the Casson model does not represent paint flow as well as certain other models (see below). In Eqs 9 and 10, η_∞, sometimes called the *Casson viscosity*, is not truly an "infinite-shear viscosity," but is a limit that is approached, corresponding to some unknown high shear rate. The value obtained for the Casson viscosity will depend on the maximum experimental shear rate. As with all such models, the user must be aware that the constants resulting

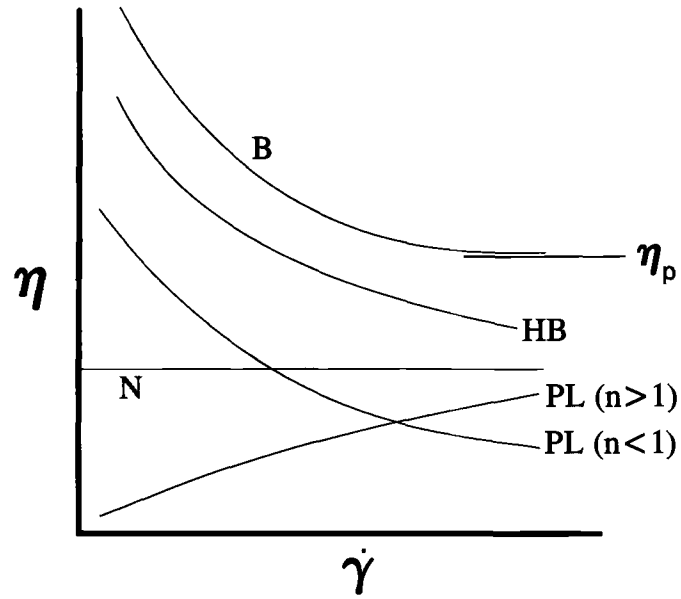

FIG. 2–Viscosity-shear rate curves for simple flow models. Symbols represent the following fluid models: N = Newtonian; B = Bingham (η_p = plastic viscosity); HB = Herschel-Bulkley; PL = power law (*n* = exponent).

from a Casson analysis are not necessarily true material constants. For example, because the analysis of flow data is simply curve-fitting, a finite yield stress will generally be obtained whether or not the material really possesses yield behavior.

The next complication we will introduce is to let the exponent of the shear rate in the Newtonian law be other than unity. In other words, the shear stress now will depend on some power of the shear rate

$$\tau = K\dot{\gamma}^n \tag{11}$$

Equation 11 is known as the power law or Ostwald-deWaele model. Here, K is a constant, sometimes called the "consistency,"[5] which has replaced the coefficient of viscosity, η. This is necessary because the exponent n can be other than unity, in which case K will not have proper viscosity units associated with it. The power law exponent, n, has been termed the "flow index." Its value is characteristic of the dependence of viscosity on shear rate, i.e., whether the viscosity rises or falls with increasing shear. Dividing Eq 11 through by $\dot{\gamma}$ yields a form of the power law which relates the viscosity to the shear rate

$$\eta = K'\dot{\gamma}^{n-1} \tag{12}$$

where $K' = (1/K)^{1/n}$. Obviously, if $n = 1$ in Eqs 11 and 12, the power law reduces to the Newtonian law. A value of $n < 1$ corresponds to shear thinning behavior and $n > 1$ to shear thickening (Fig. 2 curves PL).

The next complication we shall consider is to add a yield stress term to the power law expression

$$\tau - \tau_0 = K\dot{\gamma}^n \tag{13}$$

[3]Any definitions or descriptions of shear rate-dependent behavior may likewise be stated in terms of shear stress dependence.

[4]In the Bingham expression and in other models incorporating a yield stress term, it is important to note that the equations describe flow behavior only when $\tau > \tau_0$. When $\tau \leq \tau_0$, $\dot{\gamma} = 0$ (i.e., $\eta = \infty$), and there is no flow.

[5]Mathematically, K corresponds (in numerical magnitude but not dimensionally) to the viscosity at unit shear rate (1 reciprocal second).

which is known as the Herschel-Bulkley equation. This model describes power law behavior above the yield point (Curve HB, Fig. 2).

Figure 3 shows a generalized equilibrium flow curve [*6,7*]. This figure represents the general features of the shear rate dependence of viscosity for non-Newtonian fluids with any time-dependent or relaxation behavior removed. It consists of a low shear rate Newtonian regime, Region I, an exponential shear thinning regime, Region II, a high-shear Newtonian regime, Region III, and may include a shear-thickening regime, Region IV. The figure is explained in detail (see **Shear-Thinning Fluids**). The chief limitation of the power law models is that they are valid only over a limited range, namely, the linear portion of Region II of Fig. 3. They cannot account for the upper or lower Newtonian regions and, in fact, predict infinite viscosity at zero shear rate and zero viscosity at infinite shear rate, both unrealistic limiting behaviors. Nevertheless, the power law models are found to be quite useful within their limitations, particularly for engineering-type calculations. The Herschel-Bulkley equation has been found to be superior to a number of other models in describing the flow behavior of a wide variety of coatings materials over a useful range of deformation conditions [*8*].

Extending the range of validity beyond Region II in Fig. 3 requires more elaborate models. A simple extension of the power law model is to add an upper Newtonian limiting viscosity, η_∞

$$\eta = \eta_\infty + K'\dot{\gamma}^{n-1} \tag{14}$$

This expression is known as the Sisko model [*9*] and includes Regions II and III of Fig. 3.

Of several proposed models encompassing Regions I, II, and III inclusively, two in particular have perhaps found wider acceptance and utility in the literature. These are the Cross and Carreau models. Hieber et al. [*10*] recently wrote a general form of which the Cross and Carreau models are special cases (here modified to include Region III)

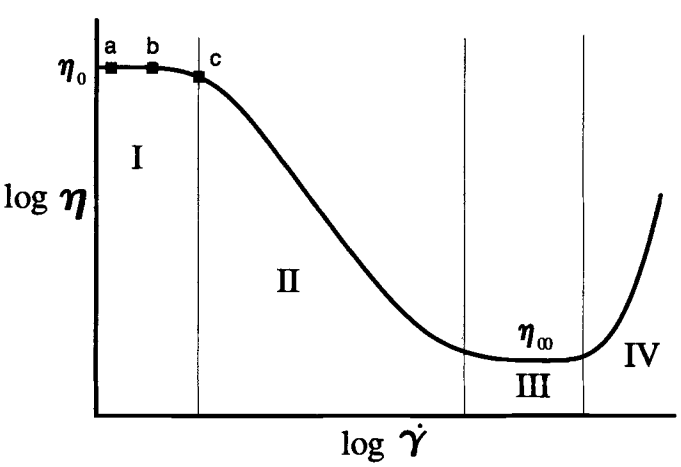

FIG. 3–Generalized equilibrium flow curve: η_0 is the zero-shear viscosity (random structure, maximum disorder); η_∞ is the high-shear limiting viscosity (maximum order). Region I is the first Newtonian plateau; Region II the power law regime; Region III the second Newtonian plateau; Region IV the shear-thickening regime. (Adapted from Ref *6*.)

$$\eta = \eta_\infty + \frac{\eta_0 - \eta_\infty}{(1 + [\beta\dot{\gamma}]^a)^{(1-n)/a}} \tag{15}$$

Here, η_0 is the first Newtonian plateau viscosity and a is a constant that determines the curvature of the transition region between the lower Newtonian regime and the power law regime. The value of a can be a measure of the breadth of the molecular weight distribution of a polymer [*10*] or perhaps the particle-size distribution of a colloidal dispersion. Setting $a = 1 - n$ in the above expression yields the Cross equation; setting $a = 2$ gives the Carreau-B model. The parameter n has the identical meaning as in the simple power law model (Eqs 11 and 12), i.e., it is the slope of the power law region in a log-log plot of shear stress versus shear rate. The constant β has the dimension of time and is actually a time constant representing a characteristic time of the system. This time constant may be related to, for example, the diffusional or rotational relaxation time of the flow units (be they colloidal particles or polymer chains) or to the time for rupture of particle flocs or aggregates under shear. The location of the transition from the initial Newtonian plateau (Region I) to the shear thinning regime (Region II) in Fig. 3 is governed by the value of β in an inverse sense: increasing β decreases the shear rate of the onset of shear thinning and vice versa. In other words, β defines a characteristic shear rate of transition, $\dot{\gamma}_{tr}$ [*11–13*].

$$\dot{\gamma}_{tr} = \frac{1}{\beta} \tag{16}$$

It is tempting to postulate that β corresponds to the time constant for Brownian diffusion of the primary flow units of a fluid. Stokes-Smoluchowski-Einstein theory gives us the value of β for a particulate dispersion from

$$\beta = \frac{48\pi\eta R^3}{kT} \tag{17}$$

where η is the viscosity of the continuous phase, R is the particle radius, k the Boltzmann constant, and T absolute temperature. For a typical aqueous latex dispersion, $R = 125$ nm, $\eta = 0.05$ P, for which (at 25°C) $\beta = 0.36$ s, corresponding to $\dot{\gamma}_{tr} = 2.8\ s^{-1}$.

When the experimental shear rate equals $1/\beta$, the shear-ordering effect begins to dominate the randomizing effects of Brownian motion, and onset of shear thinning is seen [*14*] (see **Shear-Thinning Fluids**). This event corresponds to Point c in Fig. 3. Equations 16 and 17 show how the transition from Newtonian to shear thinning behavior may be controlled. Any variation which increases the value of β (such as increasing the effective particle size, the continuous-phase viscosity, or lowering the temperature) will move the shear thinning transition to lower shear rates. Decreasing β extends Newtonian behavior to higher shear rates. While Eq 17 is strictly valid only for very dilute dispersions, it still provides qualitative guidelines for manipulating the rheology of dispersions. For concentrated dispersions, η should be taken as the viscosity of the dispersion [*15–17*].

It follows from the above discussion that the broader the size distribution of the flow units, the wider the spectrum of relaxation times and the more gradual the transition from Region I to Region II (corresponding to a smaller value of a).

The shear rate of transition is fixed by β (a *mean* relaxation time), while a represents the *distribution* of relaxation times.

Shear-Thinning Fluids

The term *pseudoplastic* has been applied to fluids which decrease in viscosity with increasing shear rate (or shear stress) and implies shear-thinning behavior without yield stress. However, the term is passing out of use in favor of the more general description *shear thinning*. Particulate dispersions, polymer colloids, and polymer solutions can display this behavior above a certain concentration threshold.

Viscosity is a measure of the dissipation of energy or the "energy cost" to flow. Shear thinning behavior, therefore, implies that an increase of shear rate causes a structural change in the fluid that allows it to flow more efficiently, consequently with less energy loss. The mechanism[6] involves a shear-induced increase in order, or anisotropy, within the system. Thermal (Brownian) motion tends to keep systems disordered (of random order). Shear forces work against this, tending to impose orderliness. If shear rates are low, the randomizing forces win out and the viscosity does not change for small increases of shear rate (Point a to Point b in Fig. 3). Since the structure is no less random anywhere in Region I than at zero shear rate, the viscosity equals η_0, the zero-shear value. As the shear rate approaches a critical magnitude (see **Shear-Dependent Viscosity**), the competition of thermal randomizing and shear ordering starts to favor ordering (Point c in Fig. 3). In the case of polymers in solution, randomly coiled polymer chains tend to stretch in the direction of shear, partially uncoil, and align in more or less parallel fashion depending on the strength of the shear field. The particles of a dispersion tend to line up like "strings of pearls" (Fig. 4) and eventually in ordered planes perpendicular to the shear gradient [*18–20*]. The result is a steadily decreasing viscosity with increasing shear rate as the degree of order increases. Ultimately, if the shear rate is high enough, the maximum amount of shear ordering possible is attained and the viscosity again becomes independent of shear rate (Newtonian).

Figure 3 shows the overall way in which viscosity varies with shear rate for systems such as those described above where Region I is the low-shear Newtonian regime (where Brownian motion controls structure). Region II is the shear-thinning segment of the flow curve (where shear forces control the structure). It is found that the viscosity decreases exponentially with shear rate here; hence, it is often referred to as the "power law" regime. Region III is the high-shear Newtonian regime. Here, the maximum degree of shear ordering has been attained; thus, the viscosity is once again independent of shear rate. The high-shear limiting Newtonian viscosity is usually given the symbol η_∞. Region IV is a shear-thickening region which is occasionally seen, especially with concentrated dispersions. In actuality, shear thickening in dispersions may occur at virtually any magnitude of shear rate depending on dispersion concentration [*21*], so that one or more of the other regimes are obliterated. That is, the equilibrium flow curve may consist of Regions I to IV, I, II, and IV only, I and IV only, or IV only.

Note, once again, that structural order and viscous dissipation are inversely related. An increase in order means decreasing viscosity (Region II), while a decrease in order results in an increase in viscosity (Region IV) [*22*]. It follows that, for Newtonian behavior, no change must occur in structural ordering with shear. If the disperse system is unstable, i.e., tending to flocculate, the dotted curve may be followed (Fig. 5) instead of displaying a low-shear Newtonian regime [*7*]. Some systems may possess an apparent yield stress (see **Plastic (Yield) Behavior**). (See **DISPERSION RHEOLOGY** for additional discussion of particulate system rheology.)

As a general statement, the range of accurate measurement of most laboratory viscometers (for typical coatings fluids) is in the power law region. It may require extraordinary methods or special instrumentation to characterize fluid behavior in Regions I or III.

Shear-Thickening Fluids

We have seen above that shear thinning involves a shear-induced increase in order of a system. This allows the elements of a fluid to move or flow with minimum expenditure of energy. Conversely, shear thickening evidences that shear has caused a decrease in order of a system. The resulting disordered system dissipates more energy during flow and hence is more viscous. An example of this is provided by the catastrophic increase in viscosity observed by Hoffman [*19*], resulting from the "buckling" or "log-jamming" of ordered, layered arrays of particles.

One frequently encountered type of shear thickening behavior is dilatancy. Properly, dilatant behavior is shear thickening accompanied by an increase in volume of the fluid. It is most commonly observed in relatively concentrated disperse systems. In a dilatant system, the disperse phase particles are "wetted" with the minimum amount of liquid continuous phase. Furthermore, at rest, the particles of the disperse phase are in a random close-packed structure for which the interstitial volume is relatively minimal (Fig. 6). If the dispersion moves only slowly, adequate time exists for the meager liquid phase to flow sufficiently to maintain the dispersed phase in a "wetted" state, and the system is able to maintain its close-packed structure. Faster or more forceful motion causes a liquid-starved condition because the interstitial volume increases when the system is deformed or made to flow (Fig. 6). There is no longer enough liquid to lubricate the system. The particles are, therefore, incompletely wetted, and forced flow would ultimately create microscopic voids, leading to fracture of the material. The surface of a dilatant material may appear dry when stressed due to the withdrawal of surface liquid into the increased interstitial volume. This is seen when walking on wet sand on the beach. The resistance to deformation of the material can increase tremendously with increased deformation rate due to these effects.

During the course of a pigment grind operation, a fairly sudden maximum in viscosity is often seen and is an indication that a good grind (i.e., to primary particles) has been achieved. In fact, the surge in viscosity and power draw result

[6]The following discussion applies strictly to "stable" systems, i.e., those in which the net force between flow units is repulsive and therefore which do not flocculate. The shear-thinning mechanism for unstable systems (net interparticle force attractive) is discussed in the subsection entitled *Mechanism of Thixotropy*.

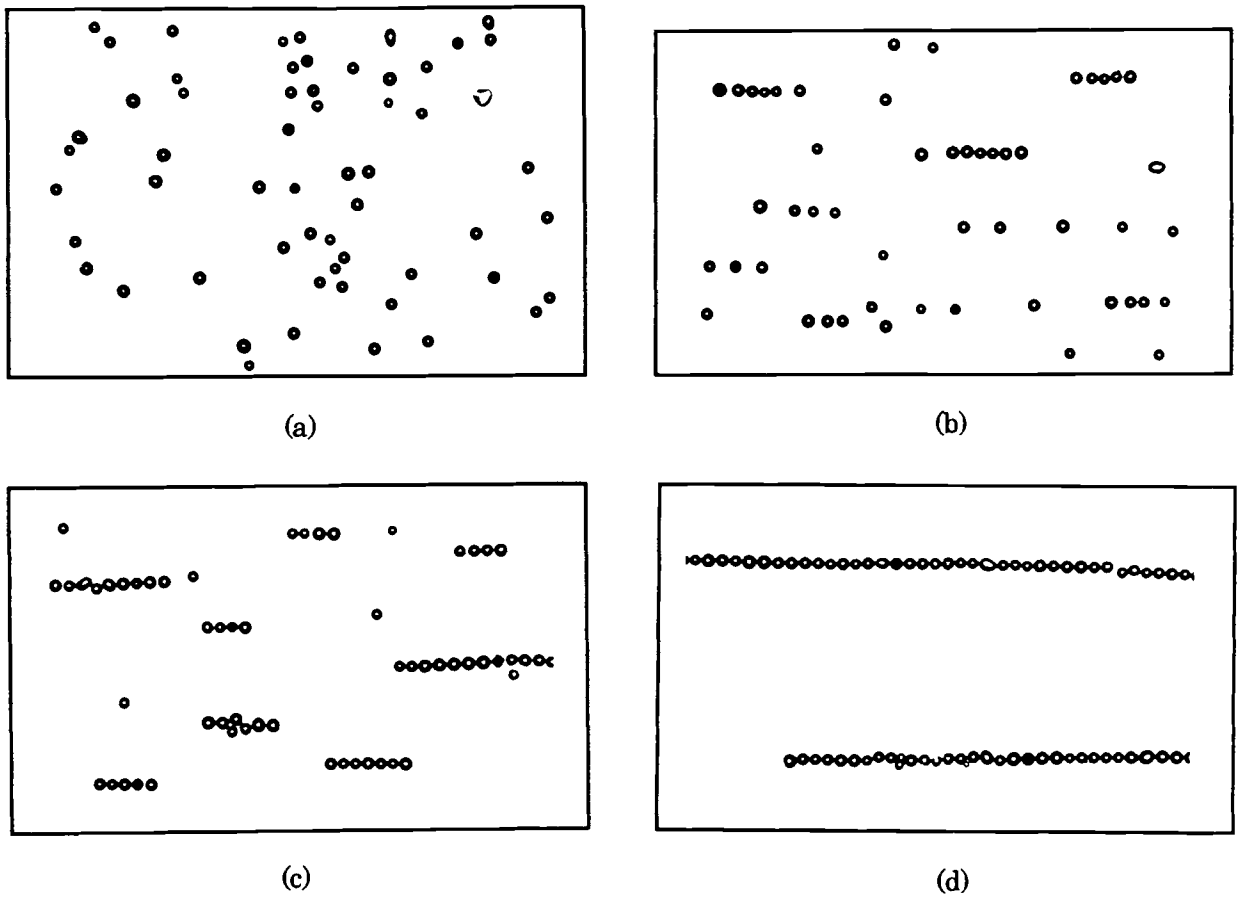

FIG. 4–Dilute suspension of glass spheres in a polymer solution confined between glass plates with small plate separation: (a) just after loading, particles are randomly distributed; (b)-(d) after being sheared in a side-to-side direction at both increasing duration and shear rate. (By permission from J. Michel, R. Pätzold, and R. Donis, *Rheologica Acta,* Vol. 16, 1977, p. 317. Cited in Ref *20.*)

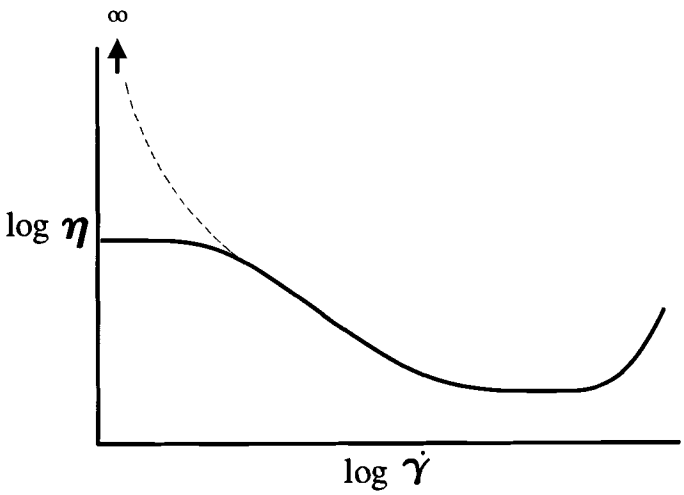

FIG. 5–Flow curve seen for unstable (flocculating) dispersions is indicated by the ascending curve going toward infinite viscosity at low shear rate.

from the grind having become dilatant. The dilatancy is desirable here because it facilitates energy transfer throughout the grind. Thus, dilatancy is frequently an indicator of achievement of a stable dispersion to primary particles. Dilatant systems, in general, are not also thixotropic and therefore permit flow under even very low stresses. For this reason, paints in a dilatant state may suffer from rapid settling and be difficult to redisperse. For most coatings operations, dilatancy is, in fact, undesirable. Pumping of dilatant dispersions may result in high back-pressure in lines, excessive

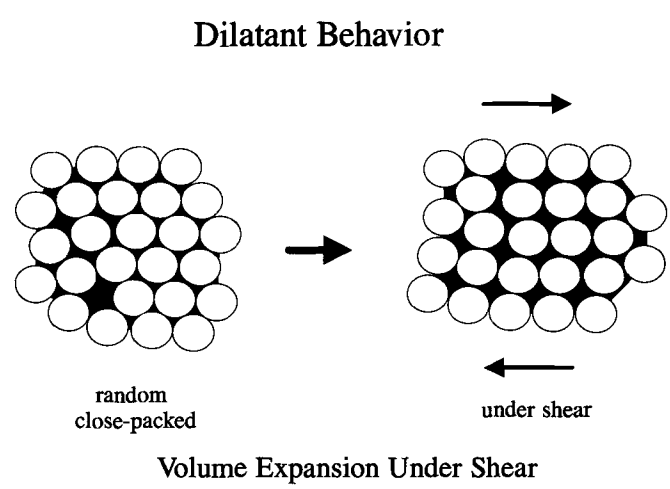

FIG. 6–Dilatant behavior-volume expansion under shear. Random close-packed structure gives way to less-efficient packing with necessary volume dilation.

wear of system components, high power consumption, and loss of metering. In industrial rollcoating, dilatancy shortens coating lifetime on the roll, causing "dry edges" and loss of film thickness control.

Dilatancy is very sensitive to dilution and can be dramatically reduced or eliminated by a small reduction in paint solids. Also, addition of flocculants, electrolyte, a particulate phase of different particle size, or warming can alleviate undesirable dilatancy. Flow curve measurement provides an excellent means of quantifying the degree of reduction of dilatancy achieved by these measures.

Time-Dependent Fluids

Time-dependent fluids are those whose viscosity is a function of both shear rate (or shear stress) and time. The most common such behavior encountered in coatings is time-dependent shear thinning or *thixotropy* [*23*]. At constant shear rate and temperature, the viscosity of thixotropic fluids will fall, eventually reaching a constant value. If the shear rate is changed, the viscosity will approach a new equilibrium value at a characteristic rate. This behavior is illustrated in Fig. 7, showing the way viscosity changes for a time-dependent system when the imposed shear rate (or shear stress) is changed in steps. Initially, the shear rate is zero, and the viscosity is very high or infinite for a thixotropic system. As a shear rate greater than zero is imposed ($\dot{\gamma}_1$), the viscosity drops exponentially, reaching a constant value. Increasing the shear rate to $\dot{\gamma}_2$ decreases the viscosity further to a new equilibrium value. A decrease of the shear rate to $\dot{\gamma}_3$ results in an exponential rise of viscosity to a higher equilibrium value. If, instead of a multiple steady-shear experiment, just described, we were to carry out a shear rate (or shear stress) ramp experiment (Fig. 8*a*), the time dependence would result in a loop (Fig. 8*b*). The explanation of the loop is given below, but has to do with the fact that in a ramp experiment the equilibrium structure is never attained. The circuit in Fig. 8*b* is called a *thixotropic loop*. Roughly bisecting the loop is the equilibrium-structure curve generated from the equilibrium viscosity data of Fig. 7. The analogous time-dependent behavior for

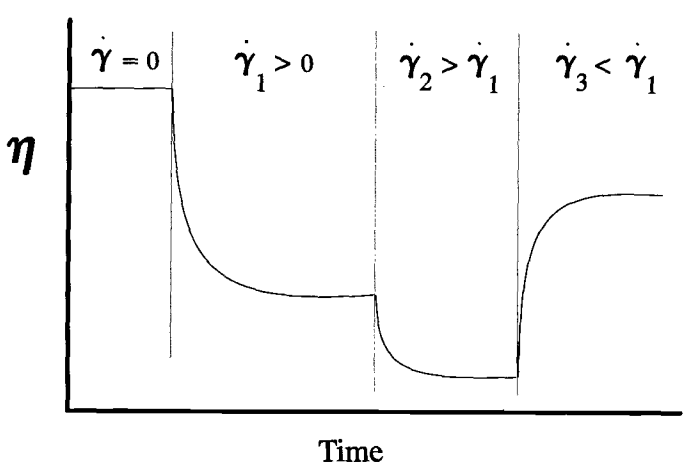

FIG. 7—Time-dependent fluid behavior. At $\dot{\gamma} = 0$, viscosity is high (or infinite). Imposing $\dot{\gamma}_1 > 0$ causes viscosity to fall exponentially, reaching new equilibrium value. Subsequent changes in $\dot{\gamma}$ result in re-equilibration of structure, hence viscosity.

shear thickening materials has been called *rheopexy* (a rather rare phenomenon). The preferred term now for the latter is *antithixotropy*.

"Thixotropic Index" Test

We emphasize that the most important characteristic of thixotropic behavior is not shear thinning alone, but time dependence. The relatively slow change of viscosity provides a means of control of flow behavior and is the reason thixotropy is formulated into coatings. Hence, it is important to correctly characterize the time-dependent aspect of the behavior. For this reason, the so-called "Thixotropic Index" test is of limited benefit for characterization of such systems.

We will digress for a moment to discuss the Thixotropic Index test since it is very widespread in practice. This misnamed test determines the ratio of viscosities measured at arbitrary high- and low-shear conditions. ASTM Test Method D 2196 specifies taking the ratio of viscosities measured on the Brookfield Synchro-Lectric viscometer at two speeds, representing a ten-fold speed ratio. Since only equilibrium viscosities are measured, the test yields no information about time dependence and should be called the "Shear-Thinning Index" instead (it is so termed in ASTM D 2196). Its value, like many quality-control tests, is in its simplicity and "quick-and-easy" character, requiring no interpretation. As long as a given coating formulation changes little, so that the hidden kinetic factor would be expected to change little, the "Thix Index" can reveal when something has gone awry (i.e., can be useful as a gross indicator whether a formulation error has occurred). However, it is always possible that the recovery kinetics of the system have changed, which would go completely unnoticed if the "Thix Index" were the only test used to evaluate the rheology. Below, we will present test methods which can be virtually as simple as the "Thix Index," but which give more useful, relevant, and complete information about thixotropic systems.

Mechanism of Thixotropy

Thixotropy is formally defined as an isothermal, reversible sol-gel (fluid-solid) transformation [*24*]. As stated, it is experienced as a viscosity which is both time- and shear-dependent. Its origin is the breakdown, under shear, of internal fluid structure to smaller flow units or the reassembly of structure from smaller units when shear is relaxed.

The mechanism of shear thinning in thixotropic (time-dependent) systems is different from pseudoplastic (time-independent) systems. In pseudoplastic systems, shear thinning is the consequence of order externally imposed by shear [*14*]. In thixotropic systems, an internally imposed, viscosifying structure exists at rest, and the viscosity falls because of the collapse of that structure under shear. (Flocculated systems possess extra mechanisms of energy dissipation [*25*]; therefore, their viscosity will be higher than that of a deflocculated dispersion of the same composition.) A further important difference between the two is in the amount of time the structure requires to respond to changes in shear rate. In the case of time-independent systems, rapid structural equilibration quickly accommodates to changes in shear rate. The accommodation process essentially is particle diffusion, which is quite rapid for submicron particles (see **Shear-Dependent Viscosity**). The viscosity (a measure of structure)

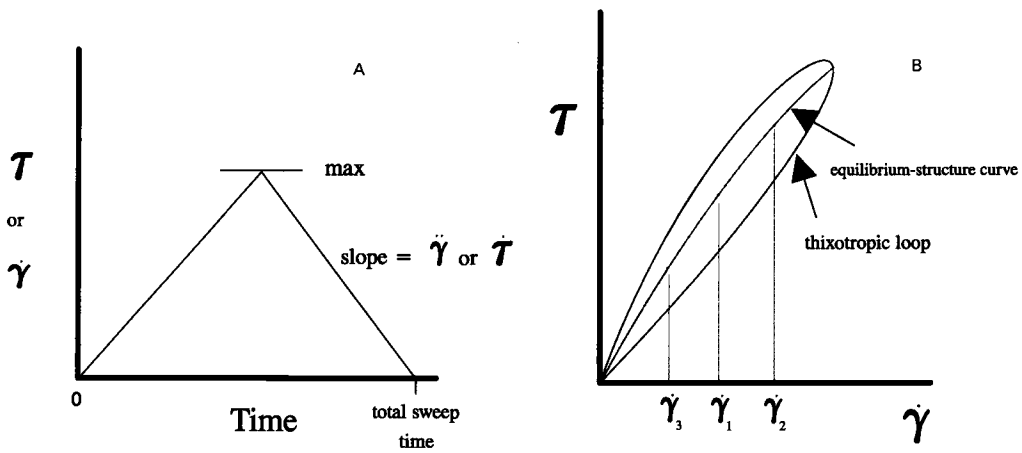

FIG. 8–(A) Shear rate or shear stress ramp experiment. Shear rate or stress increases linearly (sometimes logarithmically, optionally) to preselected maximum over a selected sweep time period, resulting in a given acceleration gradient ($\ddot{\gamma}$) or stress rate ($\dot{\tau}$); (B) Thixotropic loop. Equilibrium structure curve (approximately bisecting loop) corresponds to data from an experiment like that in Fig. 7.

thus always "keeps up" with changes in shear rate for such systems. For thixotropic systems, the rate of structural reorganization is slower than the experimental rate of change of shear rate ($\ddot{\gamma}$) or slow with respect to the time of observation at constant shear rate. In a "shear rate ramp" experiment (see below), the structural breakdown always lags behind the ever-increasing shear rate, so that the viscosity on the "up" ramp will be higher than the equilibrium viscosity at a given shear rate. On the "down" side of the ramp, the rebuilding structure lags behind the rate of reduction of shear rate, so that the measured viscosity is always lower than the equilibrium value. Thus, a "thixotropic loop" is seen, the size of which should be proportional to the structural time constant for a given ramp time. Holding the shear rate constant, as in the description above, allows the structure breakdown process to "catch up." The viscosity then continues to change until an equilibrium between structural breakdown and recovery rates is achieved (see Fig. 7).

Thixotropy Test Methods

Two common test methods for experimental characterization of thixotropy are the "Thixotropy Index" test, and the "Thixotropic Loop" test, described above. In the latter, a programmed increase and decrease of shear rate (or shear stress) is applied to a material (Fig. 8*A*), resulting in the generation of a loop (Fig. 8*B*). The size of the loop can be obtained by numerical integration and is taken as an indicator of the rate of structural breakdown and recovery for a given ramp time (the larger the loop, the slower the breakdown-recovery rates). This method is a difficult one to do correctly, however, and is more complex than first appears. The result (loop size) depends on the shear history of the sample—the time interval since its last shear experience—and the magnitude of the shear undergone. It also depends on the shear rate (or shear stress) maximum in the loop experiment and the ramp rate ($\ddot{\gamma}$ or $\dot{\tau}$).

A better method is one which puts the thixotropic material into a known state, i.e., having had a controlled shear experience, followed by the test. Such a method is the step-shear

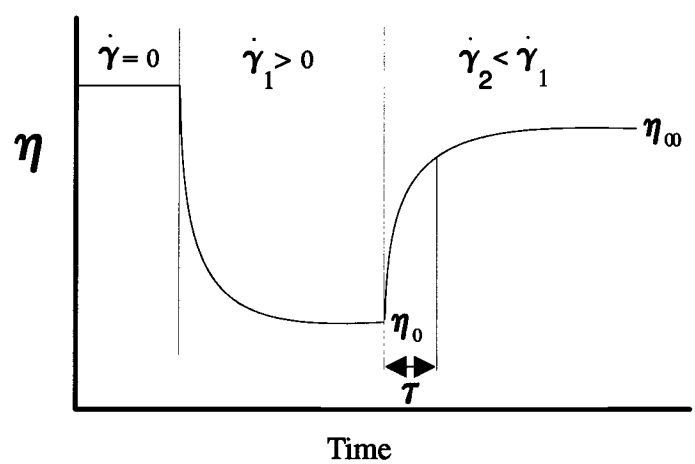

FIG. 9–Step-shear method for thixotropic recovery. High shear rate $\dot{\gamma}_1$ simulates application process, followed by low shear rate $\dot{\gamma}_2$, emulating film after application. Viscosity recovers from zero-time value $\eta_{(0)}$ with a characteristic time constant τ, eventually reaching final level $\eta_{(\infty)}$.

test (Fig. 9). In it, a high shear rate (order of 10^4 s^{-1} desirable) is applied to the material, allowing time for the viscosity (hence, structure) to reach equilibrium; then the shear rate is suddenly reduced to a very low value (order of 1 s^{-1}). The equilibrium amount of structure which can exist at the lower shear rate is greater than at the previous high shear rate, so reassembly of fluid structure occurs, accompanied by an approximately exponential rise of viscosity. Meaningful physical constants can be extracted from the data by fitting the following equation to the recovery curve

$$\eta(t) = \eta(0) + [\eta(\infty) - \eta(0)][1 - e^{-t/\tau}] \qquad (18)$$

where $\eta(t)$ is the viscosity as a function of time, t, $\eta(0)$ the sheared-out viscosity (at time zero), $\eta(\infty)$ the infinite-time recovered viscosity level, and τ the time constant describing the recovery rate. The ratio $\eta(\infty)/\tau$, which we have termed the *Recovery Parameter*, has been found in our laboratories to correlate well to thixotropy-related properties such as sag

TABLE 3—Gel coat thixotropy test data comparison: τ is the recovery time constant and $\eta(\infty)$ the recovered viscosity level from a step-shear experiment; $\eta(\infty)/\tau$ is the recovery parameter.

Composition	τ, s	$\eta(\infty)$, P	$\eta(\infty)/\tau$, P/s	Thix Index	Sag?
With additive	8.9	116	13	4.04	No
Without additive	18.2	97.3	5.4	4.24	Yes

resistance and air entrainment [*26*]. Table 3 shows data for two gel coat formulas, one sagging and one nonsagging. The conventional "Thix Index" results do not predict the sag behavior and, in fact, are opposite what would be expected from the observed behavior. The step-shear experimental parameters τ and $\eta(\infty)$ are given, along with their ratio. The nonsagging formula ("with additive") has both a shorter recovery time and a higher final recovered viscosity, and the recovery parameter takes both of these into account to predict significantly better sag resistance than for the "without additive" material.

The step-shear test puts useful thixotropy characterization within reach of any development lab, for it can be performed on an inexpensive viscometer (such as the Brookfield Synchro-Lectric or Wells-Brookfield Cone/Plate Viscometer) as well as on more sophisticated instrumentation. The latter offer advantages, of course, particularly if possessing viscoelastic characterization capability. The ideal way to characterize thixotropic recovery is to break down the structure under high, steady shear (as in the step-shear method), then step down to a small-amplitude (small strain) oscillatory-shear test, as described by Dodge [*27*] (Fig. 10*a*). The rebuilding of structure can then be followed by means of the viscoelastic parameters, which are sensitive probes of the fluid structure responsible for thixotropy. This method more faithfully mimics processes occurring in the relatively quiescent film after application. Figure 10*b* shows the recovery curves of the viscoelastic moduli G' and G'' (see *The Viscoelastic Parameters and Their Measurement*) from such a step-shear experiment.

Plastic (Yield) Behavior

An ideal plastic material behaves as an elastic solid until a critical stress is applied, whereupon it will "yield" and become fluid. This critical stress is the yield stress, the minimum stress necessary to initiate flow. Ideally, the properties of a material exhibiting yield behavior would be those of an elastic, or "Hookean," solid, below the yield stress. For such materials, the steady-shear viscosity would be infinite (or undefined), the deformation linear with stress, and the yield value a material constant. For most real materials, however, deformation below the yield point is a combination of elastic strain and viscous flow. This is because interparticle forces ("secondary bonds") are of a range of types with a corresponding range of relaxation times [*28*]. As a consequence, the measured yield value will depend on the rate at which the stress is increased up to the point where flow occurs (the faster the rate of stress increase, the higher the measured yield value).[7]

[7]For this reason, yield stress values cited in the literature are meaningless unless the exact experimental methodology is provided.

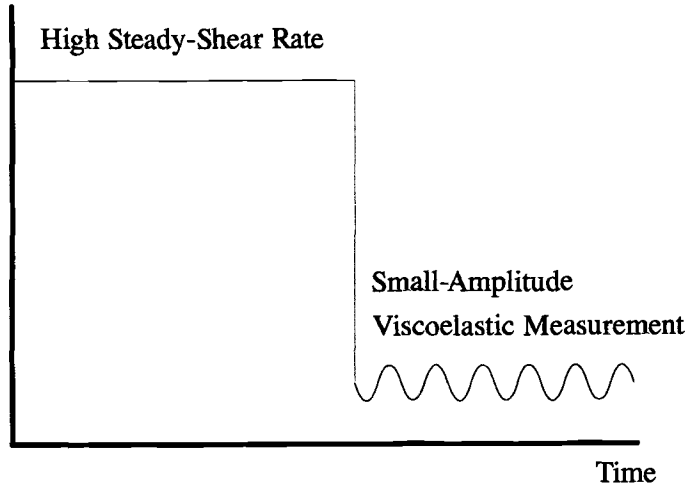

FIG. 10*a*—Viscoelastic characterization of structural recovery by step-shear method using small amplitude oscillatory strain for recovery phase.

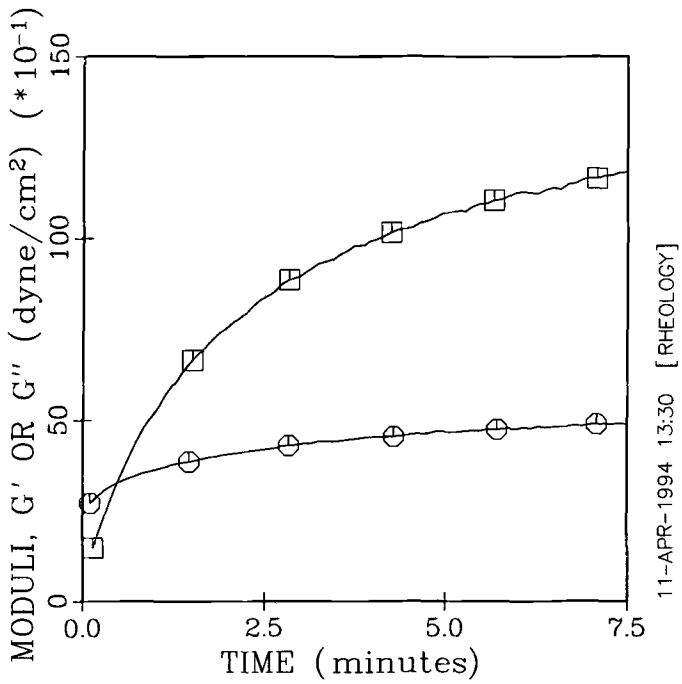

FIG. 10*b*—Experimental curves of *G'* (elastic modulus, □) and *G''* (viscous modulus, ○) versus time for a viscoelastic step-shear experiment.

Barnes and Walters [*29*] have claimed that most materials with an apparent yield stress will be found, in reality, to have a high but finite viscosity if measured at sufficiently low stresses. In practical terms, yield stress behavior can have important consequences for the processing, stability, and application of coatings. There is quite obviously some sort of flow discontinuity that occurs at low stresses, the magnitude of which is apparently related to the number and strength of interparticle attractive forces [*28,30*]. The yield stress is therefore an "engineering reality" [*31*] that must be taken into

account when formulating paints or dispersions. A yield stress may be desirable or undesirable depending on the process in question. Materials with a yield stress will often exhibit thixotropy and viscoelasticity as well.

Static Versus Dynamic Yield Stress

There are two types of yield stress which may be measured. The first is the static yield stress, measured by the startup of flow from nonflowing conditions. The second is the dynamic yield stress, which is the shear stress at which a presently fluid material suddenly turns solid (or exhibits a flow discontinuity). Experimental methods exist for measuring both [*32*], and the type which is relevant to the particular process in question should be the one measured. For example, for long-term suspension of solids or for start-up flow in pumps, the static yield stress is relevant. Postapplication leveling and sag behavior would be governed by dynamic yield stress characteristics, including the kinetics of structural recovery (see thixotropy in **Time-Dependent Fluids**). Some have used curve-fitting techniques to obtain a value for the yield stress by fitting a mathematical model for flow to a rheological flow curve. The Bingham, Herschel-Bulkley, and Casson models contain a yield stress term and have been commonly used to obtain a yield stress from measured flow behavior. Such methods are questionable, however, since one is attempting to infer a property of the solid state from behavior of the fluid [*25,33*].

Yield Stress Test Methods

Startup-of-flow methods include the use of penetrometer-type instruments such as a thermomechanical analyzer, where increasing force is applied to a standard probe. The yield stress is determined as the break point of a force-penetration curve [*34*].

In recent years, a new type of instrument known as a controlled-stress rheometer has become commercially available that is well-suited to measurement of yield stress and other properties of structured materials. For this instrument, the shear stress is the independent (or controlled) variable, while the dependent (or measured) variable is the shear rate. This allows an experiment to be done whereby the stress is gradually increased from zero or a very low value, registering zero shear rate (i.e., infinite viscosity) until the applied stress reaches the yield value, whereupon the viscosity becomes finite. The instrument reports this value as the measured yield stress. Another recent method employs a special vaned rotor to remedy problems of slip with yield-stress materials [*35–37*]. The vaned rotor consists of rectangular blades or vanes fixed to a rotating shaft. Advantages of this geometry are: (1) there is little disturbance of the sample when this type of probe is inserted, and (2) when the rotor turns, the material moves as a solid "cylinder." Thus, the shear surface is within the material itself, avoiding problems of wall slip.

Practical Aspects of Yield Behavior

Some of the practical consequences of yield behavior occur in the processing of, for example, pigment dispersions. Dispersions with high yield stresses may be difficult to dispense accurately or reproducibly via automatic metering systems. Pumps may actually refuse to move or may cavitate while attempting to pump such materials; solenoid valves may "freeze." Coatings with significant yield stresses may exhibit poor leveling [*2*] since, as the shear stress decreases during the course of the leveling process, the material effectively becomes immobile when the dynamic yield stress is reached.

On the other hand, a small yield stress can be of great value in inhibiting settling of particulate suspensions. One can easily calculate the shear stress exerted on the surrounding medium by a spherical particle falling under the influence of gravity

$$\tau = \frac{F_g}{A} = \frac{\text{Force of gravity on particle}}{\text{Surface area of particle}}$$

$$F_g = \frac{4}{3}\pi R^3(\rho_p - \rho_l)g; A = 4\pi R^2$$

$$\tau = \frac{R}{3}(\rho_p - \rho_l)g$$

where R is the particle radius, ρ_p the particle density, and ρ_l the liquid density.

For a titanium dioxide particle of radius 0.2 mm and density 4 g/cm^3, the shear stress due to gravity acting on the particle is about 0.2 dyne/cm^2. To prevent settling of such a particle, the surrounding medium need only resist with an opposing stress of greater than 0.2 dyne/cm^2. Even this, alas, is impossible for a Newtonian liquid, be it water or honey, since it will flow under all stresses no matter how slight (it is only a question of how slowly). A pigment particle will inevitably settle out of such a fluid, especially for viscosities of practical magnitudes. However, if the suspending medium possesses a yield stress equal to or greater than the particle shear stress, the particle "thinks" it is suspended in a solid and will be suspended indefinitely. This argument assumes more or less ideal yield behavior, which, as described above, may rarely be encountered. A medium with a measured yield stress of apparently sufficient magnitude may or may not permit the particle to settle over long periods of time due to the possibility of viscous flow below the apparent yield point. Therefore, to ensure adequate practical stability, one should build in a higher yield value than that calculated from the above.

Elastic Liquids (Viscoelasticity)

In ideal viscous flow, all energy input is converted either to heat or energy of motion. None is stored (i.e., none is converted into potential energy). Therefore, viscous flow results in irreversible deformation. Newtonian liquids show essentially ideal viscous (also called "inelastic") behavior over a wide range of deformation rate. For ideal elastic ("Hookean") substances, all the energy of deformation is stored, similar to a stretched rubber band. Consequently, elastic deformation is not permanent, but is in fact completely reversible. Real fluids can display elasticity, but mixed with viscous character, in varying degrees. Hence, the term *viscoelastic* is applied to such materials. Not all non-Newtonian fluids have significant elastic properties, but many do. The presence of significant elasticity in colloidal systems generally means there is a microscopic three-dimensional structure, or association network (microstructure), within the fluid. Elementary flow units are linked together in some fashion such that the struc-

tural relaxation time (see below) is measurably long. This structure, and particularly the destruction and rebuilding process that occurs during and after coating application, can have great consequences for application and film formation processes. An example of this is the influence of elasticity on leveling of an applied coating [*38*] (see also Massouda [*39*] and Glass [*40*]).

As the term implies, viscoelasticity refers to a material response which is a combination of viscous and elastic behavior. Viscous flow superimposed on elastic strain results in the "relaxation," or gradual disappearance, of stress within the strained object. This is manifested as an imperfect, or fading, stress memory. Figure 11 illustrates the material response to an applied elongational stress for a material with permanent stress memory (e.g., rubber band) and one with fading stress memory (e.g., "bouncing putty").

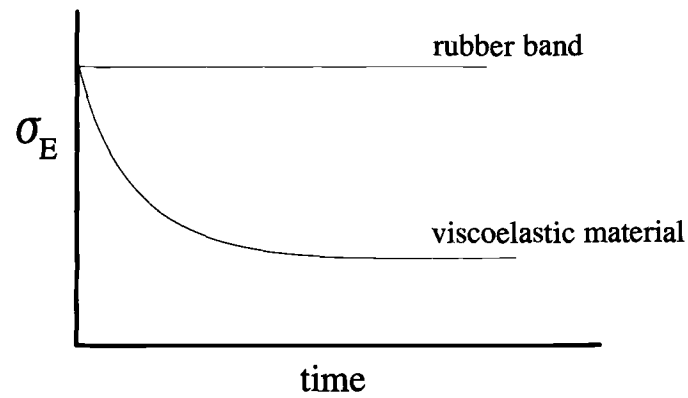

FIG. 11–Viscoelastic stress-memory loss: stretch-force experiment. Rubber band is cross-linked polymer, does not relax stress (σ_E) when stretched. Viscoelastic material can accommodate to strain by molecular motion (viscous flow), allowing elastic stress to decay.

The Viscoelastic Parameters and Their Measurement

A convenient way of experimental characterization of viscoelastic materials is by alternating the direction of strain (or stress). Most often, a sinusoidal deformation is employed (Fig. 12). The strain amplitude must be kept small so that the material response remains in the linear viscoelastic region where stress and strain are linearly related.[8] In perfectly elastic behavior (Hookean spring), the stress and strain are "in phase" with each other, that is, upon deformation, the maximum stress and maximum strain occur at the same instant in time. If there is any viscous (energy-loss) component in the material response, the stress and strain maxima will not be coincident, but will be "out of phase." This happens because viscous flow relieves the stress within the material, causing the stress maximum to occur before the strain maximum. That is, as the rate of strain decreases near the maximum (or minimum) of the strain sine wave, stress relaxation "catches up" and overtakes the stress-building effect of the strain. The separation in time of the stress and strain maxima is called the *phase shift* (or *phase angle*, the fraction of a complete cycle in degrees or radians that the phase shift represents). The phase shift is often given the symbol δ. The faster the viscous stress-relaxation process, the earlier in the cycle the stress maximum will occur, i.e., the larger the phase shift will be. The limiting value of the phase angle for purely viscous liquids is 90° (see Fig. 12). The reason is that, for sinusoidal deformation, the maximum strain rate (maximum slope of the strain sine wave) occurs 90° ahead of the maximum strain, and that, for Newtonian liquids, the stress is proportional to strain rate. Therefore, the maximum stress must occur at the maximum strain rate, which corresponds to a phase shift of 90°.

The derivation of viscoelastic parameters from a sinusoidal shear experiment begins with the calculation of the complex shear modulus, G^* (refer to Fig. 13). This is simply the ratio of the maximum stress, σ_0, to the maximum strain, γ_0 ($G^* = \sigma_0/\gamma_0$). From G^* may be separated G', the modulus of elasticity (storage modulus), and G'', the viscous modulus (loss modulus). Figure 13 demonstrates the geometric relationship of G^* to its in-phase and out-of-phase components, G' and G'', governed by the phase angle, δ. It is obvious from geometry

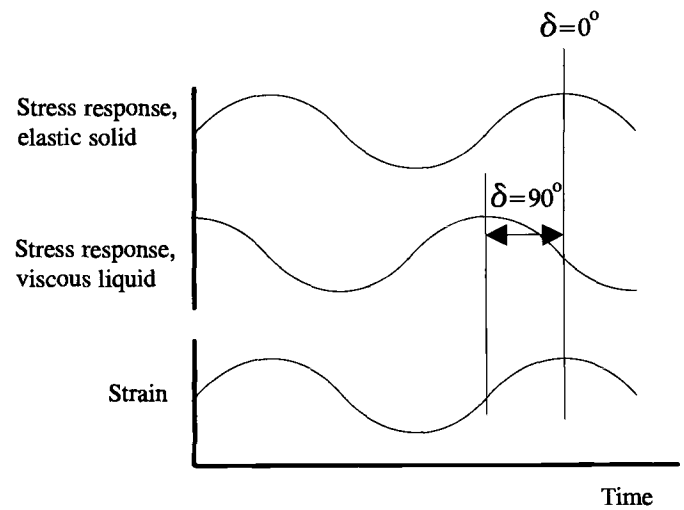

FIG. 12–Phase shift δ for ideal viscous and elastic bodies.

that when δ is zero, $G^* = G'$, and when $\delta = 90°$, $G^* = G''$. The physical meaning is that, when $\delta = 0$, all of the measured modulus is due to elastic effects, and when $\delta = 90°$, the modulus consists entirely of viscous effects. This follows from the discussion of the phase shift, above. By trigonometry, $G' = G^* \cos \delta$ and $G'' = G^* \sin \delta$. Alternately stated, G' is the component of the complex shear modulus which is in phase with the strain. G' therefore represents the elastic part of viscoelastic behavior. The viscous component (G''), on the other hand, is derived from the part of the modulus which is out of phase with the strain, but in phase with the strain rate.

Consider a dynamic test in which a sinusoidally varying strain is applied to a viscoelastic material. The angular frequency of the deformation is given by $\omega = 2\pi f$, where f is the frequency of oscillation (s^{-1}) and ω is in rad/s. Now, the amplitude of the strain with time is given by

$$\gamma = \gamma_0 \cos \omega t \tag{19}$$

which describes a cosine wave of maximum amplitude γ_0 and period $1/\omega$. The strain rate experienced by the material is then

$$\dot{\gamma} = -\omega\gamma_0 \sin \omega t \tag{20}$$

[8]This is a requirement because the equations used are valid only in the linear viscoelastic region.

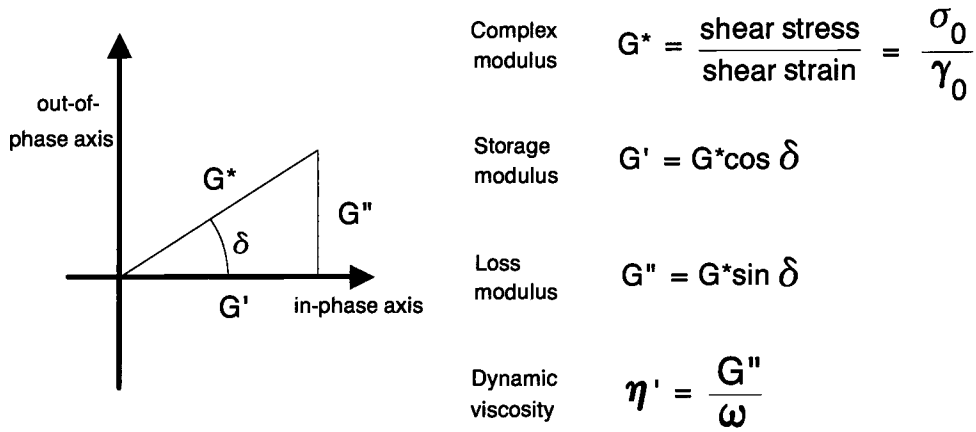

FIG. 13–Viscoelastic relationships in the complex plane.

The oscillating strain produces a stress response

$$\sigma = \sigma_0 \cos(\omega t + \delta) \tag{21}$$

where δ is the phase shift, advancing the phase of the stress relative to the strain. Equation 21 may be equivalently written [*96*]

$$\sigma^* = \sigma_0 \cos\delta \cos\omega t - \sigma_0 \sin\delta \sin\omega t \tag{22}$$

which describes a complex stress, where, by complex plane relationships analogous to Fig. 13, $\sigma_0 \cos\delta$ is the stress component in-phase with strain and $\sigma_0 \sin\delta$ the stress component which is out-of-phase with the strain (but in-phase with the strain rate). We therefore can define a dynamic viscosity, η', as the quotient of the stress in-phase with the strain rate divided by the strain rate

$$\eta' = \frac{\sigma_0 \sin\delta}{\dot{\gamma}_0} = \frac{\sigma_0 \sin\delta}{\gamma_0\omega} = \frac{G^* \sin\delta}{\omega} = \frac{G''}{\omega} \tag{23}$$

The above expression is obtained using the relationships $\dot{\gamma}_0$ (strain-rate amplitude) $= \gamma_0\omega$ and $G^* = \sigma_0/\gamma_0$.

The magnitudes of G'' and G' reveal the relative importance of viscous and elastic behavior in the mechanical response of a material. In Fig. 13, again by trigonometry, the tangent of the phase angle equals the ratio G''/G'. Thus, tan δ quantifies the balance of energy loss to energy storage measured under certain conditions of temperature, pressure, and frequency or rate of deformation. For solids, tan δ can be useful to predict the likelihood of brittle or ductile failure of a polymer or the sound absorption or vibration damping properties. For liquids, tan δ can monitor the progress of fluid restructuring in thixotropic recovery. The latter may be useful in computing sag resistance for when tan δ becomes less than unity, the system has essentially become immobolized (i.e., reached a "dynamic yield point"). When tan $\delta > 1$, viscous flow (i.e., a steady-state viscosity) is possible. When tan $\delta < 1$, however, the material is more elastic than viscous (i.e., a percolating network extends throughout the bulk, and it is essentially an elastic solid).

Viscoelastic Models

It turns out that viscoelasticity can be rather realistically modeled by simple mechanical analogues. These are useful not only as an aid to conceptualization of viscoelastic behavior, but also in helping to understand the elementary mathematics of viscoelasticity. As we have said, viscoelasticity is a combination of two idealized behaviors: Hookean elasticity and Newtonian viscosity. The mechanical analogue of Hookean behavior is a spring of force constant G, and that of Newtonian flow is a "dashpot" (a piston-in-cylinder filled with a viscous fluid of viscosity η). These elements are combined in various ways to model viscoelastic mechanical response.

To build our first model, we will connect a spring and dashpot in series (Fig. 14), an arrangement known as the Maxwell model. To imagine what response the model has, let's apply a constant stress, σ_0, to one end, the other being fixed. By the way, our dashpot is considered to be infinitely long so that the piston never runs out of travel. This being the case, one can see that an equilibrium strain would never be reached, but the dashpot would continually move as long as the stress is applied. Since the model can "flow" without limit, this is obviously a model for viscoelastic liquids (sometimes called "elasticoviscous"). We have just described what is known as a creep experiment, in which a sudden stress σ_0 is applied, and the evolution of strain, or deformation, is followed with time. The creep of a Maxwell liquid is not very interesting, however. The strain-time curve consists merely of a straight line with intercept equal to σ_0/G and slope of σ_0/η (Eq 26).

We will use the Maxwell model to illustrate how equations describing viscoelastic behavior may be derived. Just as the stress is the same in every part of a stretched string, so is the stress the same on both elements for the Maxwell model, and also, therefore, the rate of change of stress is identical as well.

$$\sigma_{\text{Total}} = \sigma_{\text{Elastic}} = \sigma_{\text{Viscous}} (= \sigma_0) \tag{24}$$

and

$$\dot{\sigma}_T = \dot{\sigma}_E = \dot{\sigma}_V \tag{25}$$

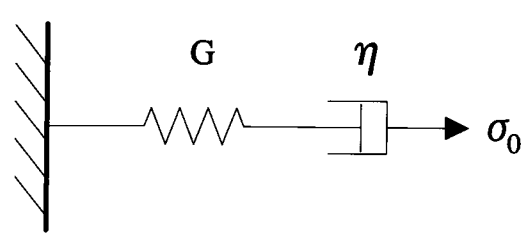

FIG. 14–Maxwell model. *G* is force constant of spring; η the viscosity of dashpot fluid; σ_0 is the applied stress.

Furthermore, the total strain is clearly the sum of the strains undergone by the two elements

$$\gamma_T = \gamma_E + \gamma_V = \frac{\sigma_E}{G} + \frac{\sigma_V t}{\eta} \tag{26}$$

The expression on the right follows from the definition of the modulus ($G = \sigma/\gamma$), Eq 4, and the fact that $\gamma = \dot{\gamma}t$. It is also true that

$$\dot{\gamma}_T = \dot{\gamma}_E + \dot{\gamma}_V = \frac{\dot{\sigma}_E}{G} + \frac{\sigma_V}{\eta} \tag{27}$$

An alternative to the creep method that is particularly useful for viscoelastic solids is to apply a sudden deformation and follow the decay of stress with time. This is similar to the experiment depicted in Fig. 11 and is known as *stress relaxation.* Sudden imposition of a strain γ_0 results in instantaneous lengthening of the spring. The dashpot experiences, in turn, an initial stress σ_0 from the extended spring, causing a gradual movement of the dashpot's piston, resulting in relaxation of the stress. By manipulation of the above equations, we can arrive at a quantitative way of describing this relaxation process.

Since the strain in a stress-relaxation experiment is constant (γ_0), the total strain rate, $\dot{\gamma}_T = 0$. Therefore, from Eq 27

$$\frac{\sigma_V}{\eta} = -\frac{\dot{\sigma}_E}{G} = -\frac{d\sigma/dt}{G} \tag{28}$$

rearranging

$$\frac{d\sigma}{\sigma_V} = -\frac{G}{\eta}dt \tag{29}$$

Integrating Eq 29 from time 0 to time t results in the Maxwell stress relaxation expression

$$\sigma = \sigma_0 e^{-Gt/\eta} \tag{30}$$

Figure 15 illustrates the decay of stress in a constant strain or stress relaxation experiment for the Maxwell model, described by Eq 30. Note that the quantity η/G has the dimension of time. We will assign to this quantity the symbol λ and refer to λ as the stress-relaxation time constant. It can be seen from Eq 30 that when $t = \eta/G$, $\sigma = \sigma_0/e$. Therefore, λ represents the time required for the stress to fall to $1/e$ of its initial value (Fig. 15) and gives a convenient way of quantifying the rate of decay of stress in viscoelastic materials.

The time constant, λ, could also be called the stress memory time constant since it is related to the time it takes for a viscoelastic material to "forget" its initial elastic stress level when subjected to a constant strain. As such, λ determines the role that viscoelasticity plays in an industrial process. That is, elastic materials generate an "extra (elastic) stress" when deformed, which may result, for example, in the stabilization of fluid structures which would ordinarily collapse too quickly to be important. These include, for example, liquid fibers and webs, which result in roller spatter [*41*]. The magnitude of the undesirable effect will depend on the rate at which the elastic extra stress decays or "relaxes," as we'll see below.

In modern rheometers, sinusoidal oscillation is the most common method of viscoelastic characterization. (Creep is also available as a viscoelastic test mode for controlled-stress instruments and stress relaxation for controlled-rate instruments—see below.) Equations derived for the Maxwell model [*42,43*] show how the viscoelastic time constant, λ, may be obtained from the oscillatory data

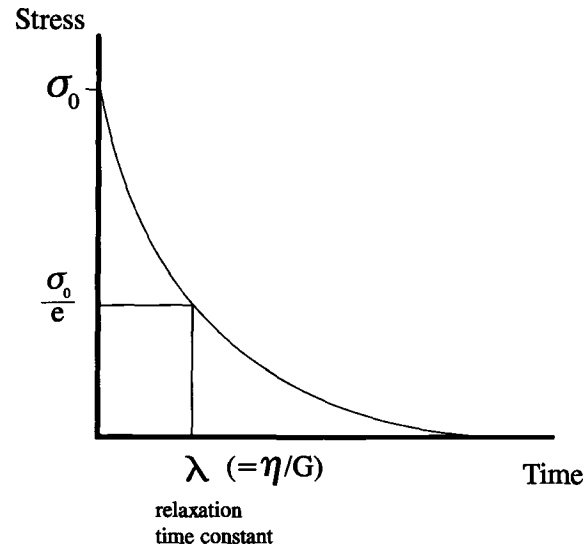

FIG. 15–Stress relaxation (constant strain) experiment. Initial elastic stress σ_0 relaxes viscously with a time constant λ (= η/G). λ corresponds to the point where stress has fallen to a value σ_0/e.

$$\eta'\omega = G'' = \frac{G_\infty \omega\lambda}{1 + \omega^2\lambda^2} \tag{31}$$

and

$$G' = \frac{G_\infty \omega^2\lambda^2}{1 + \omega^2\lambda^2} \tag{32}$$

from which

$$\tan\delta = \frac{G''}{G'} = \frac{1}{\omega\lambda} \tag{33}$$

where G_∞ is the plateau modulus (limiting value of G' reached at high frequency = Maxwell spring constant). Equation 33 says that when G' and G'' cross over ($\tan\delta = 1$), $\lambda = 1/\omega_c$ (ω_c is the crossover frequency). The plateau modulus can be obtained from Eq 32, as well, since at the crossover point $G_\infty = 2G'$. Similarly, at crossover, the zero-frequency plateau viscosity, $\eta_0 = 2\eta'$ (from Eq 31).

If the mechanical elements are connected in parallel rather than series, they each experience identical strain, but the stresses are now additive. This arrangement is called the Kelvin-Voigt model (Fig. 16). Because the elements are now in parallel, the Kelvin-Voigt model can only undergo finite strain, limited by the extensibility of the spring. Therefore, this is a model for a viscoelastic solid below its yield point. Equations for creep, stress relaxation, and $\tan\delta$ for the Kelvin-Voigt model are

Kelvin-Voigt creep

$$\gamma = \frac{\sigma_0}{G}(1 - e^{-t/\lambda}) \tag{34}$$

Kelvin-Voigt stress relaxation

$$\sigma = \gamma_0 G \tag{35}$$

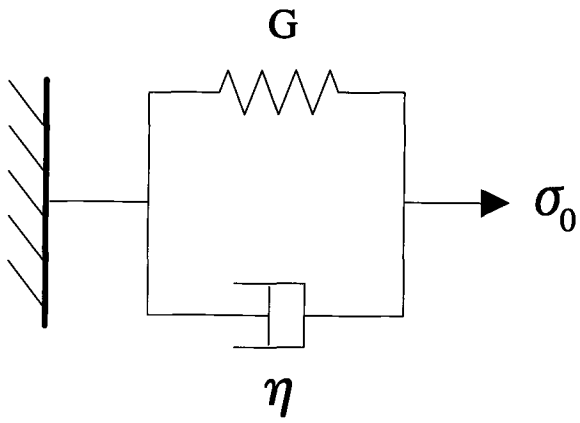

FIG. 16–Kelvin-Voigt model. Symbol definitions same as Fig. 14.

$$\tan \delta = \omega\lambda \tag{36}$$

These equations describe an exponentially increasing strain at constant stress (see Fig. 17 and Eq 34) and a nonrelaxing stress at constant strain (Eq 35), respectively.

The Maxwell and Voigt models, by themselves, are too simple to describe accurately most real viscoelastic materials. However, a Maxwell element connected in series with a Kelvin-Voigt element turns out to model the linear viscoelasticity of many real systems rather well. Figure 18 shows such an arrangement, known as the Burgers model. For completeness (and also because an error in the Burgers stress-relaxation expression has crept into the literature), equations describing creep and stress relaxation behavior for the Burgers model are given

Burgers creep

$$\gamma = \frac{\sigma_0}{G_2} + \frac{\sigma_0 t}{\eta_2} + \frac{\sigma_0}{G_1}(1 - e^{-t/\lambda_1}) \tag{37}$$

Burgers stress relaxation

$$\sigma = \gamma_0 G_2 e^{-t/\lambda_2} + \gamma_0 G_1 \tag{38}$$

where $\lambda_1 = \eta_1/G_1$ and $\lambda_2 = \eta_2/G_2$. The creep and stress relaxation behavior for the Burgers model are shown in Figs. 19 and 20. Modern rheometers of the type known as "controlled stress" (see **Rotational Instruments**) are capable of performing creep measurements. Viscoelastic constants can

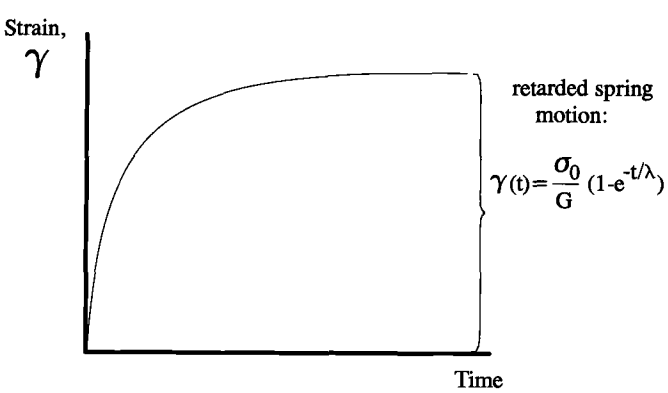

FIG. 17–Kelvin-Voigt creep (constant stress) experiment. At constant applied stress σ_0, strain increases exponentially with time constant λ (= η/G).

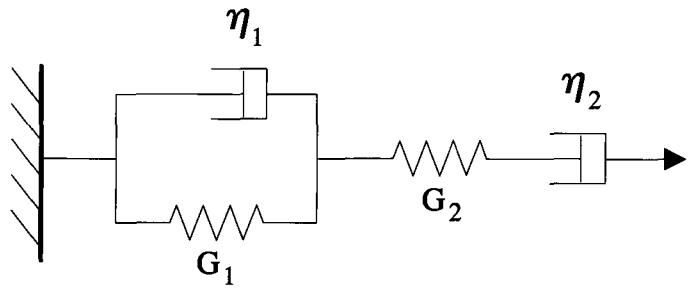

FIG. 18–Burgers model. Symbol definitions same as Fig. 13. Subscript 1 refers to the Voigt element, 2 to the Maxwell element.

then be extracted from the data by analysis according to one or more of the above models.

Viscoelasticity and Industrial Processes

Now, since industrial processes are of many types, how do we assess the effect of elasticity on a given process? That depends in part on the length of time the process stress is applied to the material. That is, what's most important is not how rapidly a stress is applied nor even the magnitude of the stress, but for how long the stress is applied relative to the time required for any elastic "extra" stress to decay. This suggests taking a ratio of the stress relaxation time, λ, to the time (duration) of the process stress, t

$$De = \frac{\lambda}{t} \tag{39}$$

This ratio is a defined rheological term known as the Deborah number, *De*. It is named for the Biblical prophetess Deborah, who prophesied that the "mountains flow before the Lord" [*44*]. This is a perfectly accurate statement, made long before being verified by the science of geology, of the fact that, on God's time scale, rock formations can be observed to undergo permanent deformation, or flow. In other words, if the stress time scale, t, greatly exceeds the relaxation time, λ ($De \ll 1$), the material will respond as a viscous fluid (because elastic stress has time to decay). Conversely, if $De \gg 1$, the stress duration is too brief to provide an opportunity for viscous relaxation, and the material behaves as if an elastic solid. Thus, the Deborah number quantifies the proportion of elastic to viscous control of a process. This is one reason why a determination of the viscoelastic properties of paints and coatings is important. The results of an analysis by Keunings [*38*] of the effect of viscoelasticity on leveling can be adapted to the situation of a typical paint, and the influence of the elastic-stress relaxation time constant on leveling rate is shown in Table 4. To be sure, real materials may not exhibit simple exponential stress decay (i.e., a single relaxation time), but rather may possess a spectrum of relaxation times. However, the mechanical response will be dominated by a "mean" relaxation time (or sometimes the longest relaxation time [*38*]), obtained from experiments such as described in foregoing sections. Simple viscoelastic dispersions can show Maxwellian behavior with a single relaxation time [*45,46*].

One of the reasons that associative thickeners (ATs) have been so successful in being able to thicken paints without at the same time adversely affecting flow and leveling is no doubt due in part to their low elasticity. Even though ATs

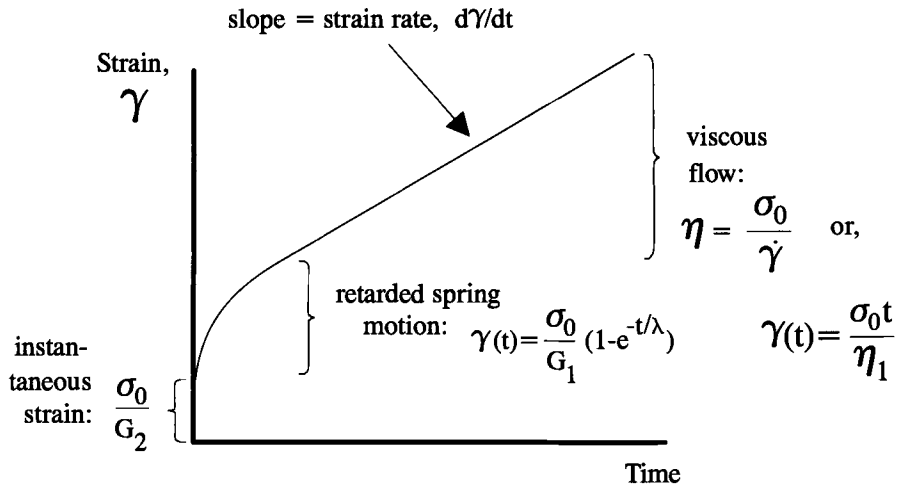

FIG. 19–Burgers creep (constant stress) experiment. Under applied stress σ_0, the Burgers model undergoes instantaneous deformation equal in magnitude to σ_0/G. In next segment of curve ("retarded spring motion") strain increases exponentially with time. Finally, spring is fully extended and viscous flow occurs with a constant strain rate.

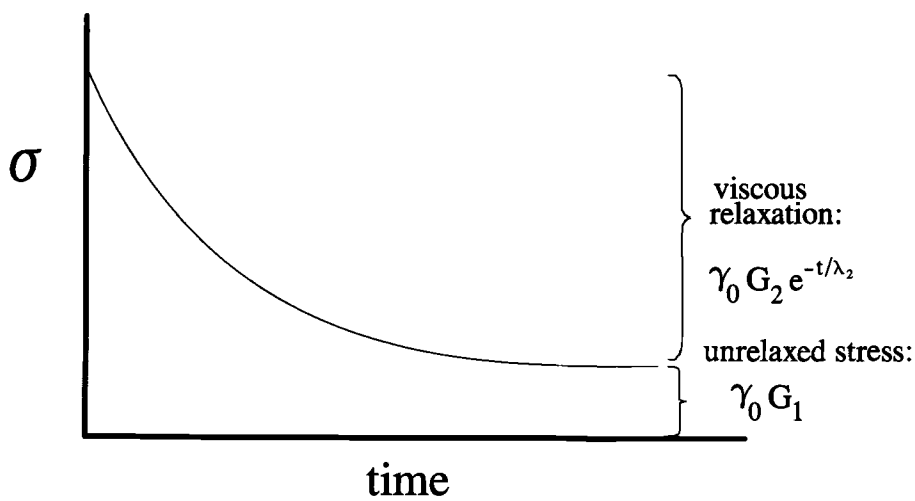

FIG. 20–Burgers model stress relaxation (constant strain). Stress generated by initial strain γ_0 decays exponentially governed by the relaxation time λ_2 (= η_2/G_2). Voigt element contributes unrelaxed stress $\sigma_\infty = \gamma_0 G_1$.

TABLE 4—Leveling rate dependence on Maxwell relaxation time, λ. $\alpha = da/dt$, where a = roughness amplitude, and $t_{1/2}$ = time for $a \rightarrow 0.5a_0$ (initial amplitude).

λ, s	0.0	0.1	1.0	10.0	50.0	100.0
α, s^{-1}	34.5	7.75	0.972	0.0997	0.02	0.01
$t_{1/2}$	0.020	0.09	0.67	6.95	34.7	69.3

generate a three-dimensional network structure within the fluid,[9] they typically would have negligible G' values, in contrast to typical cellulosic thickeners, for example. This is believed to be due to the extreme lability of the micellar junctions of the associative network, resulting in very short network relaxation times [*46,47*]. Thus, the decay of elastic stress in ATs is so rapid that such stresses are virtually unobserved ($De \ll 1$).

[9]See Chapter 30—Thickeners and rheology modifiers.

As stated before, the process consequences of viscoelasticity stem partly from the stabilization of otherwise unstable liquid structures by the elastic "extra stress." Thus, liquid fibers and "webs" which would ordinarily collapse by surface tension are stabilized, producing, for example, excessive rollcoat spatter (or "misting") and ribbing, and inhibiting atomization of sprayed materials. The importance of viscoelasticity for a particular process is gauged, using the Deborah number, by the ratio of the stress-relaxation time constant to the time duration of the process stress. Of course, both the magnitude and lifetime of the elastic stress will be important, for together they will govern the degree of stabilization.

The analysis of the problem is complicated by the fact that many processes, particularly of coatings application, involve strain magnitudes outside the range of linear viscoelasticity. Approaches to nonlinear viscoelasticity exist, but are beyond the scope of this chapter. Quantitative prediction of viscoelas-

tic effects would require the use of a model for the fluid behavior, or viscoelastic constitutive equation, also outside the scope of this presentation. However, it is often possible to build experimental correlations between coating elasticity and performance problems, so that guidance may be provided for formulation efforts to solve them.

For most modern coatings, in particular, the origin of elasticity is likely to be an associated structure built up from a dispersed phase rather than polymeric entanglement. Such particulate flocs are generally shear-sensitive and are reduced or destroyed by high-shear application processes. The elastic modulus G' will be seen to decrease with increasing strain and strain rate outside the linear regime. Thus, in most cases, G' is a measure of structure that has its greatest effect at low strain and strain rate (unless the elastic character is high-polymeric in origin). Therefore, under most conditions of application, structure (therefore elasticity) is destroyed and must rebuild in the applied film. Herein, it is seen that thixotropy and viscoelasticity are kindred phenomena.

EXTENSIONAL RHEOLOGY

The other important deformation occurring in coatings besides simple shear is extensional (or elongational) deformation. Extensional or "stretching" deformation causes an increase in length and decrease in cross section of an object. In a simple shear field, particles or polymer coils (i.e., the flow units) rotate with a velocity $\dot{\gamma}/2$. The rotational motion lessens the friction between the solvent and solute particles. In an extensional flow, this rotational accommodation to the flow field is not possible because there is no velocity gradient normal to the flow direction. The separation of flow units is thus more costly in terms of energy dissipation due to friction. Thus, the viscosity of a Newtonian fluid in extension turns out to be three times greater than its viscosity measured in shear (Trouton rule).

The extensional viscosity (η_e) is calculated as the ratio of tensile stress to extensional deformation rate

$$\eta_e = \frac{\sigma_e}{\dot{\epsilon}} \tag{40}$$

The strain in extension is usually defined as a Hencky strain, $\epsilon = \Delta l/l_0$, where l_0 is the original length and Δl the increase in length under tensile stress σ_e. The Hencky strain rate is then the time derivative of the strain or

$$\dot{\epsilon} = \frac{1}{l}\frac{dl}{dt} = \frac{d(\ln l)}{dt} \tag{41}$$

Extensional Viscosity in Coatings Processes

Many coatings processes involve stretching (elongational) flows (Table 1), and when coatings can support large extensional stresses (i.e., high extensional viscosity) performance can be dominated by such flows. As mentioned, the viscosity of a Newtonian liquid in extension is three times that measured in shear. For non-Newtonian fluids, the Trouton ratio $[\eta(\dot{\epsilon})/\eta(\dot{\gamma})]$ can be as much as 10^4. Furthermore, whereas the shear viscosity is usually a decreasing function of shear rate, extensional viscosity frequently displays strong extensional strain rate thickening. For example, Lu [*48*] observed that polyacrylamide thickeners in latex paint systems showed extensional thickening behavior, whereas hydroxyethylcellulose-type thickeners did not. Coatings application processes are generally high strain rate, so it is clear that η_e can dominate the mechanical response, generally leading to detrimental consequences. Extensional stresses can stabilize liquid "webs" and fibers, such as form in direct rollcoating, allowing them to grow large instead of dissipating. This can result in heavy ribbing and "misting" (roll spatter) [*49*]. On the other hand, the breakup of a liquid jet to form atomized droplets in spray application is suppressed by a high extensional viscosity because the liquid fibers formed intermediary to droplet formation are inhibited from disintegration. J. E. Glass has been the chief proponent of the study of extensional viscosity in relation to paint performance, correlating it to roller spatter [*41*] and the performance of sprayed coatings [*50*]. Massouda did a clever and, unfortunately overlooked study of the relationship of extensional stress measurements to viscoelastic relaxation kinetics and thence to spattering of paints [*39*].

Extensional Viscosity Measurement

There are, unfortunately, few commercial instruments suitable for extensional measurement on coatings. Carri-Med (division of TA Instruments) markets the Spin-Line Rheometer (SLR) utilizing the fiber-spinning geometry. Rheometrics' RFX rheometer is probably better suited to low-viscosity fluids, using opposed-nozzle flow to measure extensional forces (the latter instrument offers dual high-shear and extensional measurement capability). With the necessary electromechanical design and fabrication resources, one might attempt to build a simple extensional rheometer, perhaps patterned after that of Gupta [*51*]. The relatively simple technique of convergent flow analysis was used by Lu for measuring extensional properties of latex paints [*48*]. An overview of extensional rheometry has recently been published by James and Walters [*52*].

POLYMER MELT AND SOLUTION RHEOLOGY

High-polymer solution rheology is a subject of relatively little interest with respect to coatings due to the shift from solvent-borne to environmentally compliant technologies, such as water-borne, higher solids, and powder coatings. The polymers used for high solids and powder coatings are little more than oligomers in order to achieve necessary flow for satisfactory processing and film formation. Even the modest molecular weight polymers used in solvent-borne varnishes and paints are below the entanglement molecular weight, M_c, hence, both their neat and solution rheology are Newtonian. Similarly, powder coating melts are Newtonian until near gelation [*53*]. The viscosity of polymer solutions below M_c is proportional to the weight-average molecular weight, M_w,

$$\eta_0 = KM_w (M_w < M_c) \tag{42}$$

where K is a constant dependent on chain flexibility (T_g), polymer-solvent interaction, temperature, etc. If $M_w > M_c$,

the motion of entangling polymers becomes much more complex, and the viscosity now depends on M_w raised to the power of approximately 3.4 [54].

$$\eta_0 = KM_w^{3.4} (M_w > M_c) \tag{43}$$

The viscosity of polymer melts follows a similar relationship. It should be noted that polymers having highly polar or hydrogen-bonding functionalities (such as commonly used in high-solids formulations) can show nonlinear dependence of viscosity on molecular weight even below M_c due to transient intermolecular associations [55].

The sole use of high-polymer binders in coatings today is where they exist as a separate phase dispersed in a liquid carrier medium.[10] Such materials are known as polymer latexes, or latex dispersions. Because the latex polymer is segregated from, and therefore noninteracting with, the solvent, the rheology of latexes is much simpler than that of the same high polymer in the solution state. The rheology of polymer dispersions will be discussed below.

DISPERSION RHEOLOGY

A dispersion (or suspension) consists of a suspended or dispersed discontinuous phase contained in a continuous phase. As an example, for coatings in particular, this might be a system in which a fine particle size solid is wetted by and thoroughly mixed in a liquid. However, the dispersed phase may be a liquid or semisolid (or gaseous) as well. The dividing line between dispersions and suspensions is essentially one of particle size. Dispersions are generally of colloidal dimension, about 10 nm to 1 μm. Due to their small size and mass, colloidal particles are very slow settling or nonsettling because Brownian motion effectively keeps them randomly suspended. Suspensions range in size above 1 μm and generally exhibit rapid settling because Brownian forces are ineffective with such massive particles, and also because Van der Waals attractive forces increase in proportion to particle size.

Addition of a particulate phase to a liquid modifies its viscosity and sometimes its rheology. The modification to the continuous-phase viscosity made by an added particulate phase depends on characteristics of the particle and on the particle concentration. The contribution of a single particle to the viscosity of a dispersion is characterized by its intrinsic viscosity (or limiting viscosity number), $[\eta]$. The primary factors governing $[\eta]$ are particle shape and deformability. The influence of particle concentration on viscosity is expressed by the volume fraction (or internal phase volume) ϕ, the fraction of the total volume of the suspension occupied by the suspended material and which is a dimensionless number. A convenient way of expressing the effect of a dispersed phase on the viscosity of a liquid is by normalizing the dispersion viscosity to the pure-liquid viscosity. This ratio is termed the relative viscosity η_r and is also dimensionless.

$$\eta_r = \frac{\eta_d}{\eta_l} \tag{44}$$

[10]Some high-molecular-weight, water-soluble polymers are used as thickeners. However, they are used at low levels, and their effects on rheology are mainly colloidal/osmotic rather than as solution polymers.

It is reasonable that the viscosity of a liquid will be augmented by a factor equal to the product of the particle intrinsic viscosity and the concentration of particles.

$$\eta_r = 1 + [\eta]\phi \tag{45}$$

Einstein [56] was the first to calculate the intrinsic viscosity for noninteracting rigid spheres in a Newtonian liquid and obtained the number 2.5

$$\eta_r = 1 + 2.5\phi \tag{46}$$

The intrinsic viscosities of other particle shapes (e.g., prolate and oblate spheroids—discs and rods) have been calculated [57] and are always greater than 2.5. This means that any deviation from spherical particle shape will increase dispersion viscosity. Equation 46 is valid only in the very dilute regime ($\phi < 0.05$). Batchelor [58] extended the rigorous treatment to somewhat higher volume fractions by using a second-order expression in ϕ

$$\eta_r = 1 + 2.5\phi + k\phi^2 \tag{47}$$

The value of k ranges from 5.2 to 6.2. Figure 21 illustrates the typical dependence of η_r on ϕ for actual dispersions (using data of Eilers [59]) and shows curves corresponding to the predictions of Einstein's and Batchelor's equations. It can be seen that Batchelor's equation predicts a finite viscosity at $\phi = 1$, which is not realistic. Also in Fig. 21, it is seen that η_r rises toward infinity at a volume fraction considerably smaller than unity. The volume fraction corresponding to $\eta_r \rightarrow \infty$ is denoted ϕ_m, the maximum volume fraction, or maximum packing fraction. At $\phi = \phi_m$, the density of particle packing is such that the dispersion can no longer flow. The value of ϕ_m will be system-dependent and will be determined by particle shape, particle-size distribution, the ionic strength of the medium, the degree of particle flocculation, and the exact manner in which the particles arrange themselves (pack) in three-dimensional space.

Numerous models have been proposed to take account of the limiting concentration parameter ϕ_m [15,59–61]. Probably the model which has been most successful in fitting a variety of data is the Krieger-Dougherty equation [62]

$$\eta_r = \left(1 - \frac{\phi}{\phi_m}\right)^{-[\eta]\phi_m} \tag{48}$$

Figure 21 shows the fit of the Krieger-Dougherty model to some data of Eilers [59] with a value of $[\eta]$ close to the Einstein value. The maximum packing fraction will, in fact, have different, unique values at low and high shear rates because the strength of the shear field determines the way particles pack together. Recent reviews of the rheology of polymer colloids are recommended for further reading [6,14].

It should be noted here that, although the dispersion rheology is controlled by the disperse-phase volume fraction, ϕ, the effect of the particle phase on the rheology may be greater than expected on the basis of the volume of material added to make up the dispersion. This is because the disperse-phase volume may be augmented by various effects tending to increase the effective particle radius. It is the "hydrodynamically effective" particle volume that determines the rheology. Thus, the rheological behavior will be found to scale with the "effective" volume fraction, ϕ_e, rather than with

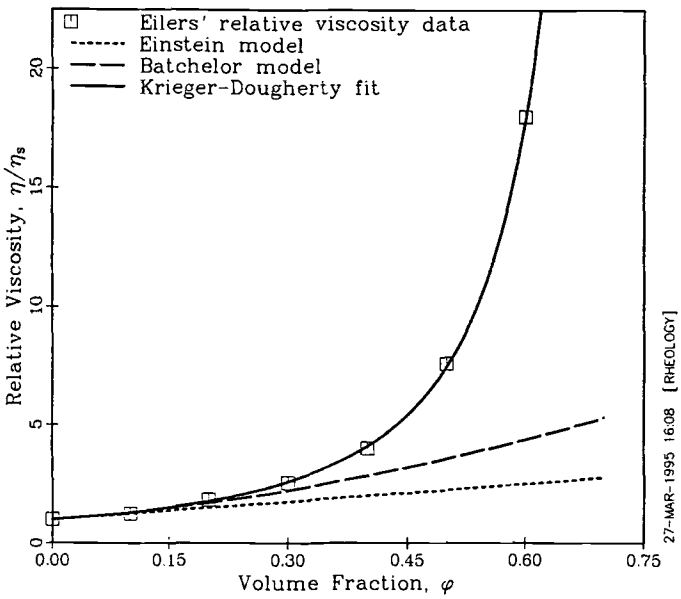

FIG. 21–Relative dispersion viscosity data of Eilers, together with best-fit curves for the Einstein model, Batchelor model, and the Krieger-Dougherty model.

the formulated volume fraction, ϕ. The effective particle radius can be increased in a number of ways, often as a consequence of employing various methods of achieving stabilization of dispersions. Adsorption of a polymeric stabilizer onto the surface of a particle adds the thickness of the stabilizer layer to the particle radius. This layer prevents the close approach and flocculation of particles by steric interactions between stabilizer layers, resulting in steric stabilization. If the thickness of the steric stabilizing layer on the particle is δ, the effective volume fraction is [*63*]

$$\phi_e = \phi\left[1 + \left(\frac{\delta}{R}\right)^3\right] \tag{49}$$

where R is the original particle radius. Quantitative viscometric methods have been developed for inferring the adsorbed-layer thickness [*63,64*].

Aqueous dispersions are often stabilized by association of repulsive electrical charge with the particle, known as electrostatic stabilization. The charge may be due to adsorption of ions, anionic or cationic surfactants or polyelectrolytes, or, in the case of polymer colloids, to the presence of ionizable groups which are part of the polymer molecules. (In the case of functionalized polymer latexes, such groups tend to migrate to the particle surface.) The surface ionic charge propagates an electrical potential field into the aqueous phase, depending on the ionic strength of the medium. In the presence of dissolved counterions, an ionic "atmosphere" develops around the charged particle. These phenomena are the origin of the so-called electroviscous effects, which have to do with the way the electrical field surrounding the particle affects the effective volume fraction or collision cross section, and the nature of the hydrodynamic interaction between particle and surrounding liquid [*57,65*]. Dispersion rheology can be greatly altered as a consequence of these effects, as the solution ion concentration or pH are varied. Krieger and Eguiluz showed the η_r of a dispersion of uniform polystyrene latex spheres (ϕ = 0.4) decreased from 10^6 to 10 for a two-orders-of-magnitude increase in concentration of electrolyte [*66*]. In that study, the low-electrolyte latexes exhibited apparent yield stress behavior, a consequence of the increase of the effective volume fraction of the latex particles due to the expansion of the repulsive electrostatic field. The effect is so great that the particles are actually "locked" into crystalline arrays that can diffract light, producing striking iridescent colors. As the electrolyte concentration is increased, the counterion "cloud" both shrinks the electrostatic field and shields particle fields from each other. Consequently, the viscosity drops dramatically (remember that the volume change depends on the cube of the radius change).

Rheology is particularly useful for dispersion characterization because of its sensitivity to microstructure. Dispersion rheology has two broad aspects: (1) the dependence of viscosity on the concentration of the dispersed phase, and (2) the dependence of viscosity on shear stress and shear rate, discussed in **CLASSES OF NON-NEWTONIAN BEHAVIOR.** To the foregoing are added effects of particle shape, rigidity, particle size and particle size distribution, and interparticle forces, both attractive and repulsive. All these factors combine to determine the microstructure of the dispersion and hence its rheology.

Dispersions can exhibit the full range of rheological behavior mentioned previously, including Newtonian, shear-dependent, time-dependent, plastic, and elastic behavior. A dispersion of noninteracting spherical particles will be Newtonian up to about ϕ = 0.2 [*15*]. Above this point, onset of non-Newtonian character begins due to particle interactions and hydrodynamic factors. Mechanisms for these effects are discussed in the section entitled **Shear-Thinning Fluids.**

SAGGING

A coating layer on any but a horizontal surface will experience a tangential shear stress due to gravity of magnitude

$$\tau = \rho g h \cos\theta \tag{50}$$

where ρ is the liquid density, g the gravitational acceleration, and h the uniform layer depth. θ is the angle of inclination of the substrate to the vertical. For a vertical substrate, $\tau = \rho g h$ (Fig. 22).

The shear stress on any layer within a coating will be equal to the load from the outer layers. For a vertical surface

$$\tau = \rho g(h - y) \tag{51}$$

is the shear stress acting on a layer a distance y from the substrate due to the weight of the outer layer of thickness $h - y$ (Fig. 22).

Coating layers having a yield stress τ_0 (see **Plastic (Yield) Behavior**) will not sag unless the gravitational shear stress exceeds the yield value. The shear plane where yield occurs will therefore be at y' (for ideal yield behavior) when the following expression is satisfied

$$\tau_0 \leq \rho g(h - y') \tag{52}$$

Since only layers deeper than y' experience sufficient stress to flow, it follows that the layer $h - y'$ (from y' to the free surface) is solid and slides as a solid sheet over the flowing

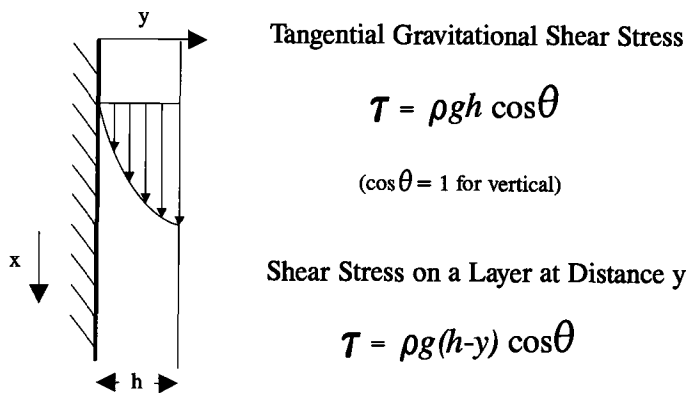

FIG. 22–Sagging, driven by gravitational shear stress.

inner layers. For a coating with a large yield stress, the load necessary to cause yield and flow is greater. Therefore, the yield plane moves deeper into the coating layer, leading to a phenomenon known as slumping. Slumping, therefore, is diagnostic of the presence of a significant yield stress. Figure 23 illustrates the effect of a yield stress on sagging, leading to plug flow (slumping). Croll [*67*] showed direct evidence of plug flow in a sagging coating possessing a yield stress.

The surface velocity of a sagging Newtonian liquid is

$$v = \frac{\rho g h^2}{2\eta} \tag{53}$$

(Wu [*68*] gives sagging velocity expressions for various non-Newtonian rheologies.) Sagging transmits substrate imperfections to the surface and amplifies them [*69*]. This is because any surface irregularity causes fluctuations in the effective local coating thickness normal to gravity and therefore in the local sagging shear stress. Furthermore, any local variations in film thickness due to application or to substrate features (e.g., a hole or a corner) can produce local accelerations of sagging in which thicker elements overtake thinner elements. This is a self-accelerating process, leading to drips, "tears," runs, or "curtaining" [*70*]. Such undesired flows can be minimized by proper characterization and control of rheology [*71*].

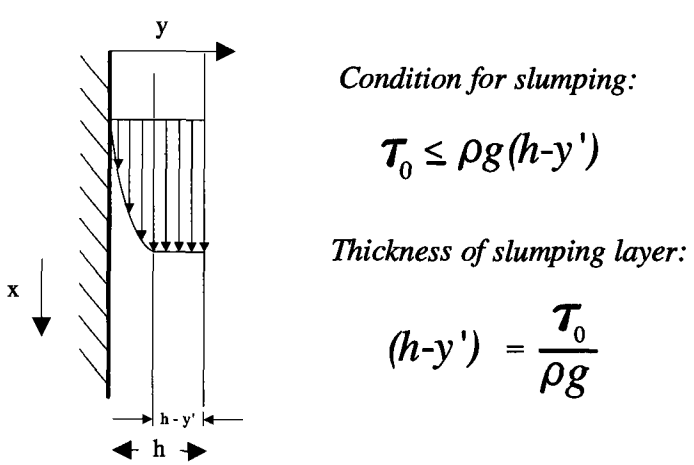

FIG. 23–Slumping (plug flow), caused by the presence of a yield stress, τ_0.

The sagging of a coating is similar to the problem of drainage of a liquid layer from an inclined surface. The difference between the two is that, in sagging, the coating layer is assumed infinite in extent; hence, sagging causes no change in the local coating thickness. If this assumption is not pertinent, then gravitational flow will result in thinning of the coating layer at the top and thickening at the bottom of a finite substrate. The distinction between the two processes may be useful for those desiring to calculate, for example, the degree of "wedging" on a dipcoated part as against simply calculating a sag length or sagging velocity. Again, in the case of sagging, h is assumed constant and a sagging distance x may be calculated, whereas, for drainage, the thickness h varies with distance x down the substrate. The equations describing the flow are otherwise identical and interchangeable. By a derivation similar to that of Wu [*68,72*] for sagging, the expressions below, describing drainage, can be obtained.

For a Newtonian liquid, the thickness at time t at a distance x down from the upper edge of the liquid layer is given by

$$h = \sqrt{\frac{\eta x}{\rho g t \cos\theta}} \tag{54}$$

The angle θ is as defined above. Most coatings are non-Newtonian, however, which will have great impact on the drainage behavior. For example, shear thinning fluids will drain to a much more uniform film thickness than Newtonian fluids. The gravity drainage of a power law fluid (see **Shear-Dependent Viscosity**) is given by

$$h = \left[\left(\frac{n+1}{n}\right)\left(\frac{x}{t}\right)\right]^{n/n+1}\left(\frac{K}{\rho g \cos\theta}\right)^{1/n+1} \tag{55}$$

In the above, K is the "consistency" term and n the exponent in the power law expression (see **Shear-Dependent Viscosity**). Here we see a practical application of mathematical flow models. The parameters obtained from fitting the power law to an experimental flow curve can be inserted into the above equation and the sagging behavior of a coating formula can be calculated and graphed. Figures 24*a* and 24*b* compare the drainage behavior of a Newtonian and a shear thinning liquid layer, showing film thickness as a function of both time and height on a vertical substrate (calculated with Eqs 54 and 55).[11] The improved uniformity of the non-Newtonian coating can clearly be seen. For shear-thinning fluids with yield stress, the drainage equation is

$$h = \left[\left(\frac{n+1}{n}\right)\left(\frac{x}{t}\right)\right]^{n/n+1}\left(\frac{K}{\rho g \cos\theta}\right)^{1/n+1} + \frac{\tau_0}{\rho g} \tag{56}$$

The constants n, K, and τ_0 are obtained by fitting the Herschel-Bulkley flow model to the experimental flow curve (see **Shear-Dependent Viscosity**).

As with leveling, a realistic description of sagging must include not only non-Newtonian effects, but also effects of drying, geometry of the applied film, and the instantaneous rheological state of the applied film. A recent review, analysis, and experimental study of sagging examines these effects [*67*].

[11]Note that $t = 0$ is excluded, since $h = \infty$.

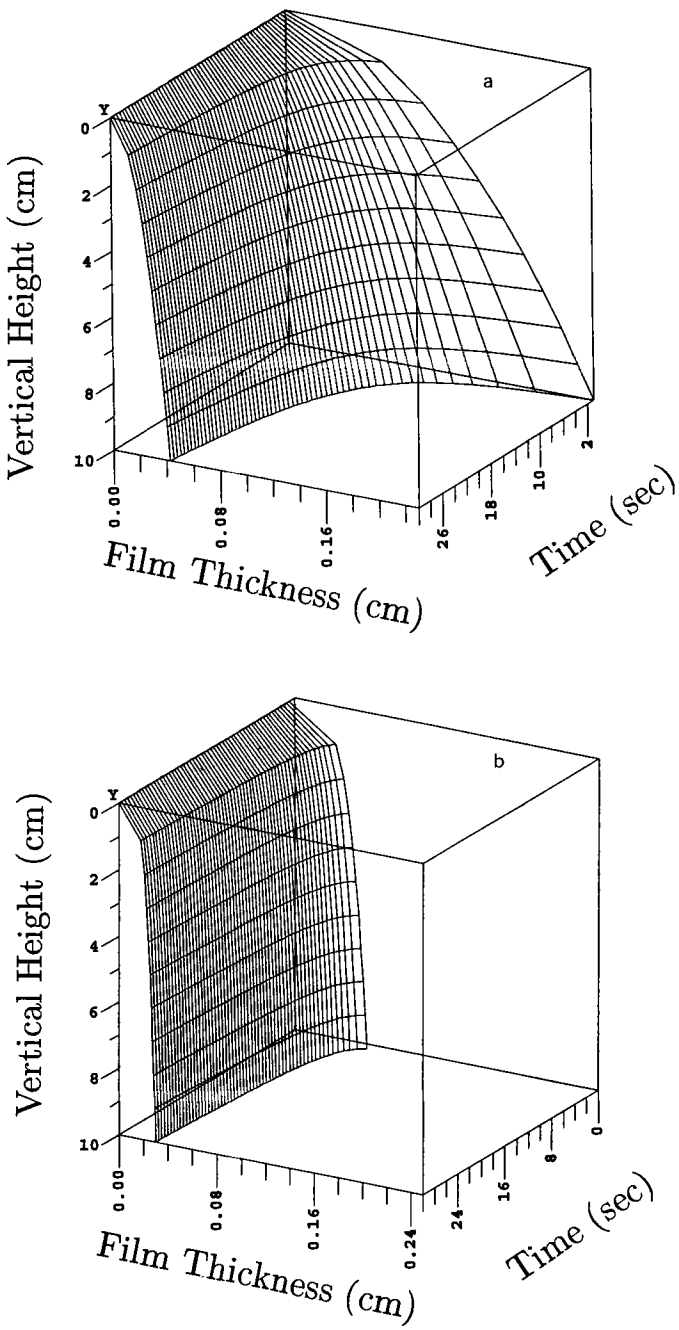

FIG. 24–(a) Drainage behavior for Newtonian fluid is represented three-dimensionally as film thickness versus vertical height versus time. Note that thickness varies strongly with height, known as "wedging"; (b) Drainage behavior for non-Newtonian (shear thinning) fluid is represented three-dimensionally as film thickness versus vertical height versus time. Note that thickness is nearly constant with height, showing that shear thinning rheology can achieve improved film uniformity in dip coating.

Measures of Sagging

A number of laboratory methods for evaluating sagging have been used, some of which measure some rheological property related to sagging behavior [*80*] and some of which measure sagging directly. Among the latter are ASTM D 4400, in which a drawdown blade with multiple slots (manufactured by Leneta) spreads paint stripes of graduated thicknesses over a nonabsorbent substrate. Sag is rated according to the thickest stripe that does not show sag (Fig. 25). A similar but somewhat simpler test involves the use of a wire device that scribes two lines, of ⅛ and ¼ in. (0.32 and 0.64 cm) width across a 3-wet-mil paint stripe, which is then hung vertically, and sagging is visually evaluated on the dry paint film.[12] The method is illustrated in Patton [*73*]. Another device which has apparently met with some success is the so-called "sagging balance" [*74*], which uses an electronic balance to measure the shift in mass accompanying drainage of a coating applied to an inclined plate.

Sagging is, of course, driven by gravitational shear stress. The sagging shear stress magnitude depends entirely on the wet film thickness and density (Eq 50). The resulting shear rate of sagging is determined by the rheology profile of the paint in question. It is imprecise to attempt to predict sagging from viscosity measurements at an arbitrary "sagging shear rate" and may lead to incorrect estimates of relative sagging. The proper way to predict relative sagging tendency is to plot viscosity as a function of shear stress rather than shear rate. Shear stress levels corresponding to the desired wet film thickness can be calculated, and the magnitude of the viscosity controlling sagging (η_{sag}) determined from the graph. Figure 26 compares two paints in this manner, with indicated gravitational shear stress levels corresponding to wet film thicknesses of 3, 6, and 12 mils film thickness indicated. Figure 27 shows flow curves for the same two paints plotted as a function of shear rate, with the calculated sagging shear rates at 3, 6, and 12 mils indicated ($\dot{\gamma}_{sag} = \tau_{sag}/\eta_{sag}$). The solid line in Fig. 27 indicates approximately the shear rate of the Stormer™ paddle viscometer. The ratio of the viscosities of the two paints at the Stormer™ shear rate is less than 2, whereas the ratio computed at the true sagging shear rates is as high as 6. Clearly, comparison of viscosities measured at an arbitrary shear rate can lead to incorrect predictions of relative sagging behavior, particularly if flow curves should cross over.

LEVELING

The mechanics of coating application generally cause the applied coating layer to be initially rough and consequently of varying thickness. Uniform film thickness is desired both for reasons of appearance (color and hiding uniformity) and for substrate protection (necessary minimum film thickness). The process of smoothing of the initial rough surface is called *leveling*. Adequate leveling is of obvious critical importance to the success of a protective or decorative coating; hence, a very large number of studies of the subject have been published (e.g., Refs *2,38,75–82*). Despite this, there is not complete agreement on how best to predict leveling behavior from rheological measurements. Leveling generally correlates reasonably well to low-shear viscosity, but not always because of complicating factors such as viscoelasticity, time dependence, volatilization, wicking, and surface tension gradients, which can greatly confuse the picture. The leveling and film formation of a paint layer is so complex that, in the opinion of

[12]Federal Test Method 4493, September 1965.

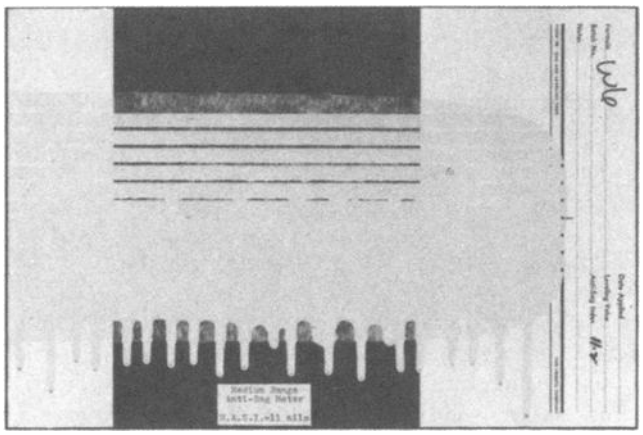

FIG. 25–Sagging evaluated by Leneta drawdown blade. Sagging is rated by the thickest paint stripe that does not show sag.

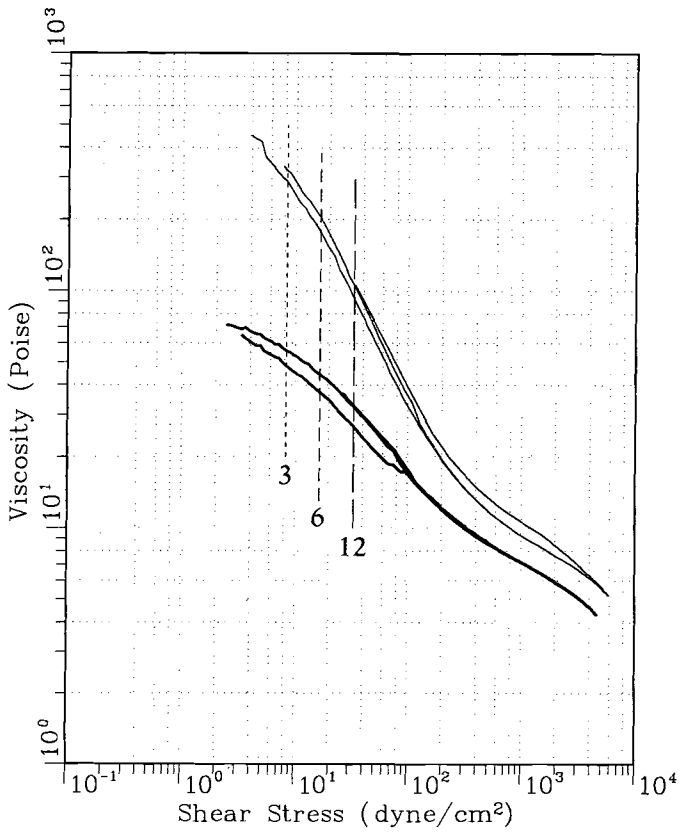

FIG. 26–Viscosity versus shear stress for two paints, together with lines indicating sagging shear stress acting on films of 3, 6, and 12 wet mils thickness. Relative sagging behavior is indicated by the ratio of viscosities at the appropriate film thickness. From this, $\dot{\gamma}_{sag} = \tau_{sag}/\eta_{sag}$.

this author, only computer modeling has the potential to provide a wholly satisfactory method of analysis and prediction (see, for example, Schwartz and Eley [*79*]). However, such modeling capability is not readily available to most practitioners, so we will review some of the analytical models of leveling. These can provide at least qualitative understanding of the role of rheology and other factors in leveling.

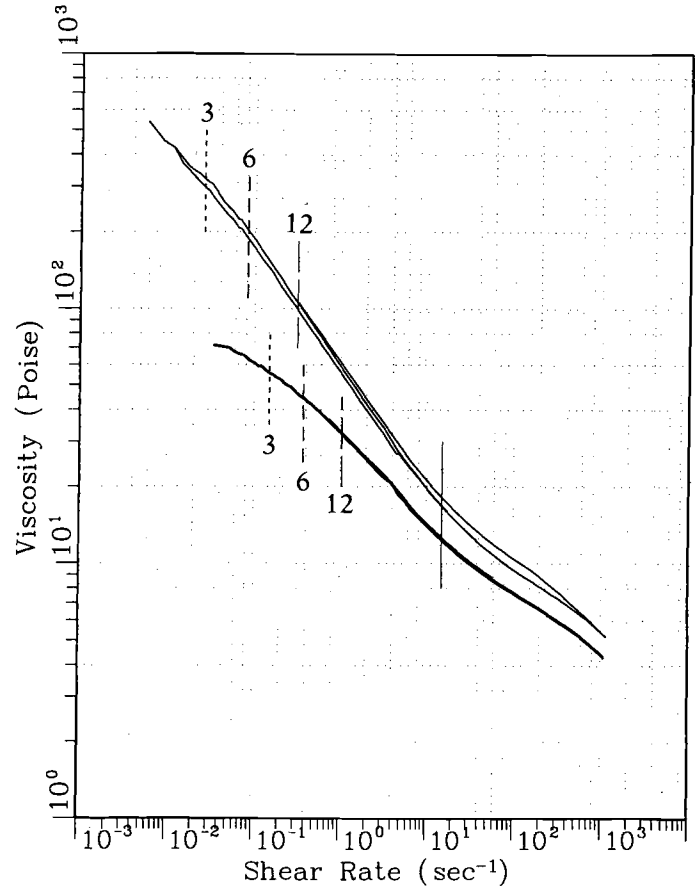

FIG. 27–Viscosity versus shear rate for two paints, together with lines indicating sagging shear stress acting on films of 3, 6, and 12 wet mils thickness. Solid line is approximate shear rate of the Stormer viscometer.

The mechanics of leveling is illustrated in Fig. 28 for a liquid without surface tension gradient, having a sinusoidal surface profile. The sum of all surface tension vectors in the curved surface produces a net force downward at the "peaks" and upward in the "valleys," the liquid-air interface acting as if it were a stretched elastic membrane. Forces due to liquid surface curvature are called *capillary forces* and result in capillary pressure variations within the liquid layer. Thus, leveling is driven primarily by capillary pressure gradients arising from local surface curvature under conditions of uniform surface tension. Liquid is "pumped" from the peaks into the valleys, ultimately producing a level surface. For thin films, gravity is of negligible effect on leveling unless a critical roughness wavelength is exceeded. For a typical paint, the critical wavelength is of the order of 1 cm [*84*].

The quantitative prediction of leveling from physical properties requires the use of some mathematical model of the process. Smith, Orchard, and Rhind-Tutt [*2*] derived such a model by a linear lubrication approximation-type analysis, assuming a uniform sinusoidal surface profile. (The Los Angeles Paint Club obtained a similar equation in 1953 [*83*] for surface roughness approximated by semicircular arcs.) Orchard later [*85*] developed a complicated expression for the leveling of a more realistic, arbitrarily rough surface profile in terms of a Fourier series. However, the expression simplifies considerably when the coating thickness is as-

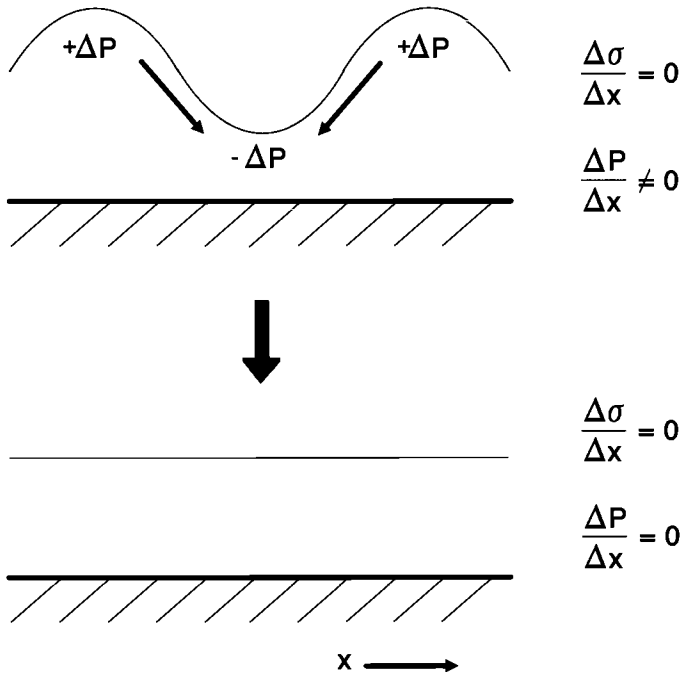

FIG. 28–Surface tension-driven leveling. Curvature of liquid surface generates capillary overpressures and underpressures, ΔP, which drive fluid flow to level the surface. There is no surface tension gradient along the film coordinate ($\partial\sigma/\partial x = 0$). Pressure is not uniform, however ($\partial P/\partial x \neq 0$).

sumed to be small relative to the roughness wavelength. Assuming a single sinusoidal wavelength (which is a reasonable approximation since the leveling behavior will be dominated by the longest wavelength), the Orchard equation is

$$\ln\frac{a_t}{a_0} = -\frac{16\pi^4 h^3 \sigma t}{3\lambda^4 \eta} \tag{57}$$

for constant surface tension σ and viscosity η. The equation indicates that the logarithmic ratio of surface wave amplitude a at time t to its initial amplitude a_0 depends on the coating layer thickness h to the third power and inversely on the wavelength of the surface roughness λ to the fourth power. For roughness geometry other than sinusoidal, the constant term $(16\pi^4/3)$ will take on other values.

The Orchard equation, as written above, is only an approximation to the leveling behavior of most real paints because it assumes Newtonian fluid behavior and neglects time-dependent (and other[13]) effects. The latter effects include thixotropy and changes in rheology from loss of solvent due to drying and also due to "wicking" (absorption) of the liquid phase into a porous substrate. Nevertheless, the Orchard model conveys the importance of film geometry and physical properties on leveling rates and allows an estimation of the order of magnitude of effects of changes in these variables. For example, it should generally hold, despite complicating factors, that doubling the wet film thickness will increase the leveling rate eight-fold. However, a more realistic description is warranted, taking into account other film properties and processes that affect leveling significantly. A step was taken by Murphy [*86*] (see also Refs *87* and *76*), who rederived the Orchard equation for pseudoplastic paints assuming power law behavior (see **Shear-Thinning Fluids**)

$$a^{(n-1/n)} = a_0^{(n-1/n)} - \frac{n-1}{2n+1}\left(\frac{\sigma}{K}\right)^{1/n} \left(\frac{2\pi}{\lambda}\right)^{(3+n)/n} h^{(2n+1)/n} t \tag{58}$$

This expression contains the power law coefficients, K and n, all other terms retaining the same definitions as above. Note that the leveling rate increases as the power law exponent, n, decreases (i.e., as the paint becomes more shear thinning). As expected, the leveling rate decreases with increasing K (consistency). Lu [*48*] found the Murphy equation valid for correlating the change of brushmark amplitude with time for systems where the leveling was clearly dominated by the viscosity. However, the Murphy equation still assumes that viscosity depends only on shear rate and that surface tension does not change during the leveling process. In reality, both will change due to evaporation of the volatile phase of the coating or to wicking. The Murphy equation may be modified to take account of time-dependent viscosity increase by including a time-integral expression for the viscosity

$$a^{(n-1/n)} = a_0^{(n-1/n)} - \frac{n-1}{2n+1}\sigma^{1/n}\left(\frac{2\pi}{\lambda}\right)^{(3+n)/n} h^{(2n+1)/n} \int_0^t \left(\frac{1}{\eta(t)}\right)^{1/n} dt \tag{59}$$

where $\eta(t)$ is some time function of viscosity relating effects of thixotropy, drying, wicking, etc. The effect of time-dependent viscosity on leveling is dramatic, as shown in Fig. 29. Here, for two different paints, the decay of surface amplitude is calculated using Eq 58 (Curves A) and Eq 59, together with an experimentally determined expression for the increase of viscosity with time due to drying (Curves B). Camina [*76*] reported that the viscosity of a drying paint increases exponentially in the initial stages. Therefore, an expression such as the following would fit drying-viscosity data

$$\eta(t) = \eta_0 e^{kt} \tag{60}$$

where η_0 is the viscosity before drying has begun, k a drying rate constant, and t the time. Such an expression can be inserted into Eq 59 in place of $\eta(t)$ and integrated[14] to calculate the leveling curve for a paint whose viscosity is increasing with time due to solvent loss. In fact, Eq 60 can account for all time-dependent effects if k is understood as the reciprocal of a sum of time constants representing all time-dependent processes [*78*]

$$k = \frac{1}{\tau_{\text{dry}} + \tau_{\text{wick}} + \tau_{\text{thix}}} \tag{61}$$

Here, τ_{dry} is the time constant (inverse of rate constant) for drying. Similar time constants can, in principle, be obtained

[13]Overdiep [*78*] has demonstrated that, for some solvent enamels whose leveling is influenced by surface tension gradients, the Orchard equation fails even to give a qualitative description of behavior.

[14]Provided that the viscosity during drying is measured at unit shear rate, K, in Eq 58 becomes η in Eq 59.

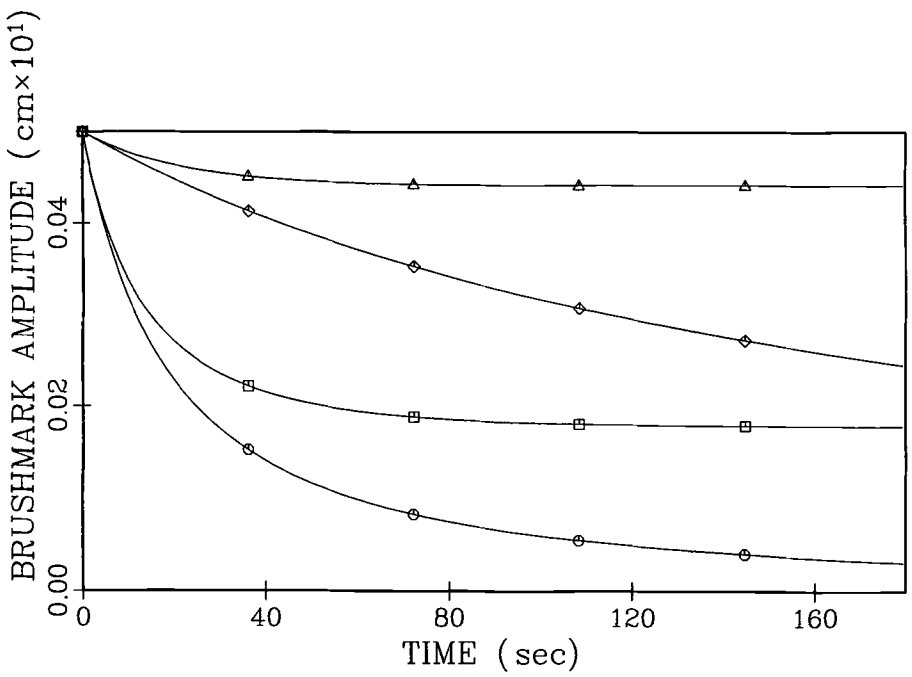

FIG. 29–Calculated brushmark leveling for two paints, with and without effects of drying. Curves calculated using Eqs 59 and 60: □—Paint A, with drying; ○—Paint A, without drying; △—Paint B, with drying; ◇—Paint B, without drying.

for solvent loss through wicking (τ_{wick}) and for viscosity increase due to thixotropy (τ_{thix}) (see *Thixotropy Test Methods*).

Quach [*84*] has discussed and summarized the shortcomings of various laboratory methods of leveling evaluation. As noted by Quach, much work on leveling has been done without adequately taking into account the numerous interacting subprocesses whose final result is the dried film profile. An additional important factor recently dealt with experimentally and theoretically is the influence of surface tension gradient-driven flows (Marangoni flows) [*78,88,90*]. Surface tension gradients may arise due to a number of causes during film formation and when present can have consequences for the course of film leveling, among other things. Figure 30 illustrates the mechanism of surface tension gradient-driven flow, which can result in the deleveling of an initially level liquid layer. Local surface tension gradients may develop due to differential evaporation or to temperature gradients (or other causes). This results in a surface flow from regions of low surface tension toward regions of high, in an attempt to reach surface equilibrium. The moving surface "drags" subsurface liquid along, creating a bulk flow. This is the Marangoni effect. The driving force for Marangoni flow in the case of differential evaporation is a shear stress tangent to the film surface, τ_s, proportional to the strength of the dependence of surface tension on solvent concentration, $\partial\sigma/\partial[S]$, and to the magnitude of the solvent concentration gradient, $\partial[S]/\partial x$ (x is the film coordinate). Hence

$$\tau_s = \frac{\partial\sigma}{\partial[S]}\frac{\partial[S]}{\partial x} = \frac{\partial\sigma}{\partial x} \tag{62}$$

the surface tension gradient $\partial\sigma/\partial x$ drives the flow. For the case of Marangoni flow driven by thermal surface tension gradients, replace $\partial[S]$ by ∂T in the above. Persistence of surface tension gradients until the film is incapable of reflow

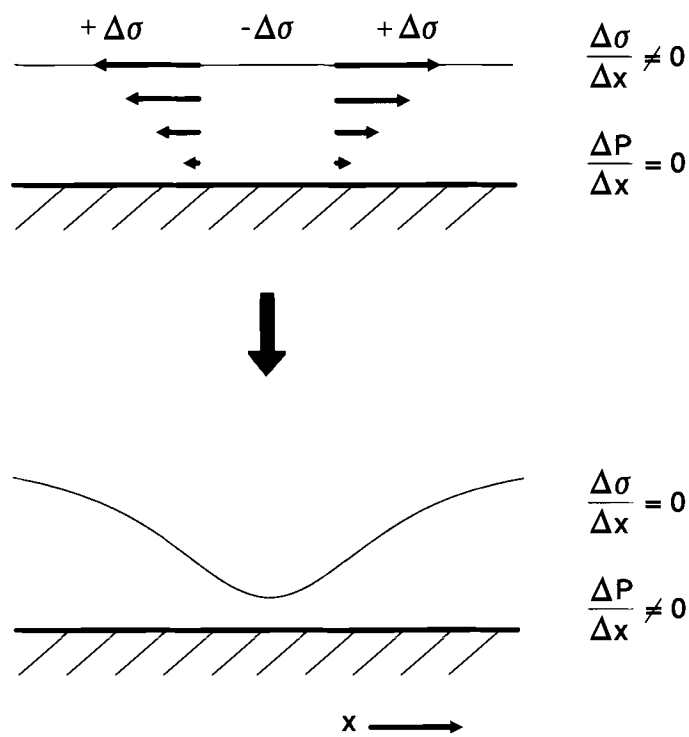

FIG. 30–Deleveling by Marangoni (surface tension gradient-driven) flow. Surface tension gradient ($\partial\sigma/\partial x \neq 0$) drives surface flow, resulting in bulk flow and deleveling of initially level surface.

will result in an appearance defect. Overdiep [*78*] demonstrated (for solvent-based paints) that Marangoni flows initially enhance the leveling rate, but can produce a "rebound" effect that ultimately worsens film roughness. Wilson [*90*]

recently modeled this behavior by a linear perturbation analysis. Other authors have discussed the importance of Marangoni flows for waterborne, cosolvent-containing coatings [*79,89*].

The role of viscoelasticity in leveling has been a subject of some debate, with some authors concluding that elasticity enhances leveling [*91*] and some that it retards leveling [*38,92*]. The evident link between elasticity and the underlying structural rheology for coatings (see **Viscoelasticity and Industrial Processes**) suggests the presence of a gel-like structure of some sort in systems possessing significant elasticity. Such a structure would be expected to inhibit flow at low stress levels so that coatings which exhibit elasticity should also show poorer leveling. In any case, the leveling behavior of viscoelastic systems has been modeled by Keunings [*38*] and the presence of viscoelastic relaxation shown to retard leveling. The leveling rate, α, as a function of the Newtonian leveling rate, α_{Newt}, was shown to be

$$\alpha = \frac{\alpha_{\text{Newt}}}{1 + \lambda\alpha_{\text{Newt}}} \tag{63}$$

where $\alpha = da/dt$ (rate of change of roughness amplitude, a, in s^{-1}), and λ is the elastic stress memory time constant (or relaxation time) (see *Viscoelastic Models*). In Eq 63, the Newtonian leveling rate is always positive, hence elasticity ($\lambda > 0$) always retards leveling. Interestingly, if surface tension gradients are present, α_{Newt} may actually become negative (i.e., deleveling, or crawling). In such cases, late-developing elasticity will be of benefit by retarding the deleveling. Table 4 shows the results of a calculation similar to that of Keunings adapted for the case of a typical paint. It is seen that the leveling rate dramatically decreases and the leveling half-time increases (by a factor of 3500), relative to the Newtonian ($\lambda = 0$) values, for $\lambda = 100$ s.

Measures of Leveling

Visual evaluation of leveling is common practice. However, it is generally agreed that visual rating is subjective to the degree that leveling rankings are often found to be operator-dependent. Numerous objective methods and standards have been published. Quach [*84*] reviewed aspects of both scientific and laboratory practical studies of leveling. For the latter, special drawdown blades have been used such as the NYPC leveling test blade (ASTM D 2801), which has pairs of notches over a range of depths. Leveling is judged by the flowing together of adjacent paint stripes. This method has been criticized by Quach and others [*27*] because the paint passing through the notches experiences a varying shear rate due to varying notch depth, resulting in a different shear history for each stripe, and because the shear rate achieved is unrealistically low. The latter test has been superseded by ASTM D 4062, based on a grooved drawdown rod. In this method, the paint is presheared, simulating brushing shear rates, by ejection from a syringe and 15-gauge needle prior to drawdown. The leveling quality is then estimated by visual comparison of the dried film with plastic leveling standards viewed against oblique lighting.

Kornum [*93*] gives a good discussion of issues of measurement under test conditions approximating real paint processes, including leveling. Dodge [*27*] also emphasizes that the best rheological test for leveling should most closely simulate the application experience of the paint. This means: (1) the paint should experience shear rates/stresses of similar magnitude and duration to those of the application process; (2) the shear rate/stress should then be step-changed to values representative of the leveling process; (3) the change of viscosity with time should then be followed under the latter conditions. This protocol is essentially identical to the "step-shear" method of characterizing thixotropic recovery described in **Thixotropy Test Methods.** This kind of procedure is most easily accomplished by employing a rheometer capable of "job streaming" or "linked methods." However, the foregoing method still suffers from the limitation that the effect of drying on viscosity during the leveling period is neglected. Figure 29 demonstrates that this can be a very significant effect. Paints "A" and "B" were commercial formulas which differed markedly in leveling performance. The increase of viscosity with time during drying of a film of typical applied thickness was measured for both and found to obey Eq 60. The latter expression was then inserted into Eq 59 as the time-integral function for viscosity (as described in the previous section) and the leveling curves in Fig. 29 were calculated. There are two curves for each paint, one showing how the paint levels without the effect of drying, and one calculated taking the increase of viscosity due to drying into account. The effect of drying is most dramatic on Paint B, where the reduction of surface roughness achieved after 3 min decreases from 50 to 10%.

It is established that leveling shear stress decays exponentially as leveling progresses [*80*]. A controlled-stress rheometer with programmable logarithmic stress ramps offers the ability to simulate the variation of viscosity with realistic shear-stress decay using variable ramp times. Leveling efficiency might then be judged by numerically integrating the fluidity over the "leveling" period.

$$\Phi = \int_0^t \frac{1}{\eta} dt \tag{64}$$

The leveling might be expected to be logarithmically related to the fluidity integral [*81*].

A very promising method for direct observation of paint leveling has been described by Klarskov [*82*]. It is an optical interferometric method which is simple but quite precise for real-time surface profile measurement, having a vertical resolution of a fraction of a micron. At present, unfortunately, there is no commercial instrument based on Klarskov's method.

ATI Systems[15] offers a relatively inexpensive noncontacting Laser profilometer. Laser confocal microscopes can also measure the real-time evolution of surface profile during leveling, but are quite expensive.

RHEOLOGY INSTRUMENTATION

There are a great many instruments that have been devised to measure viscosity or "consistency." However, a number of them have in common a serious limitation in their design

[15]ATI Systems, Inc., P.O. Box 71460, 32355 Howard Street, Madison Heights, MI 48071.

which makes them generally unsuitable for measurements of non-Newtonian fluids. The importance of this issue becomes apparent when it is realized that the majority of coatings and coatings components are non-Newtonian, yet many laboratories continue to use methods which are not suited for such materials. The difficulty with many of the "traditional" laboratory viscometers is that the "flow field" (the total description of the trajectories of the fluid elements) is complex and not subject to practicable mathematical description. The result is that an accurate strain rate cannot be calculated. Therefore, even if the stress is known, the true viscosity cannot be obtained. Furthermore, the shear field is often so nonuniform that, for non-Newtonian materials, the viscosity of the material itself varies within the test sample. For complex flow fields, such an error cannot be corrected. The measurement error will be in proportion to the deviation from Newtonian character. Nevertheless, such instruments have been in use throughout the industry for decades and no doubt will continue to be used for the foreseeable future. The approximate measurement given is somehow related by the practitioner to something believed relevant to the performance. One suspects that when the result is contradictory, as is probably often the case, it is either ignored or "worked around." We shall refer to this type of device as a "Q/C (quality control) instrument" or a "qualitative viscometer." It should be emphasized that these instruments are accurate for Newtonian or near-Newtonian materials and are generally useful as Q/C test devices even when the measurement is approximate. However, the practitioner should be alert to situations where their deficiencies can be of significance.

In years past, many coating fluids were nearly Newtonian, which accounts in part for the success of Q/C-type instruments. As alluded to before, it is very easy to characterize a Newtonian fluid. Virtually any type of flow measurement device may be used to obtain accurate information on the viscosity of such a material provided the device used is calibrated with known standard fluids and the temperature is controlled. It is not even necessary to know the shear rate of the measurement since Newtonian fluid viscosity is independent of the shear rate. Consequently, Newtonian viscosity measured by any test is valid for all process conditions (except turbulent flow). Even instruments which measure viscosity according to some arbitrary scale may be used since they may be calibrated in absolute units using Newtonian standard fluids.

A requirement for an instrument to measure non-Newtonian fluids properly is that the flow field within the test fluid be viscometric, defined as "everywhere indistinguishable from steady simple shear" (or other ideal deformation) [*1*]. Instruments which measure under such well-controlled conditions we will call "research instruments." Nonviscometric flows such as tube flow can be used for non-Newtonian fluids when necessary corrections are applied.

Q/C INSTRUMENTS

These are of three types: (1) efflux devices, (2) rotational devices, and (3) obstructed-flow devices (following Barnes et al. [*94*]).

Efflux Devices (Orifice flow)

Efflux devices, or orifice cups, come in a variety of types, but share one principle: measuring viscosity by flow from a reservoir or cup through a restriction of some type. In most cases, the restriction is simply a hole in the bottom of the reservoir, but in some it is a short tube. These devices have the advantages of low cost, ease of cleaning, durability, and simplicity in the measurement, which is simply the time to empty (in whatever manner "empty" is defined). They also have, however, a number of limitations. The first is that the flow is never viscometric. Even when a short capillary tube is the exit, the length-to-diameter ratio is too small for proper tube flow to develop, so that the flow is dominated by entrance effects. In fact, the orifice cups have been described as "poor capillary viscometers." Since substantial shear stress is not developed in the exit hole, orifice cups are not suitable for very thin liquids because a significant fraction of energy is dissipated not in viscous flow, but merely in accelerating the fluid. In other words, measurements on low viscosity fluids are subject to significant fluid inertia errors. Thus, for the Ford No. 4 Cup (ASTM Method D 1200), liquids with an efflux time of less than 20 s should not be used. The flow in efflux cups is stress-driven, controlled by the hydrostatic head, i.e., the fluid depth in the cup. The pressure varies as the liquid drains; consequently, the flow rate (shear rate) varies during the test. The viscosity of shear-thinning liquids, therefore, will increase in the course of the test, and in extreme cases such materials may not fully drain from the cup. Because the flow field is complex, the shear rate cannot be calculated, and from the previous argument will depend on the viscosity-shear stress relationship for non-Newtonian materials. For the above reasons, it must be concluded that orifice cups are really only suitable for viscosity measurements of Newtonian liquids of moderate viscosity. Non-Newtonian liquids should not be tested unless only mildly shear-dependent. Materials with possible yield stress (meaning any thixotropic materials) should not be tested with efflux devices. A final caution for these devices is that, unless the temperature of the cup is controlled by means of a water jacket, large errors are likely to result. Even if the test liquid is thermostatted in a water bath prior to test, it can rapidly change in temperature and viscosity when placed in a cup which is at the temperature of the room. Figure 31 shows data for replicate measurements on cups with and without temperature control. Obviously, the errors in the data taken with the standard cup would hide the real batch-to-batch differences of the product. A good Q/C test should reveal, not obscure, product variability.

Rotational Devices

Stormer™ Viscometer

The widely-used Stormer[16] Viscometer was one of the earliest controlled-stress rotational viscometers. Rotors of various geometries are available, but the "paddle" rotors, in which two paddles are attached in offset fashion to a rotating shaft, are exclusively used for the measurement of the consistency of paints. During a measurement, the rotation is driven by a

[16]The name "Stormer" is a trademark of the Thomas Scientific Company.

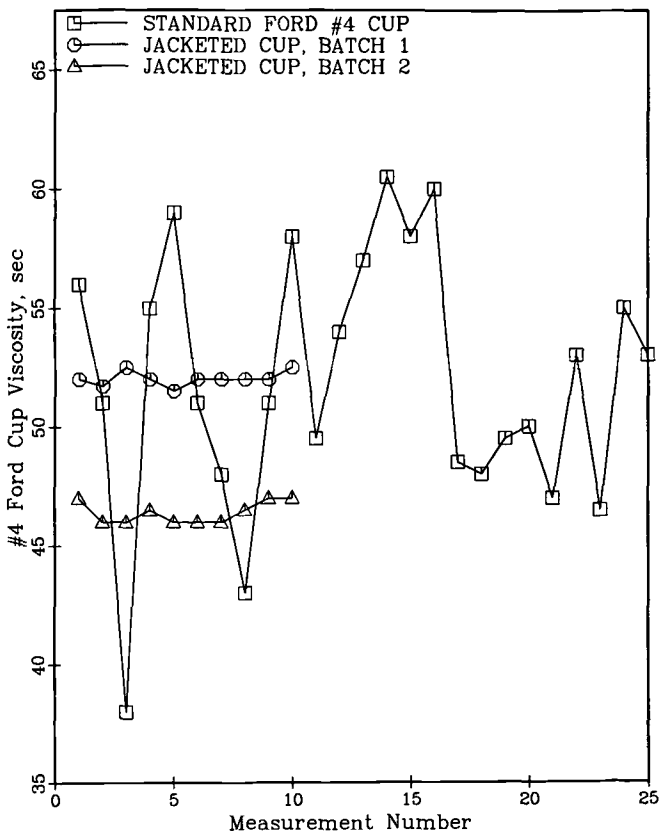

FIG. 31—Ford cup viscosity data taken with and without temperature control of the cup. Test temperature was 130°F (54°C).

free-falling weight attached to a string and pulley arrangement, the string being wound around a drum. The shear stress is varied by use of different weights. A counter tallies up the number of revolutions as the weight falls. After the first ten revolutions, the time required for the next 100 is measured. (Stroboscopic timers are available.) The apparent viscosity is calculated from a plot of applied torque versus rotor rpm. The measurement is also made in terms of the weight, W, required to achieve a rotational speed of 200 rpm. The viscosity is obtained according to an arbitrary scale called "Krebs Units" (KU). A conversion table of W versus KU is supplied. As with any viscometer whose measurement geometry is complex, an absolute viscosity (i.e., in engineering units of poise or pascal-seconds) cannot be calculated with this instrument for non-Newtonian fluids. The Stormer viscometer is specified in a number of standard test methods.[17]

For its purpose, i.e., to measure the in-can "feel" of paint, the Stormer is a very good viscometer, that is, the Stormer measures while stirring the paint with a constant force, just as the consumer would. Thus, the instrument satisfies the criterion of measuring under conditions closely approximating those of the process. This justifies the use of an arbitrary measurement scale, in this case, and makes the Stormer a valuable component of the paint laboratory. The only caveat would be not to violate the above-mentioned principle by attempting to use Stormer data to predict paint performance for a process which is far removed from the flow kinematics of the instrument.

Thomas-Stormer™ Viscometer Model ETS-1000

This instrument is an electronic implementation of the Stormer paddle viscometer by the Thomas Scientific Company.[18] Weights are done away with, as the instrument is motor-driven. A selector switch allows a digital readout to display the measured viscosity in centipoise, Krebs Units, or in grams (for comparison to the standard Stormer instrument).

Brookfield Digital Viscometer Model KU-1

The Brookfield Model KU-1 is likewise an electronic paddle viscometer, similar to the Stormer, by Brookfield Engineering Laboratories. A digital panel readout displays either the weight in grams corresponding to the applied motor torque or the viscosity in Krebs units (KU).

ICI Rotothinner

The Rotothinner, originally developed by ICI Paints, is driven by a constant-speed motor and utilizes a large, disk-shaped rotor which is immersed in the sample under test. A standard sample container is used, which is held magnetically to a turntable. The torque transmitted through the sample rotates the turntable until a steady position is reached. (The rotary motion is resisted by a spring.) The turntable is graduated in poise units, and the viscosity is indicated by a pointer attached to the instrument base. The viscosity range of a given model is somewhat narrow, and measurement over a wide viscosity range necessitates purchase of separate instruments. The instrument is calibrated for use only with standard containers. There is no provision for temperature control of the specimen. For "rheologically structured" materials, the manufacturer recommends to allow up to 4 min under shear for the reading to become steady, thus providing for a more or less constant shear history. However, temperature may vary during this period due to the input of energy resulting from the 575-rpm rotor speed.

Although the instrument has a scale graduated in poise units, the shear rate of test is unknown since the flow field is not viscometric. Flow in the vicinity of a rotating disk can be quite complex, especially for non-Newtonian and viscoelastic materials. Consequently, the apparent Rotothinner viscosity must be considered only approximate and the scale graduations arbitrary for such materials.

The Rotothinner is manufactured by Sheen Instruments, Ltd. and is widely used in Europe.

Obstructed-Flow Devices

These are gravity-driven instruments in which flow is due to density differences between the test fluid and a falling object (falling ball viscometer, falling needle viscometer) or a rising bubble (bubble tube viscometer). In each case, the fluid has to flow around the moving object; hence, they are classed as obstructed-flow devices. In the falling ball and rising bubble instruments, the flow field is complex with the conse-

[17]Test methods include ASTM D 115, D 562, D 816, D 856, D 1084, D 1131, D 1337, D 1338, and Federal Test Methods 3011.1, 3012, 3018, 3019, 3022, and 4281.

[18]The Thomas-Stormer ETS-1000 is available from the Cannon Instrument Company.

quence that these devices are generally not useful for non-Newtonian fluids. The falling needle viscometer, however, possesses a well-defined flow field [*95*], is therefore suitable for non-Newtonian materials, and will be discussed in the section on Research Rheometers.

Falling Ball Viscometer

A ball falling in a viscous fluid will reach a terminal, or constant, velocity U_∞, which depends on the density difference of the sphere and the liquid, the diameter of the ball, d, and the fluid viscosity, η. The viscosity of an unknown fluid may be calculated from the Stokes equation

$$\eta = \frac{(\rho_s - \rho_l)gd^2}{18U_\infty} \tag{65}$$

where g is gravitational acceleration. This deceptively simple method has several drawbacks, however. For one, the Stokes solution is only valid for low Reynolds numbers (viscous forces controlling, rather than fluid inertia, i.e., slow flow), and for low-viscosity fluids the ball density must be small enough to produce correspondingly slow rates of fall. For another, a wall correction may be needed to account for the interference of the container wall with the flow field of the ball and hence its falling rate. Perhaps the greatest difficulty, however, is the fact that the flow field around a moving sphere is complex, and when the fluid is non-Newtonian the complexity becomes mathematically intractable. Therefore, for non-Newtonian fluids, the falling-ball apparatus will not yield absolute viscosity, and the results would not be expected to correspond with those from an instrument having viscometric flow geometry. A solution to the above problems is provided by a relatively new instrument called the falling needle viscometer (see below).

Rising-Bubble Viscometers

If certain flow field assumptions are made for a rising air bubble in a liquid, the viscosity of the liquid can be calculated from [*42*]

$$\eta = \frac{1}{3}\frac{\rho g R^2}{v} \tag{66}$$

where ρ is the liquid density, R the radius of the air bubble, and v the rising velocity. However, the calculation is only approximate because the air bubble shape often deviates from the assumed sphericity due to buoyancy. Furthermore, if the liquid phase were non-Newtonian, significant errors would result for which there is no correction available.

The Gardner-Holdt bubble tubes provide a rapid means of estimating the kinematic viscosity (see **Capillary Viscometers**) of transparent liquids such as varnishes and resins using the rising bubble principle. These consist of a series of sealed glass tubes containing mineral oils comprising a range of standard viscosities. The test liquid is placed into a similar tube (ensuring the contained air bubble is the same volume) and thermostatted in a water bath. The test material and a rack containing the standard tubes are inverted, and the test viscosity is identified according to the letter (or sometimes number) designation of the standard tube whose rate of bubble rise is nearest the same. Interpolation between the standards is sometimes done. Bubble tubes are disposable, easy to use, and the results can be converted to kinematic viscosity by means of tables. Bubble tubes can be used also to measure resin color. For process resins nearing the gelation point, the bubble can display a pointed "tail," or pronounced "teardrop" shape, an indication of the onset of viscoelasticity. As a reference for the use of the Gardner-Holdt method, see ASTM D 803.[19]

RESEARCH RHEOMETERS/VISCOMETERS

Research-quality rheometers are of several types, chiefly employing: (1) steady rotational shear, (2) dynamic (oscillatory) shear, and (3) capillary tube flow. Acoustic wave devices constitute a fourth, less common, type. Useful summaries of instrumentation and methods are found in Refs *96–98*. Although dated, Van Wazer's book is still a valuable source [*42*]. Appendix A lists vendors of research rheometers and viscometers.

Rotational Instruments

Controlled Stress and Controlled Rate

There are two basic types of rotational viscometers, which work in the following ways: (1) apply a controlled rotation rate and measure the opposing viscous torque, or (2) apply a controlled torque and measure the resulting rate of rotation. In the first case, which may be termed "controlled-rate," the applied angular velocity is the independent variable and the viscous drag torque the dependent variable. In the second case, termed "controlled-stress," the applied torque is the independent variable and the measured angular velocity the dependent variable. Instruments of the controlled-rate type include, for example, the Brookfield Synchro-Lectric Viscometer, Haake CV, Rheometrics RFS, and Bohlin VOR instruments. Instruments of the controlled-stress type include the Carri-Med CSL, Rheometrics DSR, Bohlin CS, Haake RS, and Physica MC rheometers.

The choice between the two types of instruments depends on the material under test and the kind of results desired. For characterizing highly structured materials or "weak gels" (e.g., thixotropic alkyds and unstable colloidal systems such as some pigment dispersions, thixotropes, etc.), the controlled-stress instruments are likely to be more appropriate. The reason is that controlled-rate instruments impose a shear field upon the specimen over a relatively short time scale, say, in the course of a shear rate ramp experiment. The resulting relatively rapid deformation tends to destroy shear-sensitive structure very quickly, making it difficult to gather much information about the structure. In contrast, with controlled-stress instruments, the applied stress can be gradually increased, allowing the specimen to "obey its own rules" of stress-strain (rheological) behavior, thus resolving the maximum amount of information. This is particularly true when one is concerned with materials possessing an apparent yield stress. Controlled-stress instruments can, in principle, directly measure the stress at the onset of yield, avoiding errors associated with indirect methods of yield stress measurement (see *Yield Stress Test Methods*).

[19]Additional standard test methods using bubble tubes are: ASTM D 1131, D 1545, D 1725, and Federal Test Method 4271 (141-a).

In selecting the appropriate instrument type, one should take into account also the type of coatings process in question. Some coatings processes are stress-controlled (or stress-limited), and some are rate-controlled (or rate-limited). A stress-controlled process is one whose shear rate is determined by the rheology of the material; that is, a relatively small amount of force drives the process, and the rate of the process is therefore determined by the viscosity of the material at the process shear stress. For example, different paints at a given wet-film thickness experience a constant gravitational shear stress, but will sag at different velocities depending on their viscosities at the sagging shear stress. A rate-controlled process is one whose shear rate is independent of the material rheology, that is, the available driving force is so large that the process rate or throughput is essentially not affected by viscosity. Examples of stress-controlled coatings processes and their driving forces include sagging (gravity), leveling (surface tension), particle settling (gravity), and airless spraying (hydrostatic pressure). An example of a rate-controlled process would be industrial rollcoating.

Since many coatings processes are stress-controlled or stress-limited, the controlled-stress rheometer offers the advantage of more convenient simulation of these processes. For example, a constant stress (simulating sagging) or a programmed exponential stress decay (simulating leveling) may be conveniently applied with the latter-type instrument. One capability unique to controlled-stress rheometers is the creep test, whereby a constant load is applied to the material and the deformation is recorded with time.[20] Creep has been found to be very useful, both for characterizing viscoelastic materials (see **Viscoelastic Models**) and for determining Region I of the equilibrium flow curve (see **Shear-Thinning Fluids**). The latter is obtained by applying a series of very low torques and measuring the equilibrium strain rate. The equilibrium flow method permits viscosity measurements to be made at the lowest possible rate of shear. A limiting factor in the accuracy of such methods, however, is the ability to minimize or correct for spurious air bearing torque.

Other advantages of controlled stress over controlled rate have been pointed out by Gleißle [*99*]. For example, using data for polymer melts, he demonstrated that measurements at constant stress are of greater sensitivity and better able to discriminate among materials than measurements at constant shear rate. Furthermore for controlled stress, the sensitivity, in terms of both absolute and relative measured viscosity differences among materials, is independent of the stress level chosen, unlike for controlled rate. In fact, the ratios of viscosities of two different materials, A and B, are independent of the shear stress

$$\frac{\eta_A(\tau_1)}{\eta_B(\tau_1)} = \frac{\eta_A(\tau_2)}{\eta_B(\tau_2)} \tag{67}$$

where τ_1 and τ_2 are two arbitrary stress levels. Since this would also hold true at low stress levels where the viscosity is constant, we are led to a very useful relationship: that the ratio of the shear rates for A and B, measured at a given shear stress, gives the inverse ratio of the zero-shear viscosities of the two materials.

$$\frac{\dot{\gamma}_A(\tau)}{\dot{\gamma}_B(\tau)} = \frac{\eta_{0,B}}{\eta_{0,A}} \tag{68}$$

The value of this fact to experimentalists is considerable. For example, it is often difficult to accurately measure η_0 for very low- or very high-viscosity fluids because of limited instrument range, sensitivity, or accuracy. Let us suppose $\eta_{0,A}$ is measurable but $\eta_{0,B}$ is not. However, reliable data for Material B are obtainable at higher (or lower) shear stresses, where the instrument is accurate. Equation 68 allows us then to calculate the unknown zero-shear viscosity, $\eta_{0,B}$. As another example, many dispersions, particularly those of importance to coatings, are colloidally unstable with the result that the zero-shear viscosity may not be measurable (see **Shear-Thinning Fluids** and Fig. 5). A similar technique to the above may obviously be used to obtain an inferred value of η_0 for such a system as it would be in the absence of the instability by comparison to another, colloidally stable material.

Gleißle also showed that the local flow exponent, n (see **Shear-Dependent Viscosity**), is constant at constant shear stress, independent of differing material rheology. As a consequence of this, the Weissenberg-Rabinowitsch correction to the capillary viscosity for non-Newtonian fluids becomes a constant at a given shear stress, independent of material rheology, since it depends only on the value of n (see **Capillary Viscometers** and Eq 11).[21] Gleißle's findings are apparently empirical and will need to be verified for systems other than the ones reported.

Inertia Correction

It can be particularly important for rotational rheometers of the controlled-stress type to correct the data for inertia error. If the test fluid is low in viscosity, and/or the test rotor has a large moment of inertia, and/or the acceleration is too high (short ramp time), a significant portion of the applied torque is dissipated not viscously, but in the acceleration of the rotor. A correction for this error has been published by Krieger [*100*]. Some commercial controlled-stress instruments now feature on-line inertia correction.

Brookfield Viscometers

Brookfield Synchro-Lectric

The Brookfield Synchro-Lectric viscometer utilizes a set of spindles or disks as the rotor/sensor, which are rotated in the test fluid at selected rpm's, so that the apparent viscosity may be measured at several shear rates to obtain a flow curve. Its advantages include low cost, simplicity of use, ease of cleaning, and durability. The instrument is in wide use throughout the industry and is the basis for a number of ASTM test methods.[22] It is included here in the list of "research quality" viscometers because the viscosity can be reported in absolute units over a range of shear rate, although often it is not (see below). Its limitations include the latter fact, plus that tem-

[20]Correspondingly, only controlled-rate instruments can perform a step-strain or stress relaxation test.

[21]This would also hold true of the Burgers correction to the parallel-plate viscosity of non-Newtonian fluids for the same reason.

[22]These include ASTM D 115, D 816, D 1076, D 1084, D 1286, D 1337, D 1338, D 1417, D 1439, D 1638, D 1824, D 2196, D 2364, D 2393, D 2556, D 2669, and Federal Test Method 4287.

perature control is not integral to the instrument. The Synchro-Lectric is available with digital output, automatic viscosity calculation, and computer-interfaced versions with analysis and graphing software.

Brookfield spindle viscometer measurements suffer from the use of arbitrary or nonfundamental units in reporting the result. Even though the viscosity is reported in absolute units (cP or mPa·s), the shear rate is not. Thus, both the spindle speed (rpm) and the spindle identity must be reported along with the measured viscosity. The measured viscosity can be different at the same rpm if a different size spindle is used. Without knowing the actual shear rate of measurement, a true flow curve cannot be constructed from the results. The true flow curve is desirable for several reasons, among them the possibility of comparison with results from other instruments, the quantitative description of the sample rheology by use of mathematical flow models and the subsequent application of such models to predict paint performance (see **LEVELING** and **SAGGING** for example). Methods for calculation of the corrected shear rate for Brookfield RVT spindles were given by Williams [*101*] and also Pierce [*102*]. Smith [*87*] has given a simplified method. (See also Ref *22*, pp. 28–31.) Some of the foregoing issues are at least partially answered with certain accessories available from Brookfield. These include options which have small-gap bob-in-cup geometry and temperature control, e.g., the small-sample adapter.

Wells-Brookfield Cone and Plate Viscometer

Brookfield also offers an instrument possessing a well-defined geometry and good temperature control—the Wells-Brookfield cone and plate viscometer. Its operation and appearance are very similar to the Synchro-Lectric, except the lower end has been modified to mount a cone and plate geometry with integral temperature control via a water jacket. Because the true shear rate can be calculated from the cone geometry and rpm, the viscosity of non-Newtonian materials can be measured in absolute units and an equilibrium flow curve determined. This instrument, therefore, is recommended over the standard Synchro-Lectric for routine viscosity measurement.

ICI Cone and Plate Viscometer

The ICI cone and plate viscometer is a relatively high shear rate instrument capable of absolute viscosity measurement. It is normally sold in a room-temperature, single-speed configuration. Temperature control is integral to the instrument, but there is no provision for control of solvent loss from the sample. This can be improvised, if desired. A high-temperature version is available, which is useful for resin melt viscosity measurement. The chief use of the instrument has been the measurement of viscosity at a shear rate of approximately 10 000 s^{-1} for the prediction of brushability. (See ASTM method D 4287 for high-shear viscosity by ICI cone and plate.)

Brookfield CAP 2000 Viscometer

The Brookfield CAP 2000 multispeed digital cone-plate viscometer was very recently introduced. It is very similar to the ICI cone and plate viscometer, but represents an improvement in that it is capable of variable shear rate measurement (to 24 000 s^{-1}). It also provides a digital display of viscosity and temperature as well as a data interface to a personal computer or data logger with applications software.

Falling-Needle Viscometer

This is an "obstructed-flow" device which utilizes a long, slender needle as the falling object. In so doing, it overcomes the objections to the falling ball viscometer while retaining the latter's simplicity of operation and relatively low cost [*103*]. The needle is hollow (allowing a wide range of needle densities) with hemispherically capped ends. End effects due to the finite needle length are mathematically correctable. This geometry produces a well-behaved flow field known as "annular-ducted flow," with the central tube (needle) moving at constant velocity. Because of the well-defined flow field, the true velocity gradient between the needle and container wall can be obtained, and the instrument therefore is suitable for measurements of non-Newtonian fluids [*104*]. The falling-needle viscometer may be especially useful for determination of very low shear stress or shear rate behavior of non-Newtonian fluids, for example the zero-shear viscosity (Region I of Fig. 3) and measurement of yield stresses [*105*].[23]

Capillary Viscometers

Capillary tube flow is a classical viscometric method which is useful for coatings in two main ways. Capillary viscometry is the method of choice for measurement of intrinsic viscosity (ASTM Method D 445) (see also **DISPERSION RHEOLOGY**) and also the measurement of very high shear rate rheological properties (see below).

For fluid flowing through a tube, the shear stress at the tube wall is

$$\tau_w = \frac{\Delta PR}{2L} \tag{69}$$

where ΔP is the decrease in pressure occurring over tube length L of radius R. The shear rate at the tube wall for a Newtonian fluid is given by

$$\dot{\gamma}_w = \frac{4Q}{\pi R^3} \tag{70}$$

where Q is the volumetric flow rate (cm^3/s). The viscosity is then

$$\eta = \frac{\tau_w}{\dot{\gamma}_w} = \frac{\pi R^4 \Delta P}{8LQ} \tag{71}$$

which is the well-known Hagen-Poiseuille equation. For applied pressure-driven capillary flow, particularly for high-shear measurements, a correction to Eq 71 is required because the fluid undergoes a large acceleration as it enters the capillary. Therefore, part of the energy loss represented by the pressure drop ΔP is in accelerating the fluid. This would result in a calculated viscosity which is too high and so necessitates a subtractive term or kinetic energy correction

[23]A new ASTM method for falling-needle viscometry is D 5478.

$$\eta = \frac{\pi R^4 \Delta P}{8LQ} - \frac{m\rho Q}{8\pi L} \tag{72}$$

where ρ = fluid density and m is a constant which is equal to unity for Newtonian fluids. For non-Newtonian fluids obeying the power law (see **Shear-Thinning Fluids**), m is calculated from

$$m = \frac{3(3n + 1)^2}{(4n + 2)(5n + 3)} \tag{73}$$

where n is the power law exponent. Various additional corrections for capillary flow are described in van Wazer [*42*].

The pressure head ΔP can be obtained two ways: by pressurizing the delivery vessel or by relying on a gravitational hydrostatic head to drive the flow through the capillary. In the latter case, the density of the fluid becomes an important part of the measurement because the rate of flow will depend both on the fluid's viscosity and on the magnitude of ΔP, which now depends on the fluid density, ρ, and on the height of the fluid above the capillary, h ($\Delta P = \rho g h$). The role of the fluid density is taken into account by the kinematic viscosity, defined as

$$\nu = \frac{\eta}{\rho} \tag{74}$$

That is, the kinematic viscosity is equal to the shear viscosity divided by the density. The viscosity obtained from gravity-driven capillary flow is in units of stokes (stoke = P/g/cm^3). The absolute shear viscosity can then be calculated from $\eta = \nu\rho$.

The velocity profile in tube flow is parabolic in shape for Newtonian liquids (as can be proven by integration of Eq 70), with the maximum shear rate at the walls and zero shear rate in the tube center. If non-Newtonian fluids are used, the velocity profile becomes nonparabolic and even more complex. As a result, the viscosity of non-Newtonian materials will vary across the diameter of the tube. Non-Newtonian fluid measurements may be made accurately only if the Weissenberg-Rabinowitsch correction is applied [*106*], which corrects for the variations in viscosity across the capillary arising from the nonuniform shear field.

$$\eta = \eta_a \left[1 - \frac{1}{4} \frac{d(\log \eta_a)}{d(\log \tau_w)} \right]^{-1} \tag{75}$$

where η_a is the uncorrected apparent viscosity.[24] The second term inside the brackets is obtained by calculating the slope of a log-log plot of the measured viscosity versus wall shear stress.

Tube flow is inappropriate for materials with yield behavior. Reviews by Schoff [*97,98*] describe the application of capillary viscometry to coatings.

[24]The "apparent viscosity" is simply the quotient of the apparent (experimentally measured) shear stress and the apparent shear rate. The "true" values of the foregoing, however, may be different from the apparent, where corrections are necessary, say, for flow fields where the shear rate may be varying across the field and must be corrected for non-Newtonian effects.

High-Shear Capillary Rheometry

It has been claimed by some that the measurement of very high shear rate viscosity is not necessary because it may be estimated from moderate-shear data. This is true to an extent, especially if one can obtain an adequate description of the general flow curve by use of one of the flow models containing the high-shear limiting Newtonian viscosity, η_∞ (e.g., the Sisko, Cross, or Carreau models). If a good fit to experimental data can be obtained, the latter models can be extrapolated to predict viscosity beyond the experimental range of shear rate with caution. The power-law-based models should not be used for estimation of high-shear viscosity since they predict unrealistic high-shear behavior (see **Shear-Dependent Viscosity**). However, under the best of circumstances, data should be extrapolated no further than about a decade of shear rate. This means that, in general, shear rates of less than 10^5 s^{-1} can be reached, even by extrapolation methods. It should be pointed out here that the onset of shear thickening (Region IV, Fig. 3) cannot be predicted by extrapolation, yet can cause disastrous consequences in high-shear application processes. For precise comparisons of materials, extrapolation will be unsatisfactory in any case. In fact, several industrial processes involve shear rates of 10^5 to 10^6 s^{-1}. These include airless spray and reverse rollcoating, for example. Performance problems of coatings exposed to such high shear will be difficult to resolve without direct experimental measurement under the appropriate deformation conditions. Such severe conditions of shear can cause a fundamental change in a material, such as gross coagulation of an emulsion, with a possible deleterious effect on rheology and hence on postapplication film formation behavior. It is recommended, therefore, to characterize materials exposed to high-shear processing by high-shear rheometry.

There are some commercial high-shear viscometers which use small-gap bob-in-cup geometry. Problems with this geometry include poor temperature control due to viscous heating and a tendency toward flow-field instabilities. Capillary viscometry has some advantages in both regards. The very short residence time in the capillary at high flow rates minimizes temperature rise, and, for length-to-diameter (L/D) ratios of 50 or greater, entrance effects are negligible and the flow field will be essentially uniform.

By use of short, small-diameter capillaries and high pressures, shear rates of approximately 10^6 s^{-1} are achievable for fluids in the range of viscosities typical of paints. At this writing, we are aware of only three commercial rheometers which may be suitable for high-shear rate measurement of coatings fluids. One is the ACAV High Shear Capillary Rheometer, marketed by ACA Systems Oy, Finland. Another capillary instrument capable of very high-shear measurements is the Paar-Physica HVA-6. The third is the Rheometrics RFX, which uses very narrow-gap annular flow in order to attain high shear rates at lower flow rates (Table 5).

Rank Pulse Shearometer

This instrument is a relatively inexpensive and easy-to-use viscoelastometer. A fixed-frequency acoustic wave pulse is passed through a test sample and the signal detected by a receiving transducer. The propagation velocity v is measured

from the signal transit time and used to calculate the shear elastic modulus according to

$$G' = \rho v^2 \tag{76}$$

The signal wave is of high frequency but very small amplitude (10^{-4} rad), so that weak gels are not disturbed (the induced strain will likely be within the linear viscoelastic regime). Because of the high frequency used, the measured shear modulus corresponds to the plateau modulus, G_∞ (see **Viscoelastic Models**). This gives a useful measure of the gel strength of even weak gels and has an advantage in this regard over instruments which subject the sample to uncontrolled shear upon closure.

Surface Energetics

by Gordon P. Bierwagen[1]

NOMENCLATURE

- a Integration limit, distance from surface into bulk of material, Eqs 3 and 6
- A Surface area
- b Variable in Eq 18, the difference in maximum and minimum diameters in elliptical orifice
- c Surfactant concentration
- c_i Concentration of species i
- c_{i0} Concentration of species i in the bulk
- D Diffusion coefficient
- $\mathscr{E}$ Surface elasticity
- f Correction factor in Eq 15
- g Acceleration of gravity
- G Gibbs free energy
- h Variable defined in Eq 9
- h Height in capillary rise measurements
- i Index identifying species i
- k Wave number = $2\pi/\lambda$ (λ = wavelength, see below)
- l Subscript indicating liquid phase
- l Length of capillary pore path in Eq 23
- $\mathbf{n}$ Normal vector to surface, Eq 3
- n Exponent in Eq 4
- n Most probable number of drops from breakup of charged drop, Eq 31
- n_i Number of moles of component i, Eq 2
- 0 Subscript indicating zeroth or bulk phase, or reference value
- p Pressure
- $\mathbf{p}$ Pressure tensor in the bulk phase, Eq 3
- $\mathbf{p}^T$ Tangential pressure tensor, Eq 3
- $\mathscr{P}$ Perimeter length
- Q Liquid flux, volume/second
- q Charge on drop
- r Variable in Eq 18, sum of maximum and minimum radii in elliptical orifice
- r Radius
- R Ring radius in Du Nouy ring surface tension measurement
- R_1, R_2 Principal radii of curvature
- s Subscript indicating solid phase
- T Temperature
- T_c Critical temperature
- x Distance from surface in Eq 6
- ν Index indicating vapor phase, Eq 10
- v Velocity
- V Volume
- W Weight
- γ Liquid surface tension
- Γ, Γ_i Surface excess concentration, of ith species
- δ_f Final film thickness in dip coating
- Δ Difference
- ϵ Dielectric constant
- η Viscosity
- λ Wavelength
- μ_i Chemical potential of species i
- π 3.141 59
- Θ Contact angle
- ρ Density

INTRODUCTION

SURFACES ACT AND PERFORM differently from bulk materials because they have two distinct properties that are not true of bulk materials. First, because of unbalanced forces on molecules or atoms at a surface as compared to the bulk, those in the surface have an excess free energy [*1*] (i.e., they are in a higher state of potential energy). This excess energy per unit area is the thermodynamic cost of forming a new surface and has the units of energy/area, or force/length. These latter units are those of tension, and the surface excess free energy is often known as surface tension and can be measured for liquids as such. (A more detailed discussion of this excess free energy identified with a surface, including the thermodynamic definition of surface tension, is given below.) Second, there is a preferred direction normal to the surface that can be defined in the mechanical definition [*2*] of surface tension. This directional effect of surfaces can be observed in molecular directionality in adsorption phenomena, surface area minimization by surface tension effects, and molecular ordering in Langmuir-Blodgett films deposited from ordered mono-molecular layers (monolayers).

Surfaces occur only when there is an energetic cost to creating an interface between two dissimilar materials or phases. Thus, there are no stable interfaces between gases, between supercritical fluids, nor among phases in a material above its critical point. However, surfaces can occur between gas and liquid (g/l), liquid and liquid (l/l), gas and solid (g/s), liquid and solid (l/s), and between solid and solid (s/s). An example of a g/l interface is the surface of a pool of water, and so forth. Liquid surface energy phenomena can be analyzed directly by equilibrium thermodynamics because a liquid

[1]Professor of Polymers and Coatings, Department of Polymers and Coatings, North Dakota State University, Fargo, ND 58105.

Copyright© 1995 by ASTM International

surface cannot support a stress. For a solid, surface energy and surface stress must both be considered in analyzing the properties of an interface, since the past history of the solid will affect the properties of a solid surface [3]. Even though this is well known, there has not been as much concern given to the surface history of solids in considering their surface properties as often necessary.

Surface effects relative to bulk properties become more important as the surface area to volume ratio for materials becomes larger. In the simplest case, a sphere, this ratio is given by

$$\frac{A}{V} = \left[\frac{4\pi r^2}{\frac{4}{3}\pi r^3}\right] = \frac{3}{r} \tag{1}$$

Surface effects thus increase in importance as the size of the object being considered becomes smaller. Statistical thermodynamics and molecular dynamics considerations indicate that the range of the range of surface effects as 2 to 5 molecular diameters [4]. An interesting feature of this type of analysis of surface effects and their ranges is that the distance of propagation of surface effects into the bulk from a polymer adsorbed at an interface can be quite large in atomic dimensions. In effect, the interface is a site of pinning one end of the polymer, taking away one of its degrees of freedom of motion, and thus making the interface a location of a layer of polymer of different thermomechanical properties than the rest of the polymer. This is exceptionally important when analyzing the adhesion of polymeric films to bulk substrates. The strength of the adhesive bond can be influenced by these directionality effects and can be even more important if the substrate is a plastic (polymer), where the ordering effects propagate on both sides of the interface. The directionality and ordering of surrounding polymeric bulk media by an interface can extend unexpectedly large distances. Many of the properties of self-ordering systems have these effects as their origin. This will be commented upon further in the discussion of surface effects in pigment dispersion and emulsions.

All who deal with coatings must realize that surface effects are very important in all stages of coatings preparation, application, and utilization. Coatings are thin films with a high surface-to-volume ratio. Pigments have large surface-to-volume ratios, and their surfaces are often chemically reactive or catalyze reactions [5]. Latex polymers also occur in fine particulate form, and their use and stability depend on surface-dominated effects. Foaming, cratering, and other defects in coatings come about through surface-mediated events [6]. Wetting and coverage of substrates by coatings and the adhesion of coatings to these same substrates are also strongly affected by surface effects. Adsorption at surfaces of particulate materials in a coating, be they pigments or polymer particles, is controlled by the energetics of the interface between the particles and the suspending liquid.

SURFACE THERMODYNAMICS—BASICS

Liquid Surfaces

To understand surface energetics in coatings, one must first understand the basics of the thermodynamics of surfaces and interfaces. The definition of the Gibbs free energy is modified when the system under consideration contains a surface. The defining equation for liquids is

$$dG = -SdT + Vdp + \Sigma_i \mu_i dn_i + \gamma dA \tag{2}$$

where G, T, S, V, p, μ_i and n_i are the thermodynamic quantities Gibbs free energy. Temperature, entropy, volume, pressure, chemical potential of component i, and the number of moles of component i, respectively, and γ and A are the surface tension and surface area. The other equations of thermodynamics can be similarly modified. As can be seen, the energetic cost of expanding a liquid surface is the γdA term. As pointed out above, this use of γ is valid only for liquid interfaces. Another equation for γ is the mechanical definition of Ref 2, also discussed by Adamson [1] and reviewed by Burshtein [7] and Navascues [8] as

$$\gamma = \int_{-a}^{+a} (\mathbf{p} - \mathbf{p}^T)\, d\mathbf{n} \tag{3}$$

where $+a$ and $-a$ are distances in either direction of the surface such that molecules at these positions are in the bulk phases, $\mathbf{p}$ and $\mathbf{p}^T$ are the bulk pressure and the tangential pressure tensors, respectively, and $\mathbf{n}$ is the normal vector to the surface. This is shown schematically in Fig. 1. The direction of $\mathbf{n}$ is the preferred direction of a surface referred to above. Even if it is not commonly included in introductory discussions of surface phenomena, it is important to consider Eq 3 when considering the thermodynamics of surfaces because it is the relationship between the bulk mechanical properties of the system and the almost "distincontinuous" behavior of the system properties at an interface. This expression describes the *directionality* that an interface possesses and is very crucial to modern theories of capillarity [9].

In general, the surface tension, γ, of pure liquids decreases with increasing temperature. An approximate form of this temperature dependence is [10]

$$\gamma = \gamma^0 \left(1 - \frac{T}{T_c}\right)^n \tag{4}$$

where γ^0 is the surface tension at $T = 0$, T_c is the critical temperature of the material, and n is an empirical exponent, ~11/9 for organic liquids.

The other important thermodynamic relation for surfaces is the Gibbs equation. In multicomponent systems, one must consider the effects of materials absorbing at the interface. When these are properly taken into account, the Gibbs equation (at constant T and p) results

$$d\gamma = -\Sigma_i \Gamma_i d\mu_i \tag{5}$$

where Γ_i is the surface excess concentration value for component i [11]. This equation gives the relationship between the surface tension of a fluid interface and the amounts of surface active materials (hereafter referred to as surfactants) in the solution (component i). The surface excess concentration Γ_i is the difference between the actual and bulk concentrations, c_i and c_{i0}, of component i and can be calculated in a manner analogous to Eq 3 as

$$\Gamma_i = \int_{-a}^{+a} (c_i - c_{i0})\, dx \tag{6}$$

where x is again the direction normal to the interface and $+a$ and $-a$ are locations equidistant from the interface in the bulk of the material. This is shown schematically for a single surfactant in Fig. 2. In adsorption of materials to an interface,

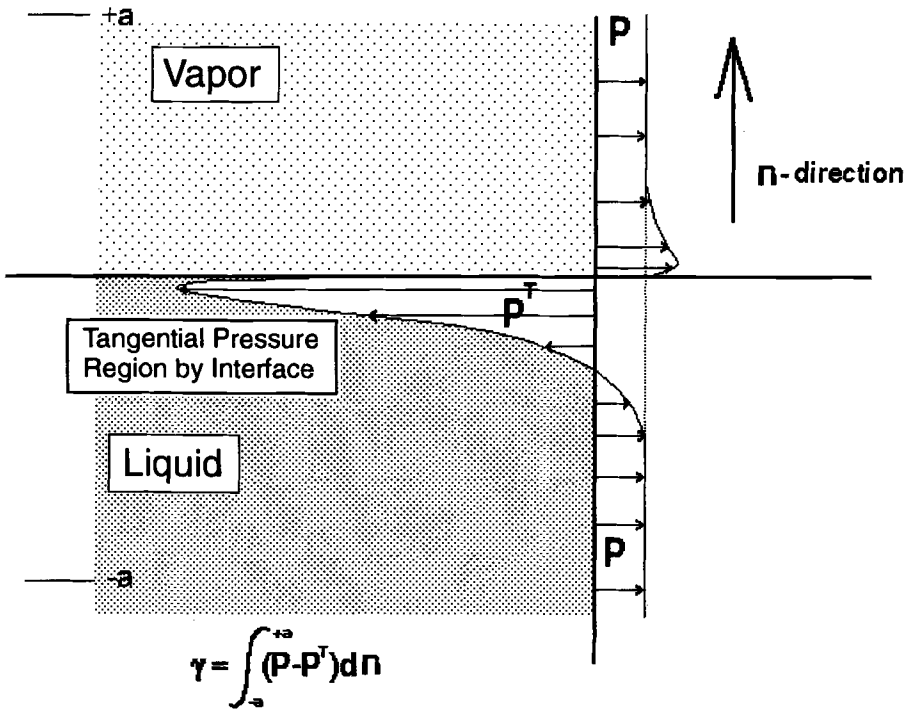

FIG. 1–Schematic of local pressure changes at surface giving surface tension.

the local concentration in the neighborhood of the interface can be much larger (by factors of up to 10^8 or larger—see Ref *1*, Chapter III for further details) than that in the bulk. The net energy of the system is minimized by the surfactant molecules adsorbing and orienting at the interface to reduce interactions between unlike molecular components. The terms often used to describe the compositional differences in surfactants are polar/nonpolar or hydrophobic/hydrophilic. Materials that act as surfactants are those that have a distinct difference between different parts of their molecules, the

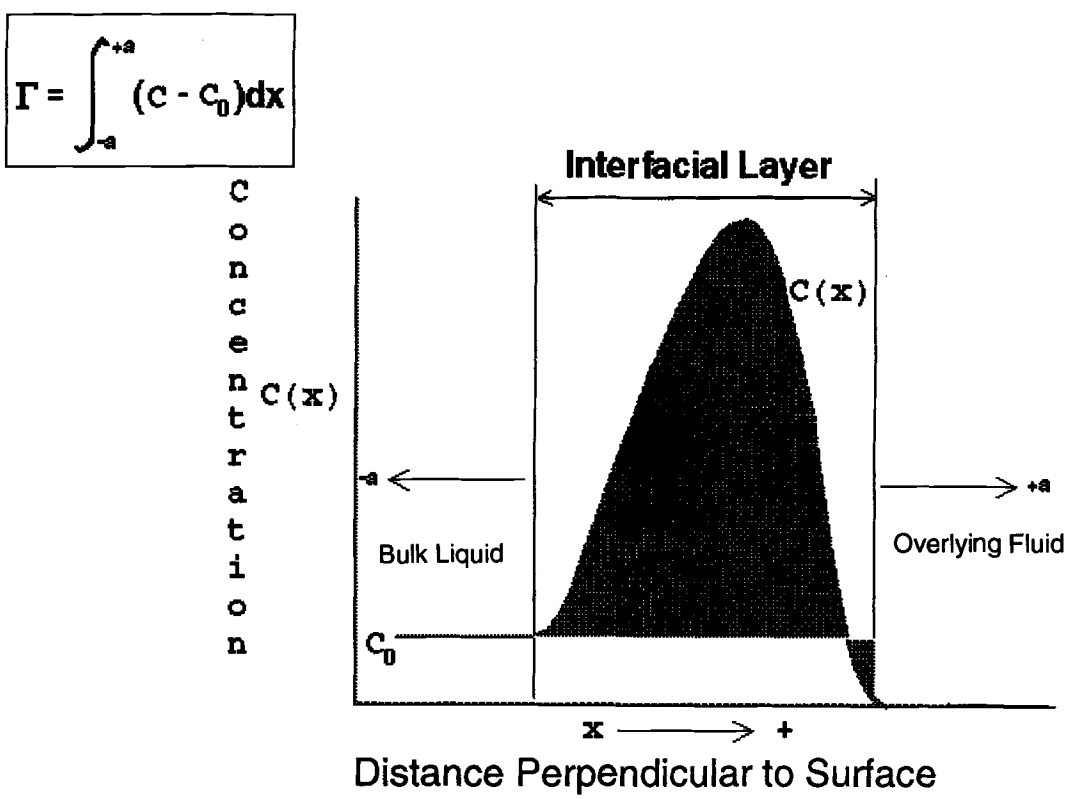

FIG. 2–Schematic of surface excess concentration as calculated as difference for bulk concentration.

classic example being soaps, with an alkyl nonpolar group and a [carboxylate + metal ion] polar group.

In concentrated systems of surface-active materials, especially those of low inherent solubility in the liquid phase, at a certain concentration the addition of further surfactant no longer depresses the surface tension, as the surface is saturated, and the molecules of the surfactant begin to form self-ordered structures in the bulk liquid called micelles [*12*]. Micelles are aggregates of surfactant molecules that form in solution to minimize the total system energy. In water they orient with the hydrophobic portion of the molecule directed toward the interior of the micelle, and in nonaqueous systems they have the polar end in the interior. At the concentration of surfactant that micelles just begin to form, many of the solution properties also undergo rapid change, and this breakpoint in surfactant solution properties is known as the critical micelle concentration (CMC) (Fig. 3). The CMC is a unique concentration for a surfactant/solvent combination at a specified temperature. The book by Rosen [*13*] gives an expanded discussion of surfactant behavior, and Tanford's book [*14*] gives an expanded description of micellar behavior in aqueous systems. These texts also describe the complex aggregates that form in surfactant/solvent mixtures, including membrane-like structures and liquid crystals.

As Gibbs first noted, the presence of a material adsorbing preferentially at an interface imparts an elasticity to the surface, as it will tend to resist expansion and contraction. This surface elasticity is given by

$$\mathscr{E} = -\frac{d\gamma}{d\ln A} = -\frac{d\gamma}{d\ln\Gamma} \tag{7}$$

where A is the surface area. This elasticity is the resistance to disturbance of a film by the presence of a surfactant. The effects of this surface elasticity have been reviewed with respect to its effects in liquid films and liquid threads [*15*]. Surface elasticity measurements have been used to characterize the properties of monomolecular layers at surfaces [*16*]. If there are diffusional effects due to soluble surfactants (see below, "Dynamic Properties of Surfaces"), they will reduce the surface elasticity, effectively short circuiting the surface tension changes by surface replenishment [*17–19*]. In these cases, Eq 7 should be modified to read

$$\mathscr{E} = \frac{-(d\gamma/d\ln\Gamma)}{[1 + (h/2)(dc/d\Gamma)]} \tag{8}$$

where c is the surfactant concentration and h is given by the relationship

$$h = 2\sqrt{\frac{D}{\omega}} \tag{9}$$

where D is the surfactant diffusion coefficient, and ω is the frequency of the surface motion [*18*]. Surface elasticity effects are a major consideration in foam stability [*20*] and in coating application processes [*21*], where there are rapid surface area changes and creation of new surfaces.

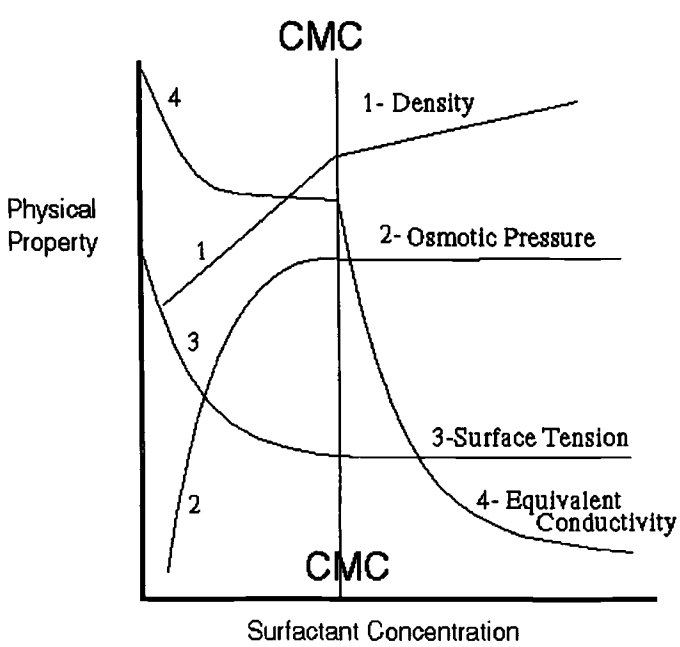

FIG. 3–Schematic of physical property changes in surfactant solution at critical micelle concentration (CMC).

Liquid/Solid Interfaces: Wetting and Contact Angles

When a liquid solution is in contact with a bulk solid, the Young equation holds true as

$$\gamma_{sl} - \gamma_{sv} + \gamma_{lv}\cos\Theta = 0 \tag{10}$$

where γ_{sl}, γ_{sv}, and γ_{lv} are the solid/liquid, solid/vapor, and liquid/vapor surface tensions, respectively, and Θ is the contact angle formed between the liquid and solid [*9,22*]. This is shown in Fig. 4 and discussed extensively in the references given above. The contact angle between a liquid and a solid is in some ways a measure of the difference in surface energies of the solid and liquid. If a liquid "wets" a solid, the contact angle is zero, and the liquid spreads spontaneously over the surface of the solid, displacing air in contact with the solid surface. If the contact angle is greater than zero, a liquid will not wet and spread on a solid. An extreme example of this is found with Teflon™, which is of such a low surface energy that it is wet by few pure liquids or solutions. In general, pure

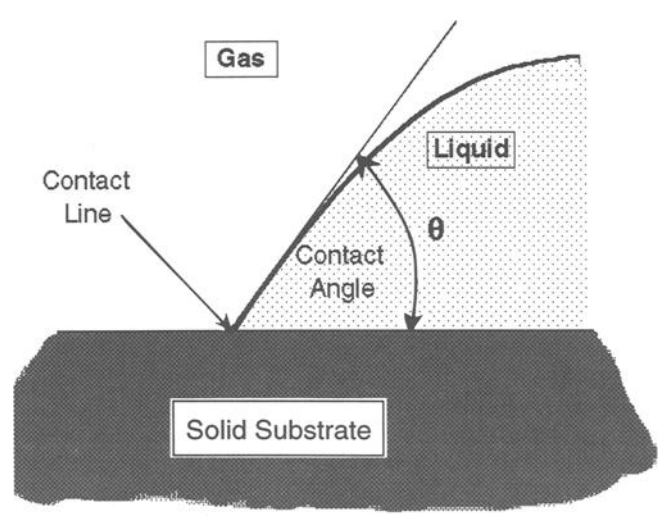

FIG. 4–Schematic of contact angle in G/L/S system.

hydrocarbon and fluorocarbon interfaces that are nonpolar in nature have very low surface energies and are difficult to wet, while polar materials such as metals and metal oxides have high surface energies and are easily wet. Oils or other impurities on the surface of a polar substrate will cause the material to act as a low surface energy solid, making it difficult to wet. There is extensive qualitative discussion in the literature concerning polar and nonpolar contributions to surface energetics, much of it of value only in a qualitative sense as a guide to interpreting the wetting behavior of pure liquids. Good and Fowkes have both published extensively in this area (see Refs *1* and *23* for a more complete listing of these citations), and the literature is full of equations of arguable theoretical value invoking empirical relations between composition and surface energetics, including acid-base interactions [*23*]. In coatings application, it is very crucial to have the liquid coating wet the substrate. Substrate cleaning and the use of surfactants to depress the liquid coating surface tension and reduce the contact angle to zero are two of the most common steps to achieve this. It is essential to have this wetting of the substrate to obtain good adhesion of the coating to the substrate, hence the importance of proper surface preparation for coatings use.

Rough surfaces tend to have lower contact angles than smooth surfaces of the same composition [*24*]. This is why sanding or other surface roughening will give better wetting of a material by a coating. There is also often a difference in the contact angle measured by an advancing drop and a receding drop, the advancing angle being the larger. This is often due to surface roughness, causing a hysteresis in the contact angle [*25*]. Surface compositional differences and their scale have also been shown to give hysteresis, both by themselves and together with surface roughness [*26*]. These literature references, plus many others (see Ref *1* for a more complete discussion), indicate the difficulties in obtaining completely unambiguous contact angle measurements, especially when considering both advancing and receding drops on solid surfaces. Zisman and coworkers have also shown that there is a "critical surface tension" characteristic of a given surface [*27*]. This is determined by plotting the cosine of the contact angle Θ versus surface tension and extrapolating to $\cos \Theta = 1$ (zero contact angle) and determining the surface tension at this value. This is often used to determine the relative surface energy of a solid and the surface tension required of a wetting liquid for that surface. Pure liquids can be used as test liquids for the measurement of critical surface tension, or surfactant solutions can be utilized [*13,28*]. Some precautions need to be taken on the choice of test liquids as the polarity of the test liquid may influence measurements and thus the extrapolation procedure used to estimate the critical surface tension (see Ref *1* for further details).

Exposure to exterior weathering has been noted to decrease contact angles of organic coatings and other polymeric films [*29*]. Similar effects are noted when these surfaces are modified by corona or flame treatment, and these treatments are often used to give wetting and adhesion of coatings to hard-to-wet plastic substrates such as polyethylene and polypropylene. In addition to these surface treatments, it has been found that certain chlorinated olefinic polymers improve the wetting and adhesion of coatings to polyolefin plastics [*30*].

DYNAMIC PROPERTIES OF LIQUID SURFACES

When fresh surfaces are formed in a liquid solution, such as in coatings application processes, manufacture, etc., the surface tension and composition of the fresh surface of a solution will be different from the equilibrium value. At the time of new surface creation, the surface tension of the liquid will be nearly equal to the surface tension of the pure solvent at the instant of the surface formation. The surface tension then decreases as the surfactant in the solution diffuses to the interface. The dynamics of the diffusion from bulk to interface, or vice versa in the case of surface compression, has been well studied, initially by Ward and Tordai [*31*] and later by Sutherland [*32*], Hansen [*33*], Joos [*34*], and others. There are also possible complicating effects if the adsorbing material is polymeric, for which case additional time-dependent changes in the surface tension may occur as the polymer molecules relax to their equilibrium conformation at the surface, or if there is an energy barrier to adsorption of the material [*35,36*]. Special methods have been developed to measure dynamic surface tension, and these are discussed below, along with static surface tension measurement methods. It is especially important to consider and eliminate dynamic surface tension effects if one is trying to measure the equilibrium value of $\gamma[\gamma(t)$ for $t \rightarrow \infty]$, meaning for example, a Wilhelmy plate rather than a Du Nuoy ring is the appropriate measurement for systems that are other than pure liquids. These dynamic effects are especially important in coating application processes and all coating operations that generate fresh surfaces [*37*]. There are also dynamic effects in the wetting of surfaces that must be considered for coating application operations. The first is the dynamics of wetting in thin film spreading as discussed by de Gennes [*38*]; the other is the dynamics of contact angles on moving substrates [*39*].

MEASUREMENT OF THE SURFACE TENSION OF LIQUIDS

Introduction

There are many ways of measuring surface tension, but in essence, they are all related to two effects of capillarity. The first effect is the excess pressure due to surface tension at a curved interface. This is described by the Young-Laplace equation as

$$\Delta p = \gamma(1/R_1 + 1/R_2) \tag{11}$$

where Δp is the excess pressure due to the curved interface, and R_1 and R_2 are the two principal radii of curvature of the interface. In the case of a sphere of radius r, where the radii of curvature are both equal to r, this equation reduces to

$$\Delta p = 2\gamma/r \tag{12}$$

The other capillary effect is that the surface tension of a liquid exerts a force on a solid body immersed in it equal to the surface tension times the perimeter of the body times the contact angle the liquid makes with the solid. If one is using a balance, one can write

$$\Delta W = \mathcal{P}\gamma \cos \Theta \tag{13}$$

where $\mathcal{P}$ is the perimeter and Θ is the contact angle, and ΔW is the extra force on the solid body due to surface tension. These two effects yield, together with various modifications of geometry, etc., many methods to measure static and dynamic surface tension. The most widely used methods are described below.

In all measurements of surface tension, the cleanliness of all apparatus and the purity of all materials is of utmost importance. Organic impurities in aqueous systems will have drastic effects in reducing the surface tension values measured. The concentration levels necessary to alter surface tension measurements are as little as 10^{-8} M. Trace amounts of impurities on solid apparatus surfaces can alter contact angles and, as will be shown, the measured surface tension values. All water used in surface tension measurements should be at least double distilled, and often the presence of a strong oxidizing agent in one step of the distillation ensures that trace surfactants are removed. The water should be used fresh, as surface active impurities can be leached from glass and plastic containers. The same holds true for all solvents used in surface characterization studies.

Static Surface Tension Measurements

There is a group of surface tension measurement methods that apply well only to a static system. These methods must thus be used on systems where there is no formation of fresh surfaces, or with pure liquid.

Capillary Rise

There will be a pressure on a liquid in a small capillary tube relative to the pressure on a large vessel of the liquid. Using Eq 12 and allowing for the contact angle between the liquid and the capillary, we have at equilibrium between the force of gravity and the capillary pressure

$$\Delta\rho g h = \frac{2\gamma \cos \Theta}{r} \tag{14}$$

where $\Delta\rho$ is the density difference between the liquid and air, g is the acceleration of gravity, h is the height of the capillary rise, and the rest of the terms are defined above. This equation allows one to measure the surface tension from a simple measurement of the height of the rise of the liquid in a capillary of known radius and contact angle with the test liquid. This method is shown schematically in Fig. 5.

Drop Weight

The weight of a drop when it is formed slowly is the weight just to exceed the force of surface tension times the radius of the capillary tip from which it is formed, with a correction factor required for the formation of small satellite drops. Thus, one has

$$W = 2\pi\gamma r f \tag{15}$$

where W is the weight of the drop and f is the correction factor which is discussed in Adamson [*1*]. This method is simple to use and accurate if precautions are taken for cleanliness and very slow flow rates of the liquid in the formation of drops. The method is shown schematically in Fig. 6.

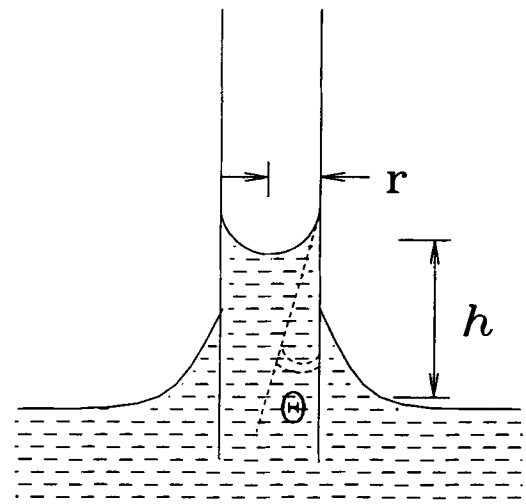

FIG. 5–Schematic of capillary rise method of measuring surface tension.

Du Nuoy Ring

Applying Eq 13 to the case where the object is a ring being pulled from the surface of a liquid, one has

$$W = W_{\text{ring}} + 4\pi\gamma R \tag{16}$$

where W is the total weight sensed by a balance, W_{ring} is the ring weight, and R is the ring radius as shown in Fig. 7. However, this formula requires correction to be accurate and holds only for a zero contact angle between the ring and test

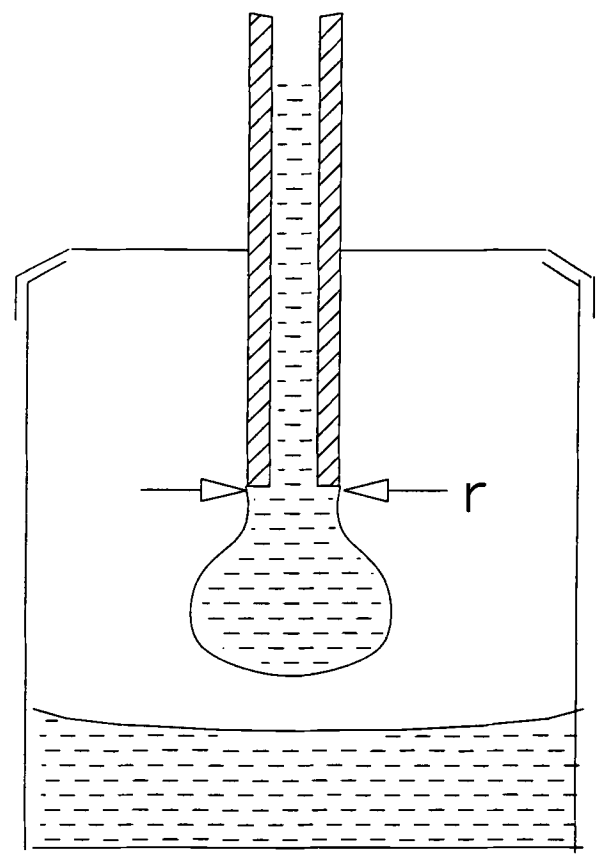

FIG. 6–Schematic of drop weight method of measuring surface tension.

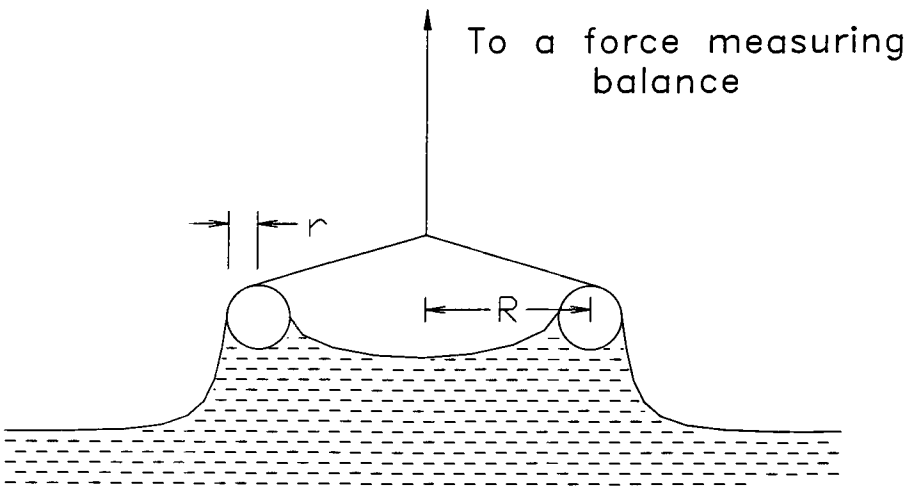

FIG. 7–Schematic of Du Nuoy ring method of measuring surface tension.

liquid. Again, see Adamson [*1*] for further details. The force measured by the balance is that force just at detachment of the ring and so involves motion of the sensor; the method is thus not an appropriate technique to use in studying solutions.

Wilhelmy Plate

If one uses a thin plate instead of a ring and measures the force exerted on the plate just touching the surface of a liquid, one has

$$W = W_{\text{plate}} + \gamma\mathcal{P} \tag{17}$$

where $\mathcal{P}$ is the perimeter of the plate. If the liquid does not perfectly wet the plate, the expression

$$W = W_{\text{plate}} + \gamma\mathcal{P}\cos\Theta \tag{17a}$$

must be used as illustrated in Fig. 8. The perimeter of the plate may be determined in practice as an experimental constant from γ measurements with liquids of known surface tension. Again cleanliness is most crucial, and a roughened platinum plate cleaned in a Bunsen burner flame is often used to give a clean plate that is wet by most liquids. As there is no motion of the plate in the measurement, this method can be used to measure dynamic as well as static values of γ. This technique may be used as well with a rod [*40*] or cone [*41*] instead of a plate and may also be used to measure the contact angle of a liquid of known surface tension against a specific plate, fiber, or cone-shaped substrate (see later in this chapter under **CONTACT ANGLE MEASUREMENTS**). Also, the method does not need corrections as with the drop weight or the Du Nuoy ring methods.

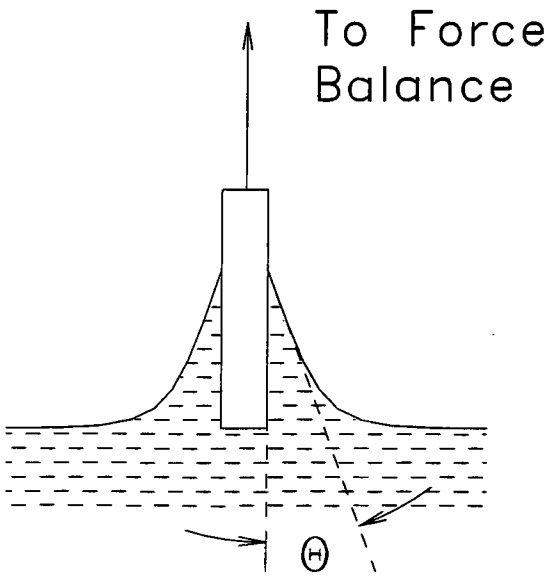

FIG. 8–Schematic of Wilhelmy plate method of measuring surface tension.

Sessile or Pendant Drop Shape Methods

If the shape of a sessile or pendant drop is measured photographically or a digitizing camera, a solution of Eq 11 for the specific shape of the drop in the presence of a gravitational field can be used with the measurements of the drop profile to back calculate the surface tension of the drop. Figure 9 gives a schematic of the method. This method works well at liquid-air or liquid-liquid interfaces and can also be used to make dynamic measurements if the camera response is continuous and rapid [*42*]. A variation of the drop-shape method of measurement is used wherein the drop is deformed by a centrifugal field or an electric field. The former, the spinning drop shape method, allows very small interfacial tensions to be measured between two liquids [*43*].

Maximum Bubble Pressure Methods

If one forms a bubble within a liquid by forcing a gas out the end of a capillary, the maximum pressure on the bubble can be used to measure surface tension by Eq 12. This measurement procedure is illustrated in Fig. 10. However, the measurement must be corrected for the nonspherical shape of the bubble. With rapid formation of the bubbles and accurate differential pressure measurement, the technique may be used to make dynamic measurements [*44*]. If capillaries of two different radii are used simultaneously and the pressure difference between the bubbles formed at the two capillaries is measured, a rapid, accurate measurement of surface tension can be made and has been used as a process monitor in emulsion polymerization [*45*]. This is known as the differential bubble pressure method and is illustrated in Fig. 11.

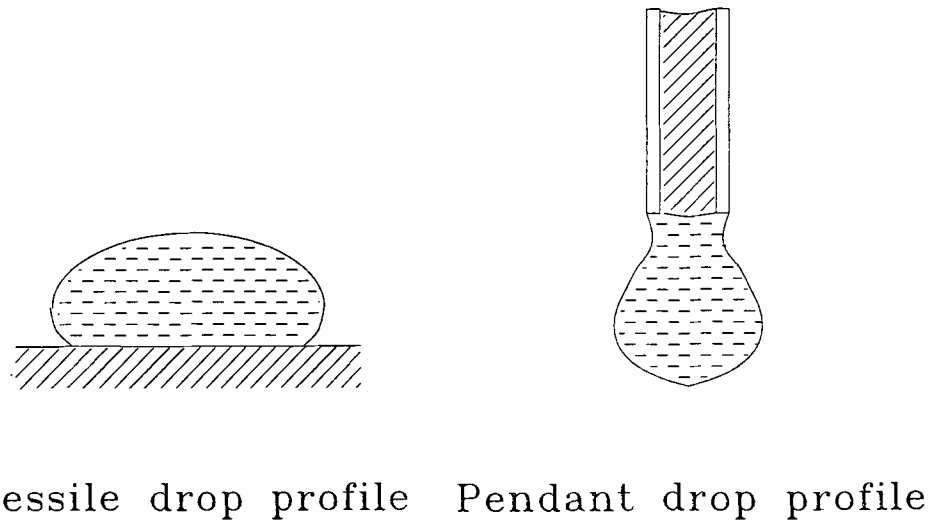

FIG. 9–Schematic of sessile and pendant drop methods of measuring surface tension.

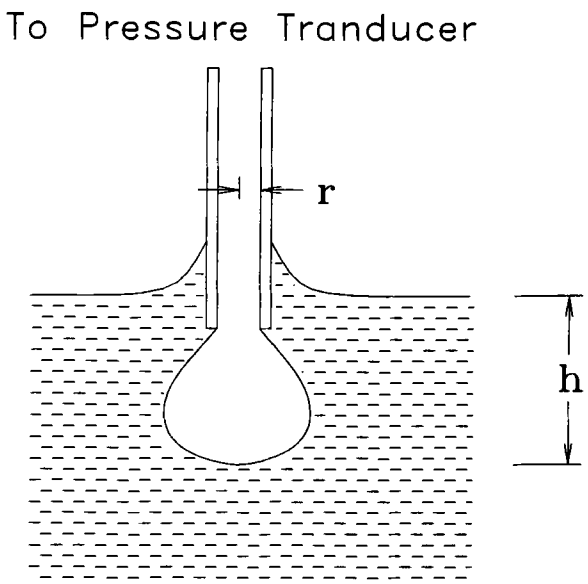

FIG. 10–Schematic of maximum bubble pressure method of measuring surface tension.

Dynamic Surface Tension Methods

If one is concerned with surface tension effects that occur in freshly formed surfaces, in flow systems, or in polymer solutions where the time for equilibrium may be quite long, one must consider methods that properly measure dynamic surface tension. As mentioned above, bubble pressure and drop-shape methods as well as the Wilhelmy plate method can be used for static as well as dynamic γ measurements. These methods are appropriate only for relatively slow changes in γ, but we discuss them briefly below and provide literature references that discuss their use in characterizing $\gamma(t)$ effects. There are techniques to measure γ that have been developed specifically for short-time scales and fresh, rapidly changing surfaces.

Oscillating Jet

If a liquid leaves as a jet through an elliptical orifice, it is mechanically unstable and will begin to oscillate about a circular shape, as shown in Fig. 12, eventually breaking up into droplets. The oscillations are periodic, and measurement of their wavelength can be used to determine γ as given by

$$\gamma_{\text{app}} = \frac{4\rho v^2 \left(1 + \dfrac{37b^2}{24r^2}\right)}{6r\lambda^2 \left(1 + \dfrac{5\pi^2 r^2}{3\lambda^2}\right)} \tag{18}$$

where ρ is the liquid density, v is the velocity of the jet, λ is the wavelength of the oscillation, r is the sum of the minimum and maximum diameters, and b is their difference [*1*]. This dynamic measurement of γ has been considered by Vijian and Ponter [*46*], who give references to the earlier work of Rayleigh, Bohr, Sutherland, Hansen, and others.

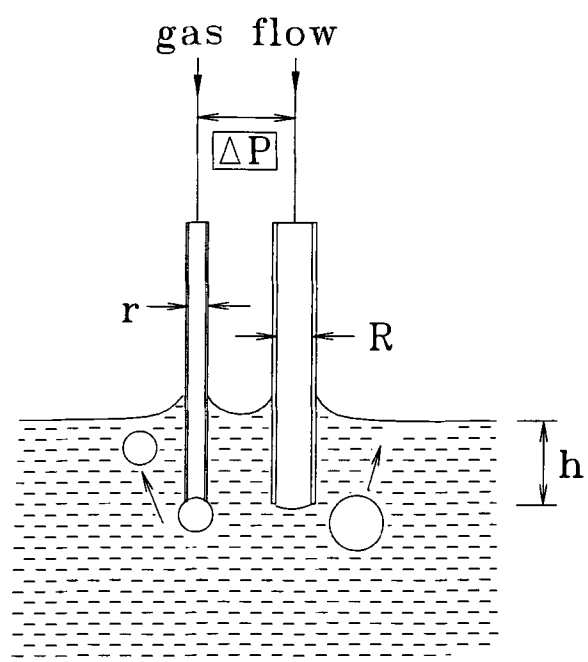

FIG. 11–Schematic of differential bubble pressure method of measuring surface tension.

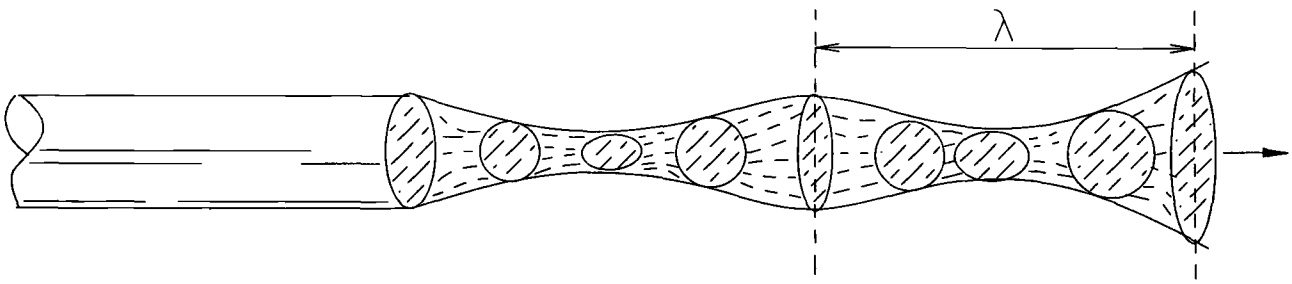

FIG. 12–Schematic of oscillating jet method of measuring surface tension.

Falling Curtain

In an analysis of curtain coating, Brown [*47*] observed that the angle Θ in the falling curtain formed by the break around a small, nonwettable obstacle could be used to measure surface tension as

$$\sin \Theta = \frac{2\gamma}{Qu} \tag{19}$$

where Q is the mass flow rate per unit orifice slit length in the curtain and u is the velocity of the liquid. This can enable one to calculate the dynamic surface tension in the falling film at the point where the obstacle intersects the falling curtain if the velocity u is greater than the "bursting velocity" of the falling sheet. A schematic of this method is given in Fig. 13. This has been considered further by Van Havenburgh and Joos [*48*]. Antoniades et al. [*49*] reconsidered the work of Brown and suggest that Eq 19, when derived correctly, should be written as

$$\sin^2 \Theta = \frac{2\gamma}{Qu} \tag{19a}$$

and give experimental evidence for this corrected equation.

Capillary Waves

The properties of capillary waves, small wavelength waves on the surface of a liquid with the dominant restoring force being surface tension, can be studied to provide a measurement of surface tension, surface elasticity, and other dynamic surface properties. For clean surfaces of an inviscid liquid, Kelvin [*50*] determined that on a liquid of density ρ, waves of frequency ω, and wave number k, the surface tension is given for small wavelengths

$$\gamma = \frac{\rho\omega^2}{k^3} \tag{20}$$

The situation for interfaces in real systems, viscous liquids with surfactants present, has been studied in detail [*8,9*], and the use of mechanically generated capillary waves for studying interfaces has been reviewed by Hansen and Ahmad [*51*]. The capillary waves generated by temperature fluctuations at a surface can be measured by laser-light scattering techniques, and these data can be used to generate very accurate values of surface and interfacial tensions [*52*]. Capillary wave studies can be used to study the time dependence of γ in some detail and are probably the most accurate and complete of the methods for measuring all dynamic surface properties.

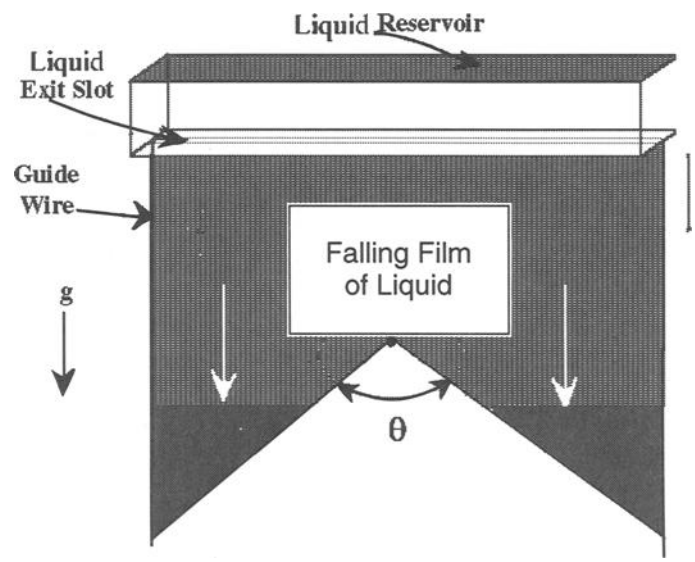

FIG. 13–Schematic of falling film method of measuring surface tension.

The Falling Meniscus Method

The measurement of the height of a column of liquid in a tube with a small opening on top can be used to measure the dynamic surface tension of aqueous systems. The height measurement versus time may be analyzed to calculate the surface tension as a function of time. This is discussed in further detail, together with a full description of the experimental apparatus and analytical equations, by Defay and Hommeln [*53*].

Modified Static Surface Tension Measurements

Maximum Bubble Pressure—If one can monitor the time response of pressure to the time-dependent surface tension, one can use the maximum bubble pressure technique described above to measure dynamic surface tension [*44*]. The equipment required for such measurements is the same as the static maximum bubble technique plus instrumentation for time-dependent measurement of the bubble pressure. Various authors have examined the theoretical and experimental aspects of this method [*34,54*].

Wilhelmy Plate—If a time-recording balance is used to monitor the force of surface tension pulling on the immersed plate, the Wilhelmy plate technique can be used for characterizing dynamic surface tension. As discussed above, the method is not useful for short times, but for slowly varying $\gamma(t)$ values. The method is used considerably with Langmuir

film balances and has been applied to various other problems [*55*].

Other Methods—If a sensing technique that can be time resolved is coupled to a specific static surface tension measurement, $\gamma(t)$ data can be acquired. Reference *42* discusses this for drop-shape methods, and Jho and Burke [*56*] present a modification of the drop weight technique for $\gamma(t)$ characterization.

CONTACT ANGLE MEASUREMENTS

Optical Measurement Methods

Contact angles are often measured by some form of optical measurement technique, either directly by a contact angle goniometer, by a measurement on a photograph of a drop shape, or digitally on a video image of the drop. A diagram of a contact angle goniometer is given in Fig. 14. This measurement often is done with the aid of a microscope. [*57*]. One can also calculate the contact angle from the dimensions of a drip on a solid surface. The corrections and information given in sessile drop, etc., measurement descriptions inherently contain information on the drop profiles, including the contact angle [*38,39*]. A more complete discussion of contact angle measurements is given by Neuman and Good [*58*], and Adamson [*1*] also surveys these measurements. Sell and Renzow [*59*] have reviewed the application of contact angle studies to pigments and give comments on the measurement of contact angles in pigments. The relation of wetting and the thermodynamics of liquid-solid interfaces to adhesion are discussed in some detail in the monograph edited by Lee [*60*].

Wilhelmy Plate Method

Using the solid substrate material to be coated as the plate and a liquid of known surface tension as the test liquid, the Wilhelmy Plate method (Eq 17) can be modified to give

$$\cos \Theta = \Delta W/\gamma\mathcal{P} \tag{21}$$

Figure 8 illustrates the principles of this procedure.

Capillary Rise Method

In a similar manner, the equation for capillary rise for a nonzero contact angle can be modified to read

$$\cos \Theta = \frac{\Delta\rho r g h}{2\gamma} \tag{22}$$

Rate of Penetration

Washburn of the National Bureau of Standards (now NIST) has developed an equation from the capillary rise equation which relates the rate of penetration of liquid into a bulk sample of powdered material to the surface tension of the penetrating liquid and the contact angle between the liquid and the powder [*61*]. This equation can be used with known materials to back calculate the contact angle as

$$\cos \Theta = \frac{4\nu\eta l}{\gamma r} \tag{23}$$

where l is the length of the capillary path in the powder, r is the average pore size, ν is the velocity of penetration, and η is the viscosity of the penetrating liquid. This equation can be used to estimate wetting properties and kinetics in the dispersion of pigments. A more recent discussion of this problem is given by Letelier et al. [*62*].

SOME SPECIFIC APPLICATIONS OF SURFACE ENERGETICS TO ORGANIC COATINGS

Coatings Application and Defects

Flow phenomena, and their control, at surfaces are very important to coatings film application technology [*6,63*]. The creation of uniform thin films at high speeds involves many problems that are determined by a combination of the application geometry, the velocity of the substrate relative to the liquid coating, the physical properties of the liquid coating, especially the energetics of the surface of the liquid coating, the surface of the substrate, and the new liquid/solid and gas/

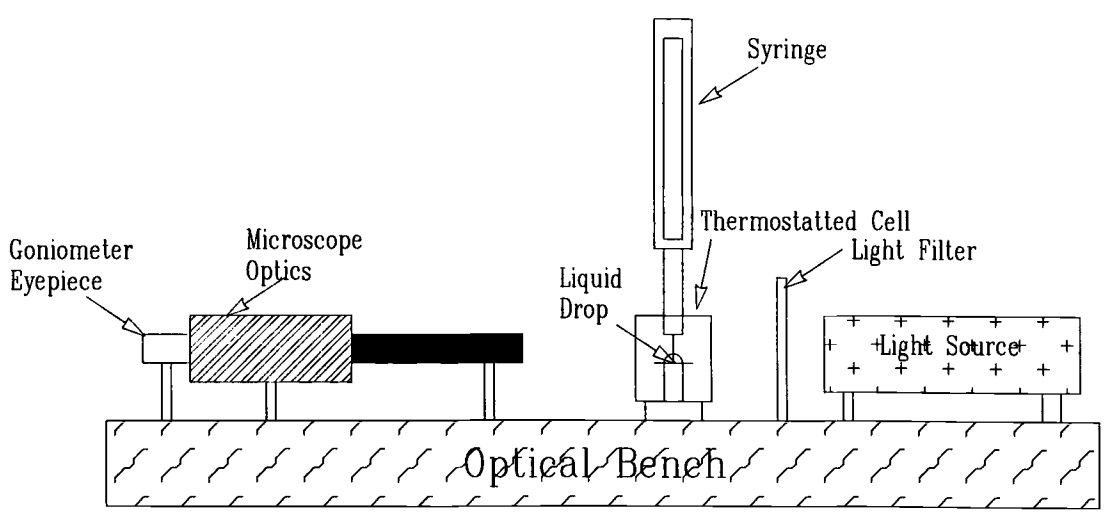

FIG. 14–Schematic of contact angle goniometer.

liquid interfaces created in the application processes. Analysis of several application techniques is given below to illustrate the importance of the use of concepts discussed in the prior portion of this chapter.

Dip Coating

Dip coating is a coating method in which a sheet of material is constantly withdrawn vertically from a coating liquid bath at constant velocity, producing a constant film thickness coating adhering to the sheet, which is usually then dried or cured to produce the final coating on the sheet (see Fig. 15). This problem was originally analyzed by Landau and Levich [*64*], and its solution has been given in modern form by Probstein [*65*]. Only the solution of the problem will be given here, but it is representative of the problems identified by chemical engineers as coating flows. In these cases, the geometry of the coating device, the relative velocity, v, of the object to be coated, and the physical properties of the coating fluid (surface tension, γ; viscosity, η; density, ρ; and acceleration of gravity, g) fix the solution to the coating flow problem. In this case, the limiting film thickness, δ_f, at large distances from the coating bath surface, is given by

$$\delta_f = 0.946 \frac{(\eta v)^{2/3}}{\gamma^{1/6}\sqrt{\rho g}} \tag{24}$$

This solution is derived from the physical effects of surface tension, as described above, plus the Navier-Stokes equation fluid mechanics. These authors assume Newtonian viscosity behavior of the liquid, i.e., the viscosity, η, is independent of shear rate, time-independent surface tension, and an absence of surface tension gradient-driven flows (Marangoi flows), with the appropriate boundary conditions determined by the coating process. This solution can be used by the coating designer and user to establish a first order estimate of the film thickness of the liquid film by the properties of the coating and the velocity of sheet withdrawal.

Curtain Coating

As described above in the section on measurement of dynamic surface tension, analysis of the curtain coating process has yielded a measurement method for dynamic surface tension. In the analyses of this problem, Brown [*45*] and Havenburgh and Joos [*46*] both modeled curtain coating by a falling liquid film held in place by two vertical wires (see Fig. 16). The flux Q of falling liquid is

$$Q = v_0 h_0 \tag{25}$$

where v_0 is the velocity of the falling film and h_0 is the width of the falling film at time zero at the slot through which the liquid exits. The velocity of the falling film at a position x from the slot is given by

$$v^2 = v_0^2 + 2gx \tag{26}$$

where g is the acceleration of gravity. Since the flux of material is constant through the slot, we know that

$$Q = v_0 h_0 = hv \tag{27}$$

and therefore

$$h(x) = \frac{Q}{\sqrt{v_0^2 + 2gx}} \tag{28}$$

This equation gives the user a description of the thickness of liquid film as a function of distance from the slot of the curtain coater. This can also be used to estimate the surface tension at a given position x [*46*] by the following relation

$$\gamma(x) = \frac{\rho h(x) v_0^2}{2} \tag{29}$$

These equations give the application engineer a reasonably complete description of the curtain coating process.

Electrostatic Spray

The application of surface energetics to the problem of charged liquid droplets was first done by Rayleigh [*66*]. In this study, the electrical repulsion forces between charges on a drop are equated to the surface tension forces holding a drop together to give the following equation as an estimate of the upper limit on the charge that can be held on a drop

$$q = \sqrt{16\pi\epsilon r^2 \gamma} \tag{30}$$

where ϵ is the dielectric constant of the drop and r is the drop radius. This can be used to gain an estimate of the drop size in electrostatic spray of liquid paints. Further stability analysis

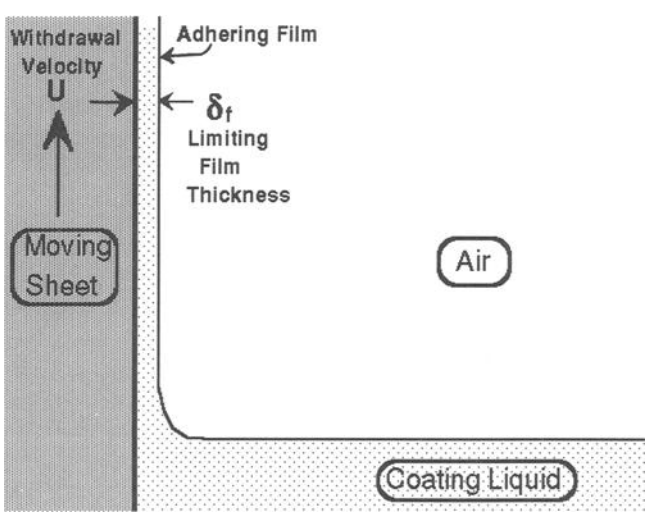

FIG. 15–Schematic of dip coating process.

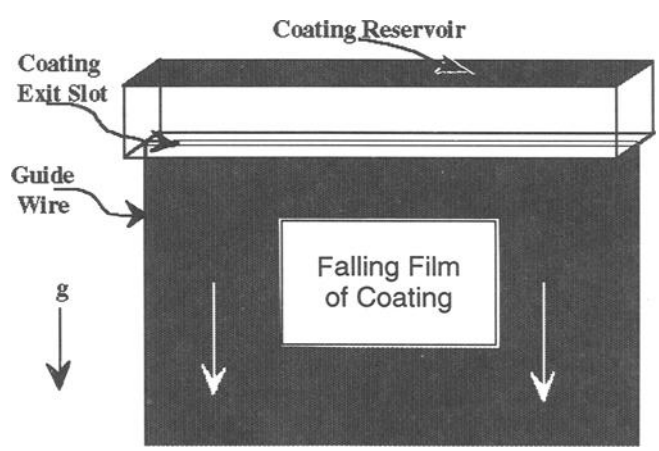

FIG. 16–Schematic of curtain coater.

of this problem indicates that if a drop at this charge limit breaks up, the total energy of the system will be minimized if it does so into n droplets, where n is given by

$$n = \frac{q^2}{4\pi\epsilon r_0^2} \tag{31}$$

where r_0 is the radius of the original drop [67]. This charge limit has been studied and verified experimentally by several workers [68,69] and also applied to problems of spray painting [70]. All of this work further illustrates the importance and extensive applications of surface energetics to coatings use.

Cleaning and Pretreatment of Substrates for Coating

A very important step in the total process of creating a high performance organic coating/substrate system is the cleaning and pretreatment of the substrate prior to the coating application step. The specific purpose of cleaning and pretreating substrate surfaces is to control and/or modify the surface energy of the substrate so that a coating may be successfully applied to the substrate and that the coating will subsequently adhere properly to the substrate and provide the performance desired. Cleaning, as a general rule, involves the removal of substances foreign to the substrate by a surfactant/detergent solution, followed with rinsing by a solvent that leaves the substrate surface clean of contaminants. This may have to be preceded by a mechanical sandblasting, grinding, sanding, scrubbing, etc., to remove thick layers of mil scale, rust, scum, and other built-up material on what is the real substrate. Vapor or organic solvent degreasing/cleaning is also often used to yield a clean surface for coating. These mechanical cleaning steps, along with the cleaning and rinsing of the surface with low surface tension solutions that leave no residue, are best done just before the coating step lest the surface become recontaminated while stored waiting for the coating step. The goal of all these cleaning procedures is to insure a uniform surface that has a uniform contact angle, usually and desirably zero, for wetting by the coating, and to insure the interface created is the coating liquid/substrate interface only. The mechanical sanding, polishing, etc., will also contribute to a lower contact angle by the surface roughness effect discussed above. Oil, dirt, rust, or other contaminants will give poor and incomplete wetting and poor adhesion of the coating at the contaminated sites. Complete wetting is further assisted by insuring the surface tension of the coating liquid is low so that all air is displaced by the coating and the contact angle between the liquid coating and the substrate is zero, or near to it. The surface tension of the liquid coating is best lowered by the polymer of the system or by surfactant additives to the liquid system. Attempts to control the surface tension by the solvent can cause problems in having the surface tension increase as the solvent evaporates.

Substrate pretreatment is usually performed just after the cleaning discussed above and is done to further insure complete wetting and adhesion of the coating, as well as, in the case of metallic substrates, to deposit a corrosion inhibitive layer. In the case of plastic substrates, the pretreatment may be corona or flame modification to oxidize the surface layer and lower the contact angle to near zero. Metal pretreatments often involve the deposition or creation of a rough-surfaced crystalline layer of metallic phosphates which give an easily wetted surface.

SUMMARY

The concepts of surface energy, surface tension, and wetting and contact angle phenomena are of exceptional importance to the science and technology of organic coating. Their understanding is vital for the proper formulation and application of coating. Many of the features of the final organic coating/substrate system are controlled by proper understanding of the surfaces of the liquid coating and the substrate, as well as creation of a proper coating/substrate interface. Both the static and dynamic aspects of liquid surface properties should be considered and the dynamic aspects properly accounted for in coating production and application. These concepts have been reviewed, and references to further reading in this important area of organic coatings science have been given.

Solubility Parameters

by Charles M. Hansen[1]

NOMENCLATURE

- C Dispersion cohesion energy from Fig. 2 and Fig. 3
- D Dispersion cohesion (solubility) parameter—in tables and computer printouts
- DM Dipole moment—Debyes
- ΔE_d Dispersion cohesion energy
- ΔE_p Polar cohesion energy
- ΔE_h Hydrogen bonding cohesion energy
- ΔE_v Energy of vaporization (=) cohesion energy
- ΔG^M Molar free energy of mixing
- H Hydrogen bonding cohesion (solubility) parameter—in tables and computer printouts
- ΔH_v Molar heat of vaporization
- ΔH^M Molar heat of mixing
- P Polar cohesion (solubility) parameter—in tables and computer printouts
- R Gas constant (1.987 cal/mole-°K)
- R_s Distance in Hansen space
- R_0 Radius of interaction sphere in Hansen space
- RED Relative energy difference, R_s/R_0
- ΔS^M Molar entropy of mixing
- T Absolute temperature
- T_b (Normal) boiling point
- T_c Critical temperature
- V_M Molar volume
- Δ_T Lydersen critical temperature group contribution
- α Thermal expansion coefficient
- δ_d Dispersion cohesion (solubility) parameter
- δ_h Hydrogen bonding cohesion (solubility) parameter
- δ_p Polar cohesion (solubility) parameter
- δ_T Total cohesion (solubility) parameter
- ϕ_i Volume fraction of component "i"
- χ Polymer-liquid interaction parameter (Flory-Huggins)

INTRODUCTION

SOLUBILITY PARAMETERS ARE USED in the coatings industry to select solvents. Liquids with similar solubility parameters will be miscible, and polymers will dissolve in solvents whose solubility parameters are not too different from their own. The basic principle is "like dissolves like." Solubility parameters help put numbers into this simple qualitative idea.

The solubility parameter approach has been used for many years to select solvents for coating materials. The lack of total success has stimulated research. The skill with which solvents can be optimally selected with respect to cost, solvency, workplace environment, external environment, evaporation rate, flash point, etc. has improved over the years as a result of a series of improvements in the solubility parameter concept and widespread use of computer techniques. Most, if not all, commercial suppliers of solvents have computer programs to help with solvent selection. One can now easily predict how to dissolve a given polymer in a mixture of two solvents, neither of which can dissolve the polymer by itself.

This contribution to the paint testing manual unfortunately can not include discussion of all of the significant efforts leading to our present state of knowledge of the solubility parameter. An attempt is made to outline developments, provide some background for a basic understanding, and give examples of uses in practice. The key is to determine which affinities the important components in a system have for each other. For coatings, this means affinities of solvents, polymers, pigment surfaces, additives, and substrates.

It is noteworthy that the concepts presented here have developed toward not just predicting solubility, which requires high affinity between solvent and solute, but to predict affinities between different polymers leading to compatibility, and affinities to surfaces to improve pigment dispersion and adhesion. Attempts are also being made to extend these developments, largely attributable to the coatings industry, to understand affinities and phenomena for a large number of other materials not specifically related to coatings. In these applications the solubility parameter has become a tool, using well-defined liquids as energy probes, to measure the similarity, or lack of same, of key components. Materials with widely different chemical structures may be very close in affinities. Only those materials which interact differently with different solvents can be characterized in this manner. Many inorganic materials, such as fillers, do not interact differently with these energy probes since their energies are very much higher. Changing their surface energies by various treatments can lead to a surface which can be characterized.

Solubility parameters are cohesion energy parameters since they derive from the energy required to convert a liquid to a gas. The energy of vaporization is a direct measure of the total (cohesive) energy holding the liquid's molecules together. All types of bonds holding the liquid together are broken by evaporation, which has led to the concepts described in more detail below. The term cohesion energy pa-

rameter is more appropriately used when referring to surface phenomena.

HILDEBRAND PARAMETERS

The term solubility parameter was first used by Hildebrand and Scott [*1,2*]. The solubility parameter is the square root of the cohesive energy density

$$\delta = (c \cdot e \cdot d)^{1/2} = \left(\frac{\Delta E_v}{V_M}\right)^{1/2} (\text{cal/cm}^3)^{1/2} \text{ or MPa}^{1/2} \quad (1)$$

where V_M is the molar volume and ΔE_v is the (measurable) energy of vaporization (see Eq 12). The solubility parameter is an important quantity in predicting solubility relations, as can be seen from the following brief introduction.

Thermodynamics requires that the free energy of mixing must be zero or negative for the solution process to occur spontaneously. The free energy change for the solution process is given by the relation

$$\Delta G^M = \Delta H^M - T\Delta S^M \quad (2)$$

where ΔG^M is the free energy of mixing, ΔH^M is the heat of mixing, T is the absolute temperature, and ΔS^M is the entropy change in the mixing process.

The heat of mixing, ΔH^M, is given by Hildebrand and Scott as

$$\Delta H^M \approx \Delta E^M = \phi_1 \phi_2 V_M (\delta_1 - \delta_2)^2 \quad (3)$$

where the ϕ's are volume fractions and V_M is the average molar volume of the solvent. It is important to note that the solubility parameter, or rather the difference in solubility parameters for the solvent-solute combination, is important in determining the solubility. It is clear that a match in solubility parameters leads to a zero heat of mixing, and the entropy change should ensure solution. The maximum difference in solubility parameters which can be tolerated where solution still occurs is found by setting the free energy change equal to zero in Eq 2. It is, in fact, the entropy change which dictates how closely the solubility parameters must match each other. It can also be seen that solvents with smaller molecular volumes promote lower heats of mixing, which, in turn, means that smaller solvent molecules will be thermodynamically better than larger ones when their solubility parameters are equal. A practical aspect of this effect is that solvents with relatively low molecular volumes, such as methanol and acetone, can dissolve a polymer at larger solubility parameter differences than expected from comparisons with other solvents with larger molecular volumes. The converse is also true. Larger molecular species may not dissolve, even though solubility parameter considerations might predict this. This can be a difficulty with plasticizers.

A serious shortcoming of the Hildebrand approach is that negative heats of mixing are not possible. Likewise, the approach is limited to regular solutions as defined by Hildebrand and Scott [*2*] and does not account for association between molecules, such as polar and hydrogen bonding interactions would require. The latter problem seems to have been largely solved with the use of multicomponent solubility parameters. The price has been that no thermodynamic calculations of the heat of mixing in the traditional sense seem possible. This is both because of a lack of detailed theory for this purpose and because of the lack of accuracy with which the solubility parameters can be assigned.

A more detailed description of the theory presented by Hildebrand and the succession of research reports which have attempted to improve on it can be found in Barton's extensive handbook [*3*]. The slightly older excellent contribution of Gardon and Teas [*4*] is also a good source, particularly for coatings and adhesion phenomena. The approach of Burrell [*5*], who divided solvents into hydrogen bonding classes, has found numerous practical applications, and the approach of Blanks and Prausnitz [*6*], who divided the solubility parameter into two components, nonpolar and "polar," are worthy of mention, however, in that these have found wide use and greatly influenced the author's earlier activities, respectively.

It can be seen from Eq 2 that the entropy change can be considered beneficial to mixing. When multiplied by the temperature this will work in the direction of promoting a more negative free energy of mixing. Higher temperatures will also promote this more negative free energy change. The entropy changes associated with polymer solutions will be smaller than those associated with liquid-liquid miscibility, for example, since the "monomers" are already bound into the configuration dictated by the polymer they make up. They are no longer free in the sense of a liquid solvent and can not mix freely to contribute to a larger entropy change. This is one reason polymer-polymer miscibility is difficult to achieve. The free energy criterion dictates that the polymer solubility parameters match extremely well since there is little help from the entropy contribution when progressively larger molecules are involved. However, polymer-polymer miscibility can be promoted by introduction of suitable copolymers or comonomers which interact specifically within the system.

HANSEN SOLUBILITY PARAMETERS

A widely used solubility parameter approach to predicting polymer solubility is that proposed by the author. The basis of these so-called Hansen solubility parameters is that the total energy of vaporization of a liquid consists of several individual parts [*7–11*]. Needless to say, without the work of Hildebrand and Scott [*1,2*] and others not specifically referenced here such as Scatchard, this postulate could never have been made. The total cohesive energy, ΔE_t, can be measured by evaporating the liquid, i.e., breaking all the cohesive bonds. It should also be noted that these cohesive energies arise from interactions of a given solvent molecule with another of its own kind. The basis of the approach is, therefore, very simple, and it is surprising that so many different applications have been possible over the past 25 years. A number of applications are discussed below. A lucid discussion by Barton [*12*] enumerates typical situations where problems occur when using solubility parameters. These are most often where the environment causes the solvent molecules to interact with or within themselves differently than when they make up their own environment, i.e., as pure liquids.

Materials having similar (Hansen) solubility parameters have high affinity for each other. The extent of the similarity in a given situation determines the extent of the interaction. The same can not be said of the total or Hildebrand solubility parameter [*1,2*]. Ethanol and nitromethane, for example,

have similar total solubility parameters (26.1 versus 25.1 $MPa^{1/2}$, respectively), but their affinities are quite different. Ethanol is water soluble, while nitromethane is not. Indeed, mixtures of nitroparaffins and alcohols were demonstrated in many cases to provide synergistic mixtures of two nonsolvents which dissolved polymers [7].

There are three major types of interaction in common organic materials. The most general are the "nonpolar" interactions, which derive from atomic forces. These have also been called dispersion interactions in the literature. Since molecules are built up from atoms, all molecules will contain this type of attractive force. For the saturated aliphatic hydrocarbons, for example, these are essentially the only cohesive interactions, and the energy of vaporization is assumed to be the same as the dispersion cohesive energy, ΔE_d. Finding the dispersion cohesive energy as the cohesion energy of the homomorph, or hydrocarbon counterpart, is the starting point for the calculation of the three Hansen parameters for a given liquid.

The permanent dipole–permanent dipole interactions cause a second type of cohesion energy, the polar cohesive energy, ΔE_p. These are inherently molecular interactions and are found in most molecules to one extent or another. The dipole moment is the primary parameter in calculating these interactions. A molecule can be primarily polar in character without being water soluble, so there is misuse of the term "polar" in the general literature. The polar solubility parameters referred to here are well-defined, experimentally verified, and can be estimated from molecular parameters as described below. As noted above, the polar solvents include those with relatively high total solubility parameters which are not particularly water soluble such as nitroparaffins, propylene carbonate, tri-n-butyl phosphate, and the like. Induced dipoles have not specifically been treated by Hansen, but are recognized as a potentially important factor, particularly for solvents with zero dipole moments.

The third major cohesive energy source is hydrogen bonding, ΔE_h. Hydrogen bonding is a molecular interaction and resembles the polar interactions in this respect. The basis of this type of cohesive energy is attraction among molecules because of the hydrogen bonds. In this perhaps oversimplified approach, the hydrogen bonding parameter has been used to more or less collect the energies from interactions not included in the other two parameters. Alcohols, glycols, carboxylic acids, and other hydrophilic materials have high hydrogen bonding parameters. Other researchers have divided this parameter into separate parts, for example, acid and base cohesion parameters, to allow both positive and negative heats of mixing. These approaches will not be dealt with here, but can be found described in Barton's Handbook [3], and elsewhere [13–15]. The most extensive division of the cohesive energy has been done by Karger et al. [16], who developed a system with five parameters: dispersion, orientation, induction, proton donor, and proton acceptor. The Hansen hydrogen-bonding parameter may be termed an electron interchange parameter as well. As a single parameter it has remarkably well accounted for the experience of the author and keeps the number of parameters to a level which allows ready practical usage.

It is clear that there are other sources of cohesion energy in various types of molecules arising, for example, from induced dipoles, metallic bonds, electrostatic interactions, or whatever type of separate energy can be defined. Hansen stopped with the three major types found in organic molecules. It was and is recognized that additional parameters could be assigned to separate energy types. The description of organometallic compounds could be an intriguing study, for example. This would presumably parallel similar characterizations of surface-active materials, where each separate part of the molecule requires separate characterization for completeness. The Hansen parameters have mainly been used in connection with solubility relations, mostly, but not exclusively, in the coatings industry.

Solubility and swelling have been used to confirm the solubility parameter assignments of many of the liquids. These have then been used to derive group contribution methods and suitable equations based on molecular properties to arrive at estimates of the three parameters for additional liquids. The goal of a prediction is to determine similarity or not of the cohesion energy density parameters. The strength of a particular type of hydrogen bond or other bond, for example, is important only to the extent that it influences the cohesive energy density.

Hansen parameters do have direct application in other scientific disciplines of interest to the coatings industry, such as surface science, where they have been used to characterize the wettability of various surfaces and adsorption properties of pigment surfaces [4,8,10,17–19]. Many other applications of widely different character have been discussed by Barton [3] and Gardon [20]. Surface characterizations have not been given the attention deserved in terms of a unified similarity-of-energy approach. The author can certify that thinking in terms of similarity of energy, whether surface energy or cohesive energy, can lead to rapid decisions and plans of action in critical situations where data are lacking. In other words, the everyday industrial crisis situation can often be reduced in scope by appropriate systematic approaches based on similarity of energy.

The basic equation which governs the assignment of Hansen parameters is that the total cohesion energy, ΔE_t, must be the sum of the individual energies which make it up

$$\Delta E_t = \Delta E_d + \Delta E_p + \Delta E_h \tag{4}$$

Dividing this by the molar volume gives the square of the total (or Hildebrand) solubility parameter as sum of the squares of the Hansen D, P, and H components.

$$\frac{\Delta E_t}{V_M} = \frac{\Delta E_d}{V_M} + \frac{\Delta E_p}{V_M} + \frac{\Delta E_h}{V_M} \tag{5}$$

$$\begin{aligned} \delta_t &= \delta_d^2 + \delta_p^2 + \delta_h^2 \\ &= D^2 + P^2 + H^2 \text{ (computer printouts)} \end{aligned} \tag{6}$$

METHODS AND PROBLEMS IN THE DETERMINATION OF PARTIAL SOLUBILITY PARAMETERS

The best method to calculate Hansen solubility parameters depends to a great extent on what data are available. Hansen originally adopted an essentially experimental procedure and established numbers for 90 liquids based on solubility data for 32 polymers [7]. This procedure involved calculation of the nonpolar parameter according to the procedure outlined

by Blanks and Prausnitz [*6*]. This calculational procedure is still in use and is considered the most reliable and consistent for this parameter. It is outlined below. The division of the remaining cohesive energy between the polar and hydrogen bonding interactions was done by trial and error to fit experimental polymer solubility data. A key to parameter assignments in this initial trial and error approach was that mixtures of two nonsolvents could be systematically found to synergistically (but predictably) dissolve given polymers. This meant that these had parameters placing them on opposite sides of the solubility region, a spheroid, from each other. Having a large number of such predictably synergistic systems as a basis, reasonably accurate divisions into the three energy types were possible.

Using the experimentally established, approximate, δ_p and δ_h parameters, Skaarup [*9*] found that the Böttcher equation could be used to calculate the polar parameter quite well, and this led to a revision of the earlier values to those now in wide use for these same liquids. These values were also consistent with the eperimental solubility data for 32 polymers available at that time and Eq 6. Furthermore, Skaarup developed the equation for the solubility parameter "distance," R_s, between two materials based on their respective partial solubility parameter components

$$R_s = 4(\delta_{d_1} - \delta_{d_2})^2 + (\delta_{p_1} - \delta_{p_2})^2 + (\delta_{h_1} - \delta_{h_2})^2 \qquad (7)$$

This equation was developed from plots of experimental data where the constant 4 was found convenient and correctly represented the solubility data as a sphere encompassing the good solvents. When the scale for the dispersion parameter is doubled compared with the other two parameters, essentially spherical rather than spheroidal, regions of solubility are found. This greatly aids two-dimensional plotting and visualization. There are, of course, boundary regions where deviations can occur. These are most frequently found to involve the larger molecular species being less effective solvents compared with the smaller counterparts which define the solubility sphere. Likewise smaller molecular species, such as acetone and methanol, often appear as outliers in that they dissolve a polymer even though they have solubility parameters placing them at a distance greater than the solubility sphere radius, R_0. This dependence on molar volume is inherent in the theory developed by Hildebrand and Scatchard as discussed above. Smaller molar volume favors lower heats of mixing, which in turn promotes solubility. Such smaller molecular volume species which dissolve "better" than predicted by comparisons based on solubility parameters alone should not necessarily be considered outliers. This statement is justified by Eq 3, where it can be seen that the molar volume and the square of the solubility parameter difference are weighted equally in estimating the heat of mixing in the Hildebrand theory.

The molar volume is frequently used as a fourth parameter to describe molecular size effects. These are especially important in correlating diffusional phenomena with the solubility parameter, for example. The author has preferred to retain the three, well-defined, partial solubility parameters with a separate, fourth, molar volume parameter, rather than to multiply the solubility parameters by the molar volume raised to some power to redefine them.

The exact reason for the constant 4 in Eq 7 is not clear, but it is currently considered more as an experimental result related to the entropy changes in the systems described rather than a theoretically well-defined constant. The author has also found in unpublished studies that values close to 5 represented solubility data equally well for the cases studied. It is thought that this constant especially reflects the entropy change beneficial to the solution process when the molecular interactions characterized by the δ_p and δ_h parameters are involved. The order in the pure liquids is reduced when they dissolve a polymer of lower solubility parameter (degree of order). This entropy change favors the dissolution process. Thus more polar and hydrogen bonded liquids can dissolve polymers of lower polar and hydrogen bonding character. The differences in solubility parameters between the solvent and solute in the polar and hydrogen bonding parameters are larger by a factor of two than is tolerated when nonpolar solvents dissolve the same polymer. This factor of 2 is squared to give the "4" in Eq 7.

Another way to view this is as follows. It is assumed that the (center-of-the-sphere) partial solubility parameters assigned by computer optimization techniques to polymers using Eq 7 are the theoretically correct ones. A solvent with parameters corresponding to the center is to be changed in quality. If the nonpolar parameter difference only is changed by one unit, the effect on R_s is four units. If the polar or hydrogen bonding parameter difference is changed by one unit, the effect on R_s is also one unit. The entropy changes associated with the polar and hydrogen interactions have reduced the total (free energy change) effect by a factor of 4 and are thus four times larger than those associated with the nonpolar interactions.

What is more probable is that the entropy changes on solution from the polar and hydrogen bonding interactions are some function of the solubility parameters and, in fact, increase with increasing polar or hydrogen bonding parameter difference between solvent and solute. If this is, indeed, true, then the currently assigned polar and hydrogen bonding parameters for the polymers are too high. Exactly what they should be from a theoretical point of view remains to be elucidated by future research. This is one reason the calculation of partial polymer solubility parameters by group contributions has not provided good agreement with the computer optimizations of experimental data.

The discussion above follows from the fact that the boundaries of the regions of solubility are characterized by a free energy change of zero for the solution process. The Flory-Huggins limiting chi parameter, χ, of about 0.5 is also characteristic for the boundary of the solubility region. Patterson [*21*], in particular, has been instrumental in showing the relations between the chi parameter and solubility parameters. A polymer of molecular weight approaching infinity will have a chi parameter of 0.5 and just be soluble [*4,6,22*]. This is strictly valid only for the interactions described by this theory. So-called theta solvents will also be located in boundary regions on solubility parameter plots with these same restrictions. Much polymer research has focused on these boundary regions only, for the above reasons and because relatively small changes in temperature, molecular weight, solvent quality, etc. give large easily measureable changes in other quantities.

The approach of computer optimizing solubility data to spheres which is currently in use still seems most favorable, at least until an improvement is offered by an improved theory. Plotting experimental solubility data defines boundaries of solubility, which in fact are fixed by the free energy of mixing being experimentally equal to zero. It should be recognized that using solubility parameters, which relate to the heat of mixing only, emphasizes the practical/empirical nature of this practical approach and reinforces the use of the term cohesion parameters.

Equation 7 is readily used on a computer (or on a hand calculator), and supplementary relations allow easier scanning of large sets of data. It is obvious that solubility, or high affinity, requires that R_s be less than R_0. The ratio R_s/R_0 has been called the RED number, reflecting the Relative Energy Difference. A RED number of 0 is found for no energy difference. RED numbers less than 1.0 indicate high affinity, RED equal to or close to 1.0 is a boundary condition, and progressively higher RED numbers indicate progressively lower affinities. Scanning a sizeable (the author has Hansen solubility parameters for about 850 liquids) computer output for RED numbers less than 1.0, for example, rapidly allows location of the most interesting liquids for a given application.

The revised set of parameters for the 90 solvents was the basis for group contribution procedures developed by (most notably) Van Krevelen [*23*] and Beerbower [*11,24*], who also used Fedors work [*25*]. These various developments have been summarized by Barton [*3*], although Beerbower's latest values have only appeared in the NASA document [*24*]. Table 1 is an expanded table of Beerbower group contributions which was distributed among those who were in contact with Beerbower in the late 1970s. Beerbower also developed a simple equation for the polar parameter [*11*], which involved only the dipole moment and the square root of the molar volume. This is also given below and has been found quite reliable by Koehnen and Smolders [*26*]. This equation has also been found reliable by the author as well, giving results generally consistent with Eq 6, which, again, is the basis of the whole approach. Koehnen and Smolders also give correlation coefficients for other calculational procedures to arrive at the individual Hansen parameters.

A sizeable number of liquids have now been assigned Hansen parameters using the procedures described here. Many of these have not been published. Exxon Chemical Corporation [*27,28*] has indicated a computer program with data for over 500 solvents and plasticizers, 450 resins and polymers, and 500 pesticides. The author's files contain the three parameters for about 850 liquids, although several of them appear with two or three sets of possible values awaiting experimental confirmation. In some cases this is due to questionable physical data, for example, for latent heats of vaporization or wide variations in reported dipole moments. Another reason for this is that some liquids are chameleonic [*29*] as defined by Hoy in that they adopt configurations depending on their environment. Hoy [*29*] cites the formation of cyclic structures for glycol ethers with (nominally) linear structure. The formation of hydrogen bonded tetramers of alcohols in a fluoropolymer has also been cited [*30*]. The term "compound formation" can be found in the older literature, particularly where mixtures with water were involved, and structured species were postulated to explain phenomena based on specific interactions among the components of the mixtures. Barton has recently discussed some of these situations and points out that Hildebrand or Hansen parameters must be used with particular caution where the extent of donor-acceptor interactions, and in particular hydrogen bonding within a compound, is very different from that between compounds [*12*]. Amines, for example, are known to associate with each other. Pure component data can not be expected to predict the behavior in such cases.

Still another reason for difficulties is the large variation of dipole moments reported for the same liquid. The dipole moment for some liquids depends on their environment, as discussed below. A given solvent can be listed with different values in files to keep these phenomena in mind.

Large data sources greatly enhance searching for similar materials and locating new solvents for a polymer based on limited data, for example. Unfortunately, different authors have used different group contribution techniques, and there is a proliferation of different "Hansen" parameters for the same chemicals in the literature. This would seem to be an unfortunate situation, but may ultimately provide benefits. In particular, partial solubility parameter values found in Hoy's extensive tables [*3,31*] are not compatible with the customary Hansen parameters reported here. Hoy has provided an excellent source of total solubility parameters. He independently arrived at the same type division of cohesion energies as Hansen, although the methods of calculation are quite different.

Many solvent suppliers have also presented tables of solvent properties and/or use computer techniques using these in their technical service. Partial solubility parameters not taken directly from earlier well-documented sources should be used with caution. In particular it can be noted that the Hoy dispersion parameter is consistently lower than that found by Hansen. Hoy subtracts estimated values of the polar and hydrogen bonding energies from the total energy to find the dispersion energy. This allows for more calculational error and underestimates the dispersion energy since the Hoy procedure does not appear to fully separate the polar and hydrogen bonding energies. The Van Krevelen dispersion parameters appear too low. The author has not attempted these calculations, being completely dedicated to the full procedure described here, but values estimated independently based on the Van Krevelen dispersion parameters are clearly low. A comparison with related compounds, or similarity principle, gives better results than those found from the Van Krevelen dispersion group contributions.

In the following, calculational procedures and experience are presented according to the procedures found most reliable for the experimental and/or physical data available for a given liquid.

CALCULATION OF THE DISPERSION SOLUBILITY PARAMETER, δ_d

The δ_d parameter is calculated according to the procedures outlined by Blanks and Prausnitz [*6*]. Figures 1, 2, or 3 can be used to find this parameter depending on whether the molecule of interest is aliphatic, cycloaliphatic, or aromatic. These figures have been inspired by Barton [*3*], who converted

[a]Based on very limited data. Limits shown are roughly 95% confidence; in many cases, values are for information only and not to be used for computation.
[b]Includes unpublished infrared data.
[c]Use formula in $\Delta V\delta_P^2$ column to calculate, with V for total compound.
[d]Twin and triplet values apply to halogens on the same C atom, except that $\Delta V\delta_P^2$ also includes those on adjacent C atoms.
[e]These values apply to halogens attached directly to the ring and also to halogen attached to aliphatic double-bonded C atoms.
[f]From R. F. Fedors [25].

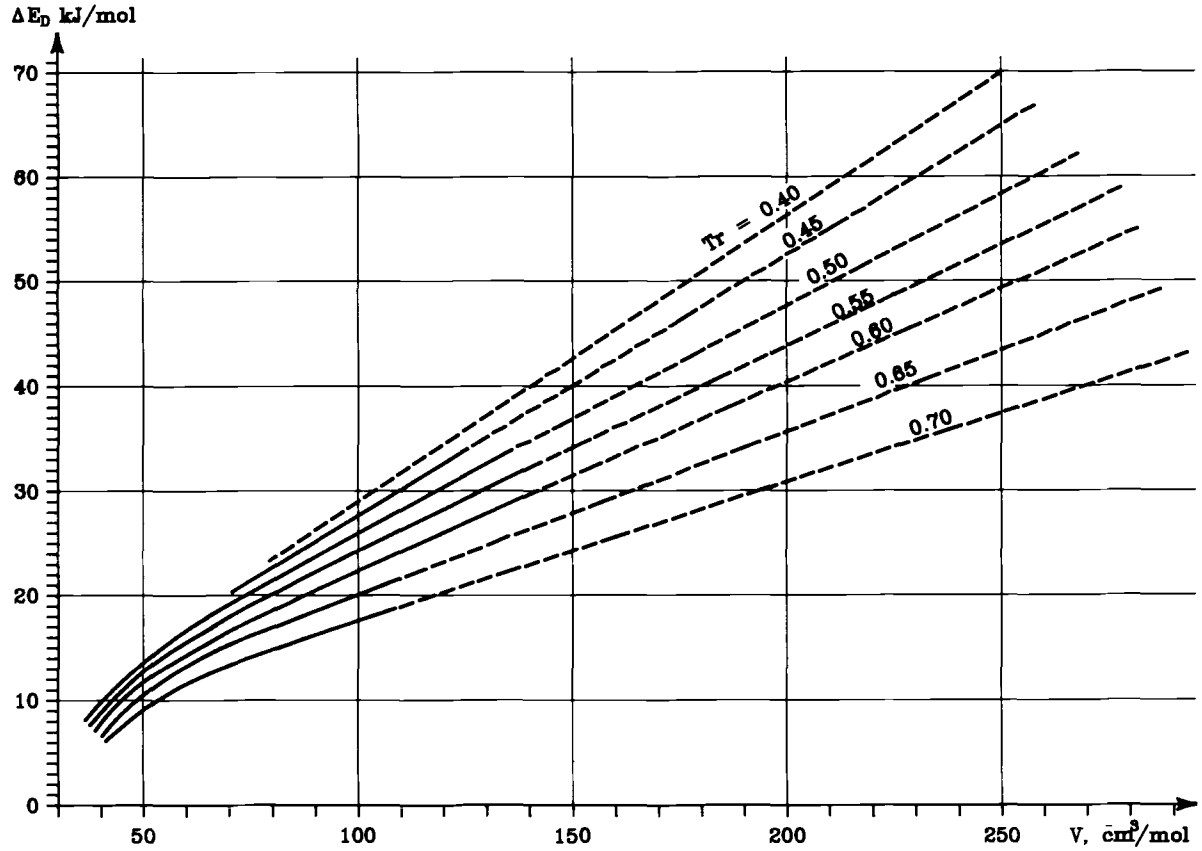

FIG. 1–Energy of vaporization for straight chain hydrocarbons as a function of molar volume and reduced temperature.

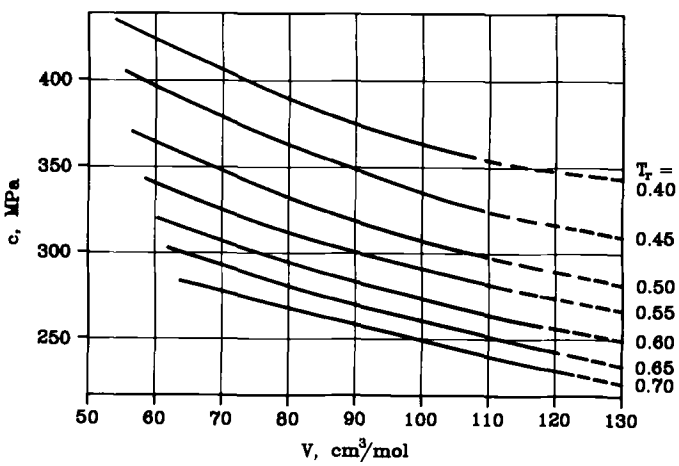

FIG. 2–Cohesive energy density for cycloalkanes as a function of molar volume and reduced temperature.

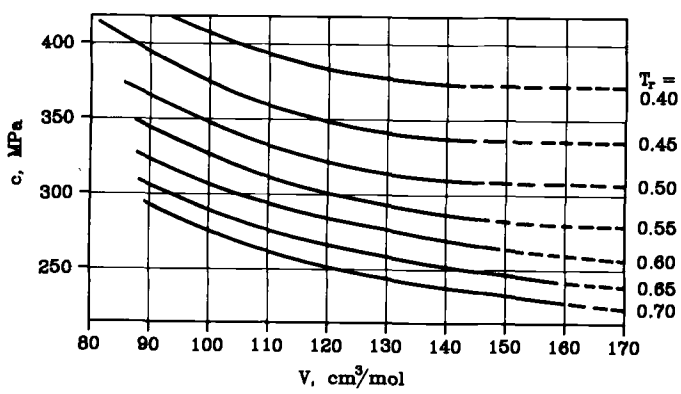

FIG. 3–Cohesive energy density for aromatic hydrocarbons as a function of molar volume and reduced temperature.

earlier data to SI units. All three of these figures have been straight line extrapolated into a higher range of molar volumes than that reported by Barton. Energies found with these extrapolations have also provided consistent results. The solubility parameters in SI units, $MPa^{1/2}$, are 2.0455 times larger than those in the older centimeter, gram, second system, $(cal/cc)^{1/2}$, which still finds extensive use in the United States, for example.

The figure for the aliphatic liquids gives the dispersion cohesive energy, ΔE_d, whereas the other two figures directly report the dispersion cohesive energy density, c. The latter is much simpler to use since one need only take the square root of the value found from the figure to find the respective partial solubility parameter. Barton also presented a similar figure for the aliphatic solvents, but it is inconsistent with the energy figure and in error. Its use is not recommended. When substituted cycloaliphatics or substituted aromatics are considered, simultaneous consideration of the two separate parts of the molecules is required. The dispersion energies are evaluated for each of the types of molecules involved, and a weighted average for the molecule of interest based on numbers of significant atoms is taken. For example, hexyl benzene

would be the arithmetic average of the dispersion energies for an aliphatic and an aromatic liquid, each with the given molar volume of hexyl benzene. Liquids such as chlorobenzene, toluene, and ring compounds with alkyl substitutions with only two or three carbon atoms have been considered as cyclic compounds only. Such weighting has been found necessary to satisfy Eq 6.

The critical temperature, T_c, is required to use the dispersion energy figures. If the critical temperature cannot be found, it must be estimated. A table of the Lydersen group contributions, Δ_T, [32] as given by Hoy [31] for calculation of the critical temperature, is included here as Table 2. In some cases the desired groups may not be in the table, which means some educated guessing is required. The end result does not appear too sensitive to these situations. The normal boiling temperature, T_b, is also required in this calculation. This is not always available, either, and must be estimated by similarity, group contribution, or other technique. The Lydersen group contribution method involves the use of Eqs 8 and 9.

$$T_b/T_c = 0.567 + \Sigma\Delta_T - (\Sigma\Delta_T)^2 \tag{8}$$

and

$$T_r = T/T_c \tag{9}$$

where T has been taken as 298.15 K.

The dispersion parameter is an atomic force parameter. The size of the atom is important. It has been found that corrections are required for atoms significantly larger than carbon, such as chlorine, sulfur, bromine, etc., but not for oxygen or nitrogen, which have a similar size. The carbon atom in hydrocarbons is the basis of the dispersion parameter in its present form. These corrections are applied by first finding the dispersion cohesive energy from the appropriate figure. This requires multiplication by the molar volume for the cyclic compounds using data from the figures here, since these figures give the cohesive energy densities. The dispersion cohesive energy is then increased by adding on the correction factor. This correction factor for chlorine, bromine, and sulfur has been taken as 1650 J/mol for each of these atoms in the molecule. Dividing by the molar volume and then taking the square root gives the (large atom corrected) dispersion solubility parameter.

The need for these corrections has been confirmed many times, both for interpretation of experimental data and to allow Eq 6 to balance. Research is definitely needed in this area. The impact of these corrections is, of course, larger for the smaller molecular species. The taking of square roots of the larger numbers involved with the larger molecular species reduces the errors involved in these cases since the corrections themselves are relatively small.

It can be seen from the dispersion parameters of the cyclic compounds that the ring also has an effect similar to increasing the effective size of the interacting species. The dispersion energies are larger for cycloaliphatic compounds than for their aliphatic counterparts, and they are higher for aromatic compounds than for the corresponding cycloaliphatics. Similar effects also appear with the ester group. This group appears to act as if it were, in effect, an entity which is larger than the corresponding compound containing only carbon (i.e., its homomorph), and it has a higher dispersion solubility parameter without any special need for corrections.

The careful evaluation of the dispersion cohesive energy may not have major impact on the value of the dispersion solubility parameter itself because of the taking of square roots. Larger problems arise because of Eq 4. Energy assigned to the dispersion portion can not be reused when finding the other partial parameters using Eq 4 (or Eq 6). This is one reason group contributions are recommended in some cases below.

CALCULATION OF THE POLAR SOLUBILITY PARAMETER, δ_p

The earliest assignments of a "polar" solubility parameter were given by Blanks and Prausnitz [6]. These parameters were in fact the combined polar and hydrogen bonding parameters as used by Hansen and cannot be considered polar in the current context. The first Hansen polar parameters [7] were reassigned new values by Skaarup according to the Böttcher equation [9]. This equation requires the molar volume, the dipole moment, DM, the refractive index, and the dielectric constant. These are not available for many compounds, and the calculation is somewhat more difficult than using the much simpler equation developed by Beerbower [11]

$$\delta_p = \frac{37.4}{(V_M)^{1/2}}(DM) \tag{10}$$

The constant 37.4 gives this parameter in SI units.

Equation 10 has been consistently used by the author over the past few years, particularly in view of its reported reliability [26]. This reported reliability appears to be correct. The molar volume must be known or estimated in one way or another. This leaves only the dipole moment to be found or estimated. Standard reference works have tables of dipole moments, with the most extensive listing still being McClellan [33]. Other data sources also have this parameter as well as other relevant parameters and data such as latent heats and critical temperatures. The so-called DIPPR database has been found useful for many compounds of reasonably common usage, but many interesting compounds are not included in DIPPR. This abbreviation is for Design Institute for Physical Property Research,[2] Project 801 of the American Institute of Chemical Engineers at the Pennsylvania State University [34]. When no dipole moment is available, similarity with other compounds, group contributions, or experimental data can be used to estimate the polar solubility parameter.

It must be noted that the fact of zero dipole moment in symmetrical molecules is not basis enough to assign a zero polar solubility parameter. An outstanding example of variations of this kind can be found with carbon disulfide. The reported dipole moments are mostly 0 for gas phase measurements, supplemented by 0.08 in hexane, 0.4 in carbon tetrachloride, 0.49 in chlorobenzene, and 1.21 in nitrobenzene.

There is a clear increase with increasing solubility parameter of the media. The latter and highest value has been found experimentally most fitting for correlating permeation through a fluoropolymer film used for chemical protective clothing [*35*]. Many fluoropolymers have considerable polarity. The lower dipole moments seem to fit in other instances. Diethylether has also presented problems as an outlier in terms of dissolving or not, or rapid permeation or not. Here the reported dipole moments [*33*] vary from 0.74 to 2.0 with a preferred value of 1.17, and with 1.79 in chloroform. Choosing a given value seems rather arbitrary. The chameleonic cyclic forms of the linear glycol ethers would also seem to provide for a basis of altered dipole moments in various media [*29*].

When Eq 10 can not be used, the polar solubility parameter has been found using the Beerbower table of group contributions, by similarity to related compounds, and/or by subtraction of the dispersion and hydrogen bonding cohesive energies from the total cohesive energy. The question in each case is: "Which data are available and judged most reliable?" New group contributions have also been developed from related compounds where their dipole moments are available. These new polar group contributions then become supplementary to the Beerbower table.

For large molecules, especially those with long hydrocarbon chains, the accurate calculation of the relatively small polar (and hydrogen bonding) contributions present special difficulties. The latent heats are not generally available with sufficient accuracy to allow subtraction of two large numbers from each other to find a very small one. In such cases the similarity and group contribution methods are thought best. Unfortunately, latent heats found in a widely used handbook [*36*] are not clearly reported as to the reference temperature. There is an indication that these are 25°C data, but checking indicated many of the data were identical with boiling point data reported elsewhere in the literature. A more recent edition of this handbook has a completely different and less voluminous section for the latent heat of evaporation [*37*]. Again, even moderate variations in reported heats of vaporization can cause severe problems in calculating the polar (or hydrogen bonding) parameter when Eqs 4 or 6 are strictly adhered to.

CALCULATION OF THE HYDROGEN BONDING SOLUBILITY PARAMETER, δ_h

In the earliest work, the hydrogen bonding parameter was almost always found from the subtraction of the polar and dispersion energies of vaporization from the total energy of vaporization. This is still widely used where the required data are available and reliable. At this stage, however, the group contribution techniques are considered reasonably reliable for most of the required calculations and, in fact, more reliable than estimating several of the other parameters to ultimately arrive at the subtraction step just mentioned. Therefore, in the absence of reliable latent heat and dipole moment data, group contributions are judged to be the best alternative. Similarity to related compounds can also be used, of course, and the result of such a procedure should be essentially the same as for using group contributions.

SUPPLEMENTARY CALCULATIONS AND PROCEDURES

The procedures listed above are those most frequently used by the author in calculating the three partial solubility parameters for liquids where some data are available. There are a number of other calculations and procedures which are also helpful. Latent heat data at 25°C have consistently been found from latent heats at another temperature using the relation given by Fishtine [*38*].

$$\frac{\Delta H_v(T_1)}{\Delta H_v(T_2)} = \left[\frac{T_c - T_1}{T_c - T_2}\right]^{0.38} = \left[\frac{1 - T_{r1}}{1 - T_{r2}}\right]^{0.38} \left[\frac{1 - T_{r1}}{1 - T_{r2}}\right]^{0.38} \tag{11}$$

This is done even if the melting point of the compound being considered is higher than 25°C. The result is consistent with all the other parameters, and to date no problems with particularly faulty predictions have been noted in this respect, i.e., it appears as if the predictions are not significantly in error. When the latent heat is given in cal/mole, the above equation is used to estimate the latent heat at 25°C. RT equal to 592 cal/mole is then subtracted from this according to Eq 12 to find the total cohesion energy, ΔE_v, in cgs units at this temperature:

$$\Delta E_v = \Delta E_t = \Delta H_v - RT \tag{12}$$

Only very limited attempts have been made to calculate solubility parameters at a higher temperature. Solubility parameter correlations of phenomena at higher temperatures have generally been found satisfactory when the established 25°C parameters have been used. Recalculation to higher temperatures is possible, but has not been found necessary. In this direct but approximate approach it is assumed that the parameters all demonstrate the same temperature dependence, which, of course, is not the case. It might be noted in this connection that the hydrogen bonding parameter, in particular, is the most sensitive to temperature. As the temperature is increased, more and more hydrogen bonds are progressively broken, and this parameter will decrease more rapidly than the others.

The gas phase dipole moment is not temperature dependent, although the volume of the fluid does change with temperature, which will change its cohesive energy density. Beerbower has suggested relations to predict the changes of the partial solubility parameters with temperature [*11*]. The coefficient of thermal expansion, α, appears in all of these relations. These are

$$\frac{d(\delta_d)}{dT} = -1.25\,\alpha\delta_d \tag{13}$$

$$\frac{d(\delta_p)}{dT} = -0.5\,\alpha\delta_p \tag{14}$$

$$\frac{d(\delta_h)}{dT} = -\delta_h\,(1.22 \times 10^{-3} + 0.5\,\alpha) \tag{15}$$

A computer program has been developed by the author to assign the three Hansen parameters for solvents based on experimental data alone. This has been used in several cases

where the parameters for the given liquids were desired with a high degree of accuracy. The procedure is to enter solvent quality, good or bad, into the program for a reasonably large number of polymers where the solubility parameters and appropriate radius of interaction for the polymers are known. The program then locates that set of δ_d, δ_p, and δ_h parameters for the solvent which best satisfies the requirements of a location within the spheres of the appropriate polymers where solvent quality is good and outside of the appropriate spheres where it is bad.

An additional aid in estimating the Hansen parameters for many compounds is that these parameters can be found by interpolation or extrapolation, especially for homologous series. The first member may not necessarily be a straight line extrapolation, but comparisons with related compounds should always be made where possible to confirm assignments. Plotting the parameters reported in Table 3 for homologous series among the esters, nitroparaffins, ketones, alcohols, and glycol ethers will aid in finding the parameters for related compounds.

Table 3 contains Hansen solubility parameters for a large number of liquids and plasticizers. These are given in SI units.

SOLUBILITY PARAMETERS FOR POLYMERS

The solubility parameters for numerous polymers and film formers are given in Table 4. Suppliers and trademarks are given in Table 5. These data are based on solubility determinations unless otherwise noted. There are four parameters, the three describing the nonpolar, polar, and hydrogen bonding interactions as for the liquids, and the fourth, R_0, a radius of interaction for the type of interaction described. Most of these are taken from a report [*39*] from the Scandinavian Paint and Printing Ink Research Institute. (This institute unfortunately no longer exists.) Additional values have been contributed according to the notes in the table to indicate the types of data which have been correlated with these techniques. Barton [*40*] has also provided solubility parameters for many polymers in a recent handbook.

Experimental determination of polymer solubility parameters involves trying to dissolve the polymer at a given concentration, usually 10% by weight, in a selection of solvents intended to maximize information regarding all types of interaction. Whenever possible the author uses a set of parameters indicated with an "*" in Table 3. The "yes" or "no" solubility data can be plotted by hand or processed by computer to yield a "spherical" characterization as described above. Teas [*41*] has developed a triangular plotting technique which helps visualization of three parameters on a plane sheet of paper. Examples are found in Ref *3* and Ref *4* as well.

Swelling, weight gain, solvent resistance, and surface attack have also been used as a primary data to characterize polymers.

APPLICATIONS

There are many applications documented in the literature where solubility parameters have aided in selection of solvents, understanding and controlling processes, and, in general, offered guidance where affinities among materials are of prime importance. To find the optimum solvent for a polymer using solubility parameters, it is most desirable to have the solubility parameters for the polymer. Matching the parameters of an already existing solvent or combination of solvents can be done, but does not necessarily optimize the new situation. The optimum depends on what is desired of the system. A solvent with highest possible affinity for the polymer is both expensive and probably not necessary.

Most coatings applications involve solvents safely within the solubility limit with a maximum of cheaper hydrocarbon solvent. Some safety is advised because temperature changes, potential variations in production, etc. can lead to a situation where solvent quality changes in an adverse manner. Balance of solvent quality on evaporation of mixed solvents is also necessary. Here again computer approaches are possible.

An oxygenated solvent frequently added to hydrocarbon solvent and which has been cost effective in increasing the very important hydrogen bonding solubility parameters has been *n*-butanol. The mixture of equal parts xylene and *n*-butanol can be used in conjunction with many polymers, but a third solvent, such as a ketone or ester, is often included in small amounts to increase the polar parameter/solvency of the mixture. Glycol ethers can also be added to hydrocarbon solvents with advantage, and the polar and hydrogen bonding parameters are higher than had *n*-butanol been added to the same concentration. There are many possibilities, and a solubility parameter approach is particularly valuable in quickly limiting the number of candidates.

Coalescing solvents in water-reducible coatings are often those with somewhat higher hydrogen bonding parameters than the polymer, which also means they are water soluble or have considerable water solubility. The distribution between the water phase and the dispersed polymer phase depends on the relative affinities for water and the polymer. Solvents which are not particularly water soluble will preferentially be found in the polymer phase. Such coalescing solvents may be preferred for applications to porous substrates, making certain they are where they are needed. Otherwise a water-soluble coalescing solvent would tend to follow the aqueous phase penetrating the substrate and not be available to do its job in the film itself.

When water evaporates the solvent must dissolve to some extent in the polymer to promote coalescence. This can be determined and adjusted by either increasing or decreasing the affinity for the polymer.

Amines are frequently added in water-reducible coatings to neutralize acid groups in polymers, thus providing a water-solubilizing amine salt. Amine in excess of that required for total neutralization acts like a solvent. Such amine salts have been characterized separately to demonstrate that they have higher solubility parameters than either (acetic) acid or organic bases [*42*]. These salts are hydrophilic and have very little affinity for coatings polymers, which means they are to be found in a stabilizing role in interfaces in the aqueous

phase, still being attached to the polymer. Electrostatic repulsion contributes to stability as well.

Surface active agents, whether nonionic or ionic, are also to be found where the affinities of the respective parts of their molecules dictate their placement. The hydrophilic end with a high hydrogen bonding parameter will be in the aqueous phase, and the hydrophobic end will seek out an environment where energy differences are lowest.

Increases in temperature lead to lower hydrogen bonding parameters, especially. For this reason solvents with high hydrogen bonding parameters, such as glycols, glycol ethers, and alcohols, become better solvents for most polymers at higher temperatures. This can markedly affect hot-room stability in water-reducible coatings, for example, since more of the solvent will partition to the polymer phase, which swells, becomes more fluid, and has altered affinities for stabilizing surface active agents, for example. They may dissolve too readily in the dispersed polymer. Carefully controlled, these temperature effects are an advantage in water-reducible, oven-cured coatings, leading to higher film integrity.

A simple approach to many practical problems is to make a two-dimensional plot of polar versus hydrogen bonding parameters with a circle (or estimated circle) for the polymer in question. One can plot the points for potential solvents and quickly arrive at a starting composition for an experiment. This can subsequently be adjusted if necessary. It should also be kept in mind that cyclic solvents generally have higher nonpolar parameters than aliphatic solvents.

A long list of applications, in coatings and elsewhere, was provided as early as 1975 in a review article by Barton [*43*]. Many applications are given in Table 6 and in the present discussion to give an idea of what can be studied systematically using this concept. More recent references and varied applications can be found in Refs *3*, *4*, and *44*.

Beerbower [*44*] has given many of the more theoretical applications for solubility parameters including correlations of the Rehbinder effect of crushing strength of aluminum oxide under various liquids, the work of adhesion for liquids on mercury, the Joffe effect of the consequences of immersion in various liquids on the fracture strength of soda-lime glass, and correlations of friction on polyethylene treated with fuming sulfuric acid $H_2SO_4 + SO_3$ [*44*].

Direct and practical applications of solubility parameters in coatings have included their use as an aid in the selection of solvents and solvent blends for many years. Most solvent suppliers and frequent solvent users have computer programs for this purpose, although as noted above, such programs are not an absolute necessity. Reformulation to meet environmental requirements is especially important in this respect since one can quickly evaluate which of the alternatives is most likely to meet the given requirements. This includes reducing amounts of volatile organic solvent (VOC) and often involves mixtures.

The main thing to remember in solvent selection using solubility parameters is that the resultant values for mixtures can be estimated from volume fraction averages for each

[b]Calculated from solubility data in *Polymer Handbook*, 2nd ed., John Wiley & Sons, Inc., New York, 1975.

solubility parameter component. Solvent quality can be adjusted by the RED number concept or graphically as described above.

A computer search for nearest neighbors for a given single solvent has been used many times to locate alternates. A similar application is to predict which other solvents will probably be aggressive to a chemically resistant coating where very limited data have indicated a single solvent or two are somewhat aggressive. A nearest neighbor search involves calculation of the quantity R_s for a whole database, for example, and then arranging the printout in RED number order with the potentially most aggressive at the top of the list. Solvents with RED less than 1.0 are "good" and easily recognized.

In many cases a marginal solvent is desired, in which case RED numbers just under 1.0 will be sought. Marginal solvent quality will ensure that polymer adsorbed onto pigment surfaces has little reason to dissolve away from that surface where it is desired as a stabilizing factor in the product. The solvent in this case should have a RED number for the pigment surface greater than 1.0 to aid in the planned affinity approach to pigment dispersion stability. A sketch of the optimum relations is given in Fig. 4, where the marginal solvent is Number 1. Solvent 2 would probably be too expensive and, in addition, will probably dissolve the polymer too well. In special applications this extended polymer chain configuration is desirable, but a solid anchor to the pigment surface is required. A good anchor has high affinity for the pigment surface and marginal or no affinity for the solvent. Solvent 3

would adsorb onto the pigment surface preferentially, and pigment dispersion stability will be poor. Pigments have been characterized by long-time suspension studies where some solvents will suspend the fines for days, months, or years, while others of similar viscosity yield rapid settling. The suspending solvents are the "good" ones and can be used to define a sphere for surface wetting/adsorption.

In other cases better matches between solvent and polymer solubility parameters are required. This is true when two polymers are mixed and one of them precipitates. This is most likely the polymer with larger molecular weight, and it must be dissolved better. Lower RED numbers with respect to this polymer are desired, while still maintaining affinity for the other polymer. Miscible blends of two polymers have been found using a solvent mixture composed exclusively of nonsolvents. This is demonstrated schematically in Fig. 5, where it can be seen that different percentage blends of Solvents 1 and 2 will have different relative affinities for the polymers. No other alternative theory of polymer solution thermodynamics can duplicate this predictive ability. Polymer miscibility is enhanced by larger overlapping solubility regions for the polymers as sketched in Fig. 6. Polymers A and B should be compatible, while C will not be. Such a systematic analysis allows modification of a given polymer to provide more overlap and enhanced compatibility. The advantages of a copolymer containing the monomers of A or B and C should also be evident. Such a copolymer will essentially couple the system together.

Van Dyk et al. [*45*] have correlated the inherent viscosity of polymer solutions with the solubility parameter. This is interesting in that the solubility parameter is a thermodynamic consideration, while the viscosity is a kinetic phenomena. Solvents with higher affinities give greater polymer chain extension in solution, and the inherent viscosity—the solution viscosity divided by the solvent viscosity at polymer concentrations approaching zero—is an expression reflecting polymer chain extension in solution. Higher intrinsic viscosities were found for solvents with solubility parameters nearest the polymer solubility parameters.

The use of supercritical gases as solvents has become more common in recent years. Space limitations prevent going into the details of these developments. It should be noted, however, that when a gas is compressed its cohesive energy density increases. This means that nonpolar gases with their low nonpolar solubility parameters can begin to dissolve given organic materials which otherwise have solubility parameters which are too high. Increasing the nonpolar solubility parameter of the gas by increasing the pressure causes a

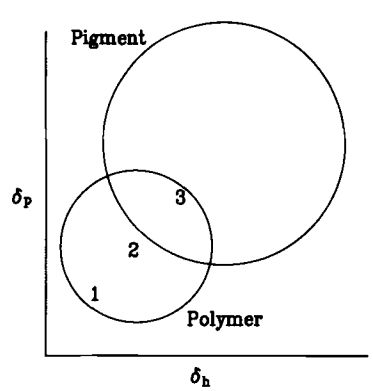

FIG. 4–Solubility parameter relations for optimum pigment dispersion stability.

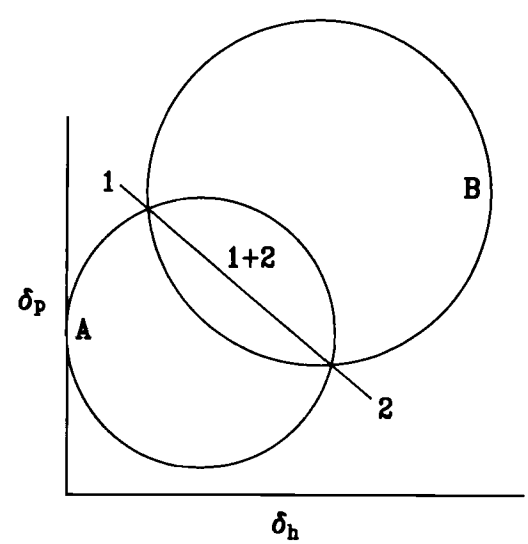

FIG. 5–Solubility relations for polymer mixtures can be quickly evaluated to ensure solution stability. Even mixtures of nonsolvents can be systematically used to regulate solution behavior.

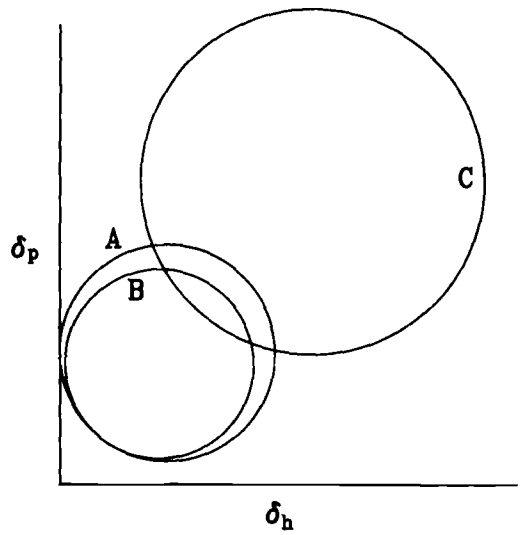

FIG. 6–Schematic representation showing expected miscibility of Polymers A and B with each other but not with Polymer C.

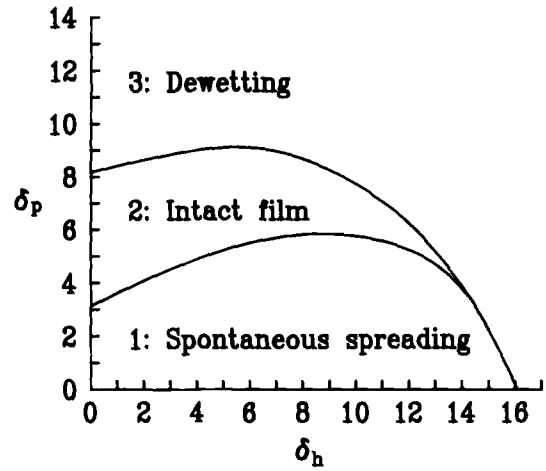

FIG. 7–Schematic diagrams showing surface energy/contact angle characterizations using the Hansen solubility parameters (cohesion energy parameters).

closer match with the corresponding parameter for potential solutes. Similar behavior is found for polar gases such as carbon dioxide. The prevailing pressure and temperature conditions determine its cohesive energy density and changes in pressure or temperature change solubility relations for this reason. Whereas nonpolar gases are most suitably used for relatively nonpolar solutes, carbon dioxide—and in principle other polar gases—are most suitably used in connection with more polar solutes. The solubility parameters for carbon dioxide have been reported [*46*] based on the room temperature solubility of the gas in different liquids (δ_d, δ_p, δ_h equal to 15.3, 6.9, 4.1). These parameters resemble those of a higher ketone.

Pigment wetting/suspension characteristics have been presented earlier [*2,4,10*]. Mixtures of nonsuspending solvents could also be found which, when admixed, provided predictably higher affinity and suspension of pigment particles for prolonged periods of time. An exceptionally clear demonstration of pigment adsorption properties is given in Ref *4* where a triangular plot of the three partial parameters shows the clearly different adsorption properties of untreated zinc oxide powder and organic phosphate surface-treated zinc oxide powder. This triangular approach to plotting was developed by Teas [*41*].

Other surface characterizations have also been given for surfaces such as coatings and metal substrates [*17,18*]. These characterizations have been of the type sketched in Fig. 7. Such cohesive energy plots can lead to systematic modifications of systems to improve adhesion. It might be added parenthetically that equal information can be obtained from plots of the cosine of the contact angle versus the solubility parameter as for plots of these same data versus liquid surface tension [*17*]. The energy information obtained in these types of studies, the critical surface tension, corresponds to the condition of RED equal to 1.0, with a solubility parameter approach, that is, marginal affinity.

The list of applications has recently been expanded to include correlations of the breakthrough times for common types of chemical protective clothing such as butyl rubber, nitrile rubber, plasticized polyvinyl chloride, neoprene, Viton rubber, polyvinyl alcohol, etc. [*47*]. Figure 8 shows the importance of combined use of the RED number and molecular volume in correlating 3-h breakthrough times for a fluoropolymer chemical protective product [*48*]. Monomers with terminal double bonds diffuse more rapidly than comparisons with non-double-bonded molecules of similar size and solubility parameter would have predicted. The smaller cross section at the end of the molecule reminds one of a nail, and the preferred direction and relative rapidity of transport become easily understandable.

In addition it should be noted that even biological materials, some of which have interest for coatings applications and use, have been assigned Hansen solubility parameters [*49*]. These include keratin (which relates to skin permeation), fat, sucrose, blood serum and zein (which are proteins), urea, lignin (wood penetration), and chlorophyll (which closely resembles lignin) [*46,49*]. The characterization of other biological materials is also possible, of course.

Even inorganic salts have been characterized by solubility parameters [*50*]. The practice of dissolving polymers in solutions of organic liquids and inorganic salts can thus be explained by the solubility parameter. A solubility parameter correlation of the chemical resistance of an inorganic zinc silicate coating is reported in Table 4. Finally it might be noted that Hildebrand presented a chapter on the solubility parameters of metals [*1*]. Unfortunately we do not often coat metal, but rather metal oxides, for which no solubility parameter work has been reported.

CONCLUSION

The background and many uses of the solubility parameter concept have been described in detail. Tables of solubility parameters for many liquids and polymers have been presented. Systematic use of solubility, swelling, or permeation

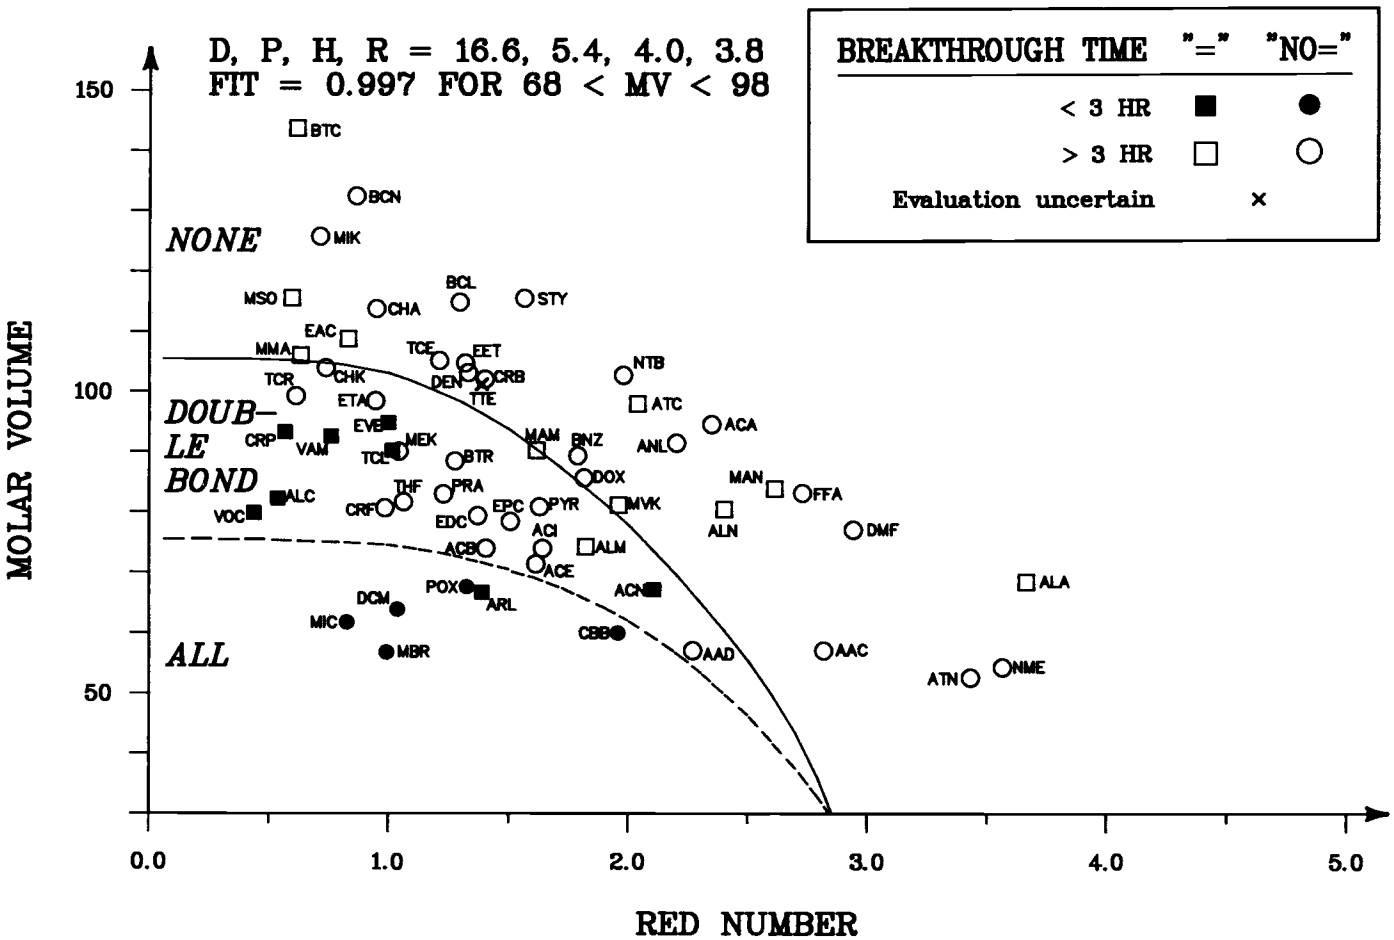

FIG. 8–Effects of molecular size (molar volume) and affinity (RED number) on the breakthrough time of Challenge 5100 [*48*].

data for polymers allows their characterization by these same cohesive energy parameters. Surfaces can also be characterized using these same parameters. This provides data for optimizing solvent selection, improving compatibility, and enhancing pigment dispersion and adhesion. When all of the materials involved in a given product and application can be characterized with the same energy parameters, the possibility exists to predict interactions among them, even in complicated situations. Methods for estimating the three Hansen solubility parameters have been given with as much detail as has been possible to ensure their more uniform use in the future. It has not been possible to deal with all the primarily theoretical problems with the solubility parameter concept. Some of these are dealt with in the literature cited, most notably in Refs *3*, *4*, *12*, and *20*.

A simple approach is described to understand affinities in such varied materials as gases, liquids, polymers, biological materials, surfaces, organic and inorganic coatings, inorganic salts, and metals. An appeal is made to the scientific community to expand research on this seemingly universal approach.

Part 9: Films for Testing

36

Cure: The Process and Its Measurement

by Thomas J. Miranda[1]

INTRODUCTION

One of the most critical, and often misunderstood properties of a coating is cure and its measurement. The optimum physical and chemical properties of a coating depend largely on proper curing conditions. For example, a thermosetting acrylic polymer when applied to a panel and dried without curing will be brittle and have poor solvent resistance and low hardness. When properly cured, the film properties will change dramatically and the properties which were designed into the coating become apparent. Similarly, an oil-based paint will be soft and tacky and slowly become hard and scratch resistant as its cure develops. To appreciate the scope of the material in this chapter, it may be well to review a few film-forming mechanisms, polymer fundamentals, and some background into the development of tests and what they mean.

Background and Film Formation

Polymers

A polymer is a high-molecular-weight interreaction product of related polyfunctional molecules [*1*]. The term *polymer* is derived from the Greek poly (many) and mer (part). Polymers are formed from monomers (mono = one) (mer = part) by a process of polymerization. Polymers consist of long chains of macromolecules with molecular weights of a few thousand up to many millions. For example, ultrahigh-molecular-weight polyethylene may have a molecular weight of 4 to 6 million, while alkyds have molecular weights of a few thousand. The concept of macromolecules was developed by Herman Staudinger in 1920 [*2*]. Staudinger's theory was supported by the work of Wallace Carothers, who introduced the concept of functionality and the distinction between thermoplastic and thermosetting polymers [*3*].

There are two types of polymers: addition and condensation. Addition polymers have high molecular weight and are characterized by fast chain reaction syntheses that are exothermic and initiated by free radical, coordination polymerization, cationic, group transfer, or anionic mechanisms. Free radical-initiated polymerization is initiated by incorporation of a free radical producer such as benzoyl peroxide which decomposes with heat to form free radicals, which in turn initiate polymerization. Coordination polymerization is initiated by complex initiator systems such as those used to polymerize ethylene or propylene and sometimes referred to as Ziegler-Natta catalysts made from an organometal and an inorganic compound like titanium tetrachloride. Cationic initiation can be done using Lewis acids such as aluminum chloride or boron trifluoride and are usually carried out at low temperatures. Butyl rubber is made by such a process. Group transfer is a relatively new type of polymer initiation, while the anionic processes use organometals (butyl lithium) to produce polymers. Block polymers are made by anionic processes. Condensation polymers have lower molecular weight than addition types and are produced by stepwise addition with elimination of water as a byproduct and require a longer time to synthesize using an endothermic process [*4*].

Cure Concept and Illustrations

We can simplistically illustrate the concept by considering a long chain polymer (thermoplastic) as a wire fence with a number of strands (Fig. 1) such as used on a farm. An individual can pass through the fence by spreading the strands apart, and standing on the fence will cause the strand to sag or elongate. If, however, we take that fence and lace it with wire such that a hogwire fence is produced, then we see the changes in the physical properties of this (thermoset) fence. First, it would be difficult to pass through the fence; second, one can stand on the fence since it is stronger and will not yield as would the single strand fence. If one considers the ability to pass through the fence as solvent action, it is easy to visualize how solvent molecules can permeate and dissolve a thermoplastic polymer, but difficult or impossible to dissolve a thermoset polymer. In fact, a thermoset polymer will tend to swell, such as a rubber band in a hydrocarbon solvent. This is because the solvent molecules can solvate the linear portions of the rubber, but are constrained by the sulfur cross-links from totally dissolving the polymer. Another aspect of cross-linking is that the molecular weight increases enormously, which explains why solvent resistance increases and certain physical properties such as hardness, scratch resistance, and toughness are enhanced. The thermoset polymer is a three-dimensional network polymer. Cure must not be confused with dry time such as that measured in oil-containing polymers which dry by interaction with atmospheric oxygen. Here such terms as *set-to-touch, print free, time to lint free,* and *time for sand pickup* relate to the speed at which solvent evaporates and not to the ultimate cure or cross-linking of a coating system. Cure, therefore, refers to the cross-linking of a polymer to produce a three-dimensional network.

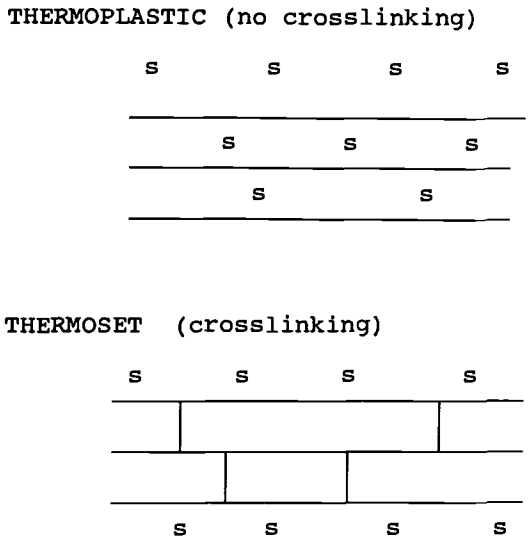

FIG. 1–Polymers.

TYPES OF FILMS

As described above, polymers can be classified as *thermoplastic* and *thermoset* in nature when derived from addition and condensation polymerization as well as by their physical response to heat and solvent action.

Thermoplastic

A long-chain polymer such as polyethylene is considered thermoplastic since it can be dissolved in certain solvents and can be repeatedly softened or melted when heated and hardened when cooled.

Thermoset

On the other hand, a polymer prepared, for example, from a phenol-formaldehyde condensate cannot be liquified and solidified repeatedly after it is formed. These polymers are termed *thermosetting* and tend to degrade if heated repeatedly. The reason for this is that they are cross-linked.

CURE MECHANISMS

Coating films can be made by a number of methods. The principal mechanisms of film formation are represented by lacquers, emulsions, and thermosetting (via oxidative cross-linking or by reactive cross-linking) coatings. For a review of film formation, the reader is referred to the Federation of Societies for Coatings Technology Monograph on Film Formation [5].

Lacquers

Lacquers consist of a thermoplastic polymer which is dissolved in a solvent. When the coating is applied, the solvent evaporates and a thermoplastic film is formed. This is the type of coating used in certain furniture and automotive finishes.

Emulsions

Another means for forming a thermoplastic film is film formation from an emulsion. In this case, a polymer, such as a vinyl acetate-acrylic copolymer emulsion (or latex), is cast onto a substrate and then the water carrier leaves the film by evaporation. In the latex, water is not a solvent but a dispersing medium. Microscopically, the polymer molecules look like tiny ball bearings suspended in water (Fig. 2). Surface active agents keep the polymer from settling. As the water evaporates, hydrodynamic pressure causes the small spheres to crowd closer and closer together until capillary action forces the particles to fuse and form a continuous film. If the polymer is too hard, a poorly adherent film forms. This is why paint manufacturers recommend that water-based, latex-type paints not be applied at low temperatures. At low temperatures, the particles cannot fuse properly, and the paint will fail prematurely. To facilitate fusion, small amounts of coalescing solvent such as diethylene glycol monobutyl ether (butyl Carbitol™ Union Carbide Corp.) are added. These solvents lower the glass transition temperature of the copolymer and facilitates fusion. These are examples of physical drying as compared to chemical drying discussed next (see Fig. 2).

Oxidative Cross-Linking

In oxidative cross-linking, a polymer is prepared from an unsaturated fatty acid or oil such as castor, tall, soya, linseed, or tung oil, and a small amount of a siccative (drier) such as

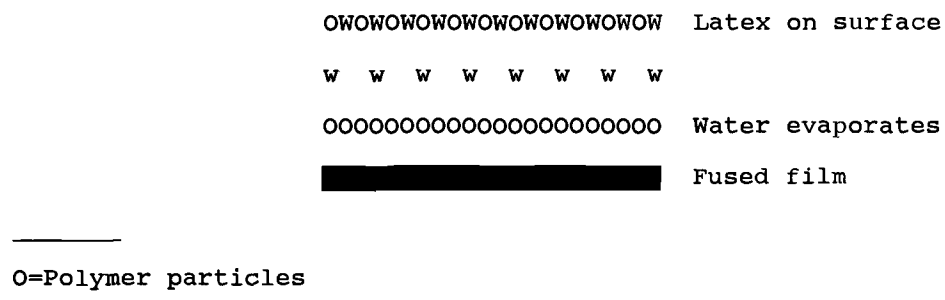

FIG. 2–Drying of a latex film.

lead, cobalt, manganese, or zirconium salts, for example, naphthenates, octoates, etc., is added. The film is cast by brushing, spraying, or other means and allowed to dry. In the first stages, the solvent evaporates, leaving a tacky film. The film can be easily deformed or thumb printed. But, as the film ages, it slowly becomes less tacky and finally print free and cured. What has happened? The film slowly absorbed oxygen from the atmosphere and formed hydroperoxides on the carbon alpha to the double bond. The drier decomposed the hydroperoxide and formed free radicals that initiated cross-links between the chains derived from the fatty acid portion of the alkyd (which imparts improved properties to the film), resulting in a cured or cross-linked film. A simplified reaction scheme is shown in the following [6]:

$$R{-}CH{=}CH{-}CH_2{-}CH{=}CH{-}R' \xrightarrow{O_2}$$

$$R{-}\underset{\underset{OOH}{|}}{CH}{-}CH{=}CH{-}CH{=}CH{-}R'$$

$$R{-}\underset{\cdot}{C}H{-}CH{=}CH{-}CH{=}CH{-}R' + \cdot OOH$$

where R is $CH_3(CH_2)_4$ and R′ is $(CH_2)_7CO_2CH_3$.

The initial products are converted to polymers according to:

Initiation:	$RH + O_2 \longrightarrow R\cdot + \cdot OOH$
Propagation	$R\cdot + O_2 \longrightarrow ROO\cdot$
	$ROO\cdot + RH \longrightarrow ROOH + R\cdot$
Termination	$ROO\cdot + R\cdot \longrightarrow ROOR$
	$ROO\cdot + ROO\cdot \longrightarrow ROOR + O_2$
	$R\cdot + R\cdot \longrightarrow R{-}R$

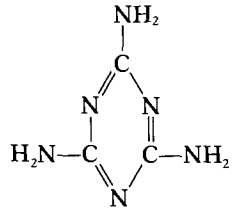
Termination by coupling doubles the size of the molecule since two fragments are now joined (assuming that the chain length is about equal). In this way oil-bearing oxidative curing leads to networks having the proper chemical and physical properties.

Reactive Cross-linking

In this type of cross-linking, a reactive intermediate is added to a polymer and a further chemical reaction is initiated either by heating alone, heating in the presence of a catalyst, or by some other form of initiation.

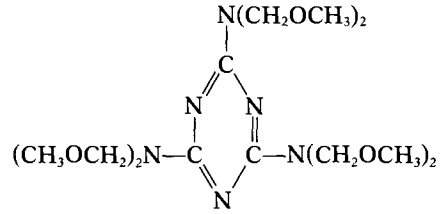
Melamine

Melamine formaldehyde condensates are used to cure a reactive polymer. Melamine is 1,3,5 triamino-s-triazine and is produced from the condensation of 3 moles of dicyandiamide:



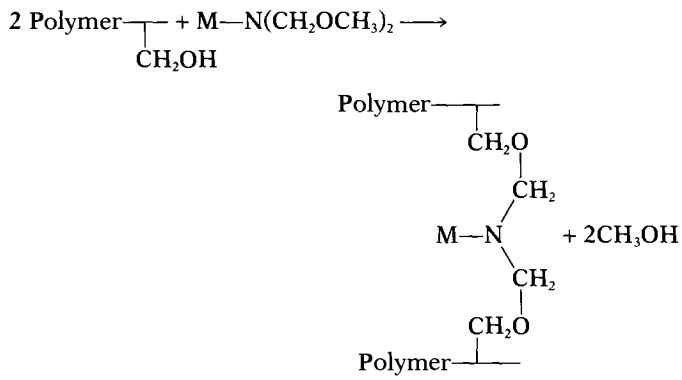
Melamine

Melamine can be condensed with up to 6 mol of formaldehyde and 6 mol of methanol to form hexamethoxymethyl melamine (HMMM). The reaction product has the following structure and is often referred to as MF resin:



Hexamethoxymethyl melamine

Hexamethoxymethyl melamine can be reacted to contain from one to six methoxymethyl groups. Methanol is used to cap the hydroxyl group to prevent premature reaction. Other alcohols are commonly used, including butanol and isobutanol. In applying a melamine formaldehyde resin, the resin usually is reacted with a functional polymer such as a thermosetting acrylic or alkyd polymer containing an acid or hydroxyl group that can react with the MF resin. This can be depicted in the following manner:



where M denotes a methoxy-substituted melamine functional unit. In this illustration, only two of the melamine methoxymethyl functions are shown reacting with the hydroxyl groups of an alkyd or other hydroxyl functional polymer. Note also the formation of a byproduct, methanol. Formaldehyde can also form as a byproduct.

Urea

A scheme similar to that described above for melamine is also applicable to urea formaldehyde (UF) resins. In this case, urea is reacted with formaldehyde and endcapped with either methyl, butyl, or isopropyl alcohols. A fully reacted urea intermediate would have a structure

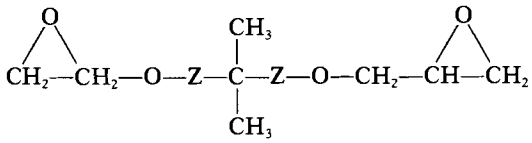
$$(CH_3OCH_2)_2{-}N{-}\underset{\underset{O}{\|}}{C}{-}N{-}(CH_2OCH_3)_2$$

N,N′ bishydroxymethylurea

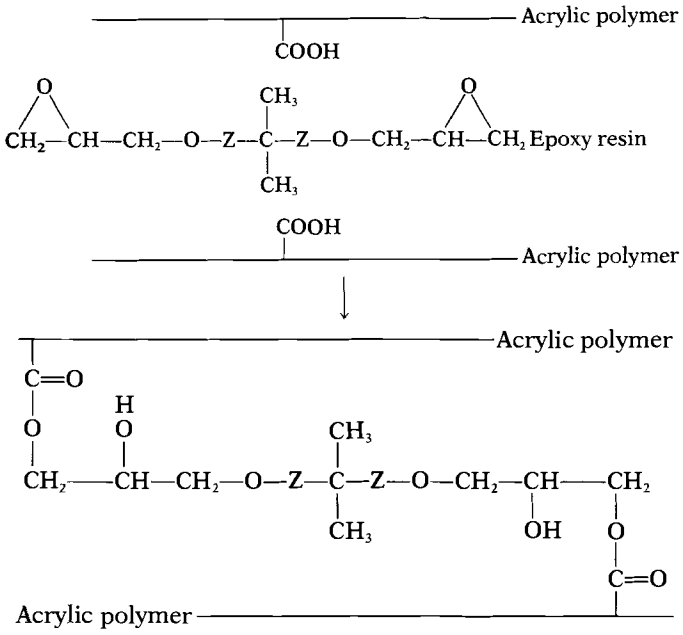
and is capable of reacting with hydroxyl groups to produce a cross-link with the elimination of byproducts as water, alcohol, and formaldehyde.

Epoxy

Epoxy resins are derivatives of cyclic ethers. Aromatic epoxy resins are produced from the reaction of epichlorohydrin and bisphenol A, and the latter is a condensation product of acetone and phenol. Aliphatic epoxy resins are prepared by the peroxidation of unsaturated linear or cyclic olefins. A simple epoxy, the diglycidyl ether of bisphenol A, is shown below (Z = phenylene group)



These epoxy functional groups can react with active hydrogen groups such as amines, hydroxyls, and acids. For example, they can react with acid groups in a thermosetting acrylic, alkyd, or other polymer and produce a cross-linked polymer. It is interesting to note that the reaction product of the epoxy and acid function produce additional hydroxyl groups which can be reacted with a melamine formaldehyde or urea formaldehyde adduct to produce improved properties, such as hardness, chemical resistance, or solvent resistance in the cured films. The reaction of two acrylic polymer chains with an epoxy resin is shown as follows:

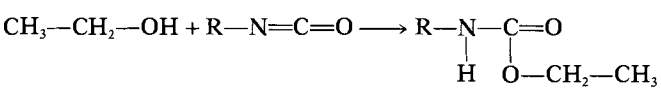


where Z represents a phenylene group.

Cross-linked acrylic polymer

Isocyanates

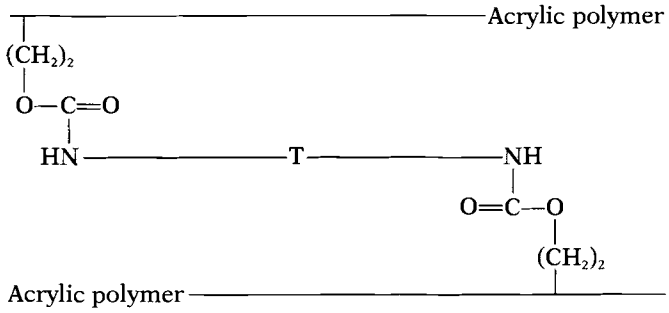
The term urethane applies to the reaction product of an hydroxyl group and an isocyanate. For example, an alcohol and isocyanate react by rearrangement to produce a urethane



Alcohol + Isocyanate Urethane

This reaction is used in applying isocyanates to the production of insulation and seating foams, reaction injection moldings, and high-performance coatings such as for aircraft. In this case the isocyanate is a di- or triisocyanate, which leads to cross-linking. Toluene diisocyanate is widely used, but other isocyanates such as 1,4-diphenyl methane diisocyanate, isophorone diisocyanate, and trimers of hexamethylene diisocyanate are also used. The higher-molecular-weight isocyanates are preferred for their lower vapor pressure, thus providing for improved working conditions.

Isocyanates are used to cross-link a variety of polymers containing hydroxyl or amine functionality. In the case of amine functionality, a urea cross-link is formed. For example, an acrylic polymer can be prepared from methylmethacrylate, butyl acrylate, and hydroxyethyl methacrylate. This polymer can be cross-linked through the pendant hydroxyl groups of the hydroxyethyl methacrylate portion by polyfunctional isocyanates:



Urethane cross-linked acrylic

T = $CH_3—C_6H_3—$ (from toluene diisocyanate)

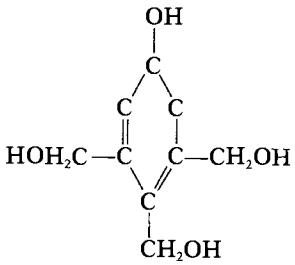
Urethane cross-linking is also used in polyesters where the hydroxyl groups are obtained from polyfunctional alcohols, such as trimethylolpropane or pentaerythritol. Similarly, epoxy resins can be cross-linked through the hydroxyl groups formed during epoxy reactions.

Catalyzed Cross-linking

This type of cross-linking is used in phenolic and silicone reactions wherein a catalyst is added to facilitate the cross-linking reaction.

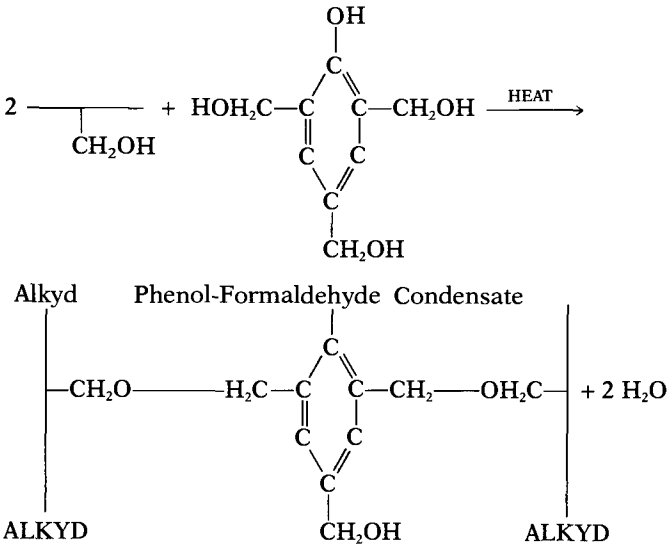
Phenolics

Phenolic resins are condensation reaction products of phenol or substituted phenols and formaldehyde. Two types of phenolics are obtained depending upon the catalyst and reaction conditions. Using an acid in its preparation, a thermoplastic, soluble novolac resin is obtained. Under basic conditions, the thermoset product formed is a resole resin which is cross-linked at the final stages of the reaction. A phenol-formaldehyde condensate may have a structure as shown:



Phenol-formaldehyde (P—F) condensate

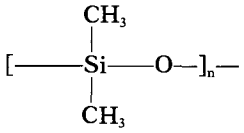
Alkyd resins can be cross-linked by reaction of the hydroxymethyl function and an hydroxyl group on the alkyd with the elimination of water:



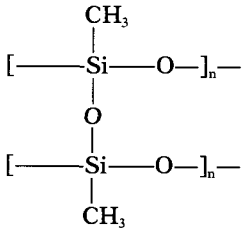
Cross-linked alkyd

Silicones

These useful polymers are prepared from silicon by chlorination, then subsequent reaction with alkyl or aryl halides to form alkyl/aryl chlorosilanes. Upon hydrolysis, these produce silicones. The alkyl silicones, such as dimethyl silicone,



are low-molecular-weight or cyclic materials used in antifoam applications. The linear forms are specialty elastomers. Blends of methyl and phenyl silicones have higher-temperature resistance and find use in heat-resistant coatings or polymers. Silicones can be cross-linked when prepared with multifunctional silane monomers such as trichloromethyl silane. Upon hydrolysis, the silicone chains can be cross-linked through siloxane bridges:



Cross-linked silicone

Silicones can also be cross-linked by peroxide initiators. In this case a silicone monomer containing a vinyl or allyl group is copolymerized to provide an active site along the chain. When used in a gasket or caulk, a small amount of a peroxide is added which initiates polymerization and cross-links the resin system. Silicone reactions are usually catalyzed by organo zinc or tin compounds.

Curing can also be accomplished using radiation as a source for initiation. Electron beam (EB) and ultraviolet radiation is used to cure coating films. These processes induce either free radical or carbonium ions to initiate polymerization, which occurs rapidly at ambient conditions.

CURE MEASUREMENT

It is very important for the user of coatings to know whether a coating is adequately cured. This can be done quickly in qualitative testing or in more sophisticated test methods requiring instrumentation. The rapid methods are desirable because of time and cost, but in some cases do not really tell the true story. In some cases, even instrumented testing only tests a certain range of cross-linking and could lead to erroneous conclusions. We shall discuss the qualitative methods first, then proceed to the more quantitative. What should be borne in mind is that we are attempting to ascertain a molecular process, cross-linking, and its relationship to coating performance.

Many thermoplastic coatings "dry" by simple evaporation of solvent, and though cure was defined above as the cross-linking of a polymeric system, such drying of lacquers can be considered a form of curing even though no cross-linking occurs. This is true for nitrocellulose lacquers, cellulose acetate, and solvent soluble acrylics where no cross-linking takes place. To measure cure for such coating, the time for either print-free or tack-free is measured. At some time during evaporation, the coating goes from tacky, to set-to-touch, to tack-free. Upon further drying, the coating becomes print-free, whereby a thumb print will not be visible on the coating. This can also be measured by dropping cotton linters onto the surface and noting the time after which they do not adhere to the coating. Also see ASTM D 2091, which describes a standard method for print resistance of lacquers.

These tests also apply to coatings which dry by oxidative cross-linking, for example, alkyds. Here, times are noted for solvent evaporation, and the coating is monitored for set-to-touch, then print-free.

Solvent Rubs (ASTM D 4752 Test Method for Measuring MEK Resistance of Ethyl Silicate (Inorganic) Zinc-Rich Primers by Solvent Rub)

A convenient, often-used method for determining cross-linking involves solvent rubs. A cloth soaked with methyl ethyl ketone (MEK) is rubbed vigorously on the film, and then the film is examined after a specific number of rubs. Acetone is also used for this test. If the film is removed, softened, or loses gloss, then the film is considered not adequately cross-linked. Films which are unaffected are considered cured. For example, certain acrylic, epoxy, or polyester coatings can survive this test. The problem with this test is that the individual testing the coating is not standardized. One person may exert much more pressure than another, and this can affect the final result.

Hardness Measurements

Another way of obtaining information concerning cross-linking is to measure some physical property such as, hard-

ness, scratch resistance, or impact resistance. There are a number of tests which provide this information.

Knoop and Pfund Hardness (ASTM D 1474 Test Methods for Indentation Hardness or Organic Coatings)

A useful test of cure is to measure the Knoop hardness in which a pyramidal diamond indenter is pressed into the film to cause indentation. The method is described in ASTM D 1474. A weight is applied to the indenter for a specific time, and the length of the indentation line is measured with a microscope. The Knoop hardness number (KHN) is calculated from [8]:

$$\text{KHN} = L/A_p = L/l^2C_p$$

where L = applied load (kg), A_p = projected indentation area (mm^2), l = length in mm of the long diagonal of the indentation mark, and C_p is an instrument constant. Because of the thinness of coating films, this method is more useful in plastics since it requires almost a 75% indentation into the film and can be influenced by substrate considerations.

The Pfund Hardness Number (PHN) is obtained using a hemispherical quartz or sapphire indenter, which is pressed into the film. The Pfund Hardness Number is calculated from:

$$\text{PFN} = L/A = 4L/\pi d^2 = 1.27\,L/d^2$$

where

L = applied load in kilograms,
A = area of projected indentation in mm^2, and
d = diameter of the projected indentation in mm.

Sward (See ASTM D 2134, Sward Rocker, and ASTM D 4366, Pendulum Damping)

Sward hardness depends upon the change in surface properties and viscoelastic properties of a film. This method, which was discontinued in 1990, is used for automotive finishes and consists of a rocker containing two spirit bubble indicators. The pendulum is rocked, and the number of swings are recorded and a reading taken at the point where the swings are equal to half the original value. Several types of pendulum units are used including Sward, Perzoz, and Koenig. As cure increases, the Sward number increases. The value of a Sward test is that a number is obtained which can be compared to other coatings. This test must also be conducted under very clean conditions, as lint and surface imperfections can interfere. Temperature control is important in this test as in other tests involving determining physical properties of coatings. The problem with this test is that it only measures cross-linking density to a point; then cannot detect over cure since a plot of Sward numbers versus cure tends to reach a limiting value. A comparison of values obtained by different test methods is shown in Table 1 [9]. Note how the values differ, especially between different brands of pencils and the limiting value of Sward Hardness.

Pencil (ASTM D 3363 Test Method for Film Hardness by Pencil Test)

Pencil hardness is a test which was developed by the manufacturers of pencils who tried to develop a means for checking the quality of pencils. Someone suggested scratching a paint film, and it was noticed that the different hardnesses of pencils were able to penetrate through the coating. This test was later used by coating technologists, and it is widely used in the industry today. In this technique a number of pencils with known hardnesses are employed. The pencil is trimmed so that 5 mm of lead is exposed. The lead diameter is 1.8 mm and is sharpened by rubbing it perpendicular to the surface of No. 400 carbide abrasive paper. The pencil is held at a 45° angle to the coating and pushed along the surface to peel away the coating. The pencil which fails to scratch the coating is the value used as pencil hardness. This method is simple, the equipment low in cost, and the results can be quickly obtained. However, values can differ depending upon the operator, the method of sharpening the lead, and the variances of lead hardness from different pencil lots and manufacturers.

Gardner Impact (ASTM D 2794 Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact))

This is a valuable test which measures the impact resistance of a coating and can be used to correlate with cure. An undercured coating may exhibit a lower Gardner Impact value, but as cross-linking density increases, the impact values improve. The test consists of placing a coated flat panel under a weighted spherical ball assembly and then dropping the weighted ball onto the panel from different heights. The cylinder in which the ball assembly is mounted is calibrated such that an operator can measure the impact directly in inch pounds. Impact measurements are done by dropping the ball directly on the coating surface or on the reverse side. The results are reported as inch-pounds direct or reverse. Direct impact is less severe than reverse impact. A dimple is formed in the test panel which can be examined visually or with a X10 glass to determine the extent of cracking which occurs. An appliance acrylic may have a direct impact of only 10 in.-lb, while a polyester urethane powder coating may have a reverse impact of 160 in.-lb. The value of the Gardner Impact test is that the test can be done quickly, it is widely recognized in the coatings industry, and it gives some correlation with cross-link density in that the optimum physical properties of a coating develop as the molecular weight increases.

Thermal Analysis

Thermal analysis is an important analytical tool for determining the response of material to changes in temperatures. This method of analysis can be used to monitor the glass transition temperature, T_g, of a coating, and this can be related to the cross-linking density. For example, a ladder of paint panels cured at various times or temperatures can be prepared and then studied by thermal analysis to determine the change in T_g as a function of bake schedule. From this, the optimum cure cycle can be determined to insure a quality finish.

Thermal analysis units have several modes for determining T_g: differential scanning calorimetry (DSC), thermomechanical analysis (TMA), and dynamic mechanical analysis (DMA) are useful tools for obtaining quantitative mea-

TABLE 1—Hardness test correlation.

14	...	40	8H	9H	7H	7H	9H

sures of cross-linking by measuring T_g. The glass transition temperature is a second order transition that represents a temperature where segmental motion occurs along a polymer chain backbone, and it is accompanied by a volume change. A comparative study of changes of cross-linking measured by Sward hardness, evaporative rate analysis, and DSC showed that T_g changes can be followed to high levels of cross-linking, whereas Sward measurements reached a limiting value while T_g continued to rise [*10*].

With DSC, a plot of endotherm/exotherm is made as a function of temperature at a set rate of temperature rise. As the T_g is reached, there is an abrupt change in the endotherm which appears on a plot. Similarly, T_g can be measured using a plot of change in expansion with temperature with the TMA mode. Here a sample is placed under a quartz probe and then heated. As the film expands a plot is obtained in which a change in slope occurs. The intersection of the tangents of the expansion curve yields the T_g value. In the penetration mode a depression occurs indicating the T_g. Plots can be made of T_g versus bake cycle to note the optimum T_g of a coating. Further details on thermal analysis applications can be found in the literature [*11–13*].

Dynamic Mechanical Analysis

Another way of obtaining T_g is to use dynamic mechanical analysis in which a coating film is fixed to the ends of a tuning fork and the fork driven over a frequency range and at different temperatures or at a fixed frequency with varying temperature to provide a plot of damping versus temperature. This information yields T_g as well as mechanical damping information about the film [*14*].

Torsion Pendulum [*14,15*]

Another method for measuring dynamic mechanical properties of coatings is to suspend the film with a weight, then twist the weight so that it will oscillate as a pendulum. This is not entirely acceptable since coating films may not have the strength to support the weight of the apparatus. One way to overcome this is to invert the apparatus so that the pendulum weight is suspended with counterweights. A more practical method is to use the torsion braid pendulum in which a fiberglass braid is saturated with a coating and the pendulum oscillated. As the coating cures, changes in oscillation can be correlated with damping and T_g.

Impedance Measurements

Myers [*16*] studied the drying behavior of latex systems using ultrasonic impedance measurements. In this work, a latex coating was cast on a quartz crystal and ultrasonic energy was beamed at an 11° angle at the underside of the coating and reflected to a detector which measured the attenuation of the initial beam as absorbed by the drying coatings. As water evaporated, there were changes in impedance that could be correlated to drying.

Evaporative Rate Analysis

A novel method for studying cure is evaporative rate analysis (ERA) developed by John Anderson [*17*]. This work was carried out to determine the cleanliness of the surface of spacecraft. Anderson reasoned that if a radioactive C^{14} liquid would be placed on a clean surface, the evaporation rate would be retarded due to cleanliness. In fact, however, the opposite was true.

Nevertheless, this method was developed to measure degree of cleanliness. If a small amount of diethyl succinate-C-^{14} is deposited on a surface and a controlled sweep of nitrogen is applied, the rate of evaporation can be monitored using a Geiger counter. The principle is that on a clean surface there is no interaction between the solvent and the clean substrate, and normal evaporation occurs. If, however, the surface contains a contaminant, then the radioactive liquid will interact with the surface contaminant and retard the rate of evaporation of the radiocarbon. Plots can be obtained relating cleanliness to evaporation rate.

Anderson applied this technique to the cure of organic coatings. He showed that in an undercured surface solvent retention increased, leading to longer residence of the radiocarbon on an undercured surface. This is understandable in view of the example given in the beginning of this chapter of the ability of a solvent to pass through a wire fence analogy. By preparing coated panels having different cure times or temperatures, then measuring the ERA of each panel, a plot of retention versus bake is obtained. This method was applied to the measurement of cure of a variety of coatings by many coatings technologists [*10,18*]. The only problem was that there was no quantitative means for measuring the relationship of ERA to cure until it was shown that DSC of T_g

could be correlated to the values obtained using ERA measurements [*10*].

Film Preparation for Coating Tests

by Robert D. Athey, Jr.[1]

THE PERFORMANCE OF A COATING FILM in a test is likely to be dependent on the physical form of the film. For instance, film thickness is an important factor in physical and appearance measurements (until the coating gets too thick), so there must be some control of the film thickness. Appearance is also related to how smooth the film surface is, and care to make the film appropriately will ensure that the appearance measurements are germane to the end-use. The substrate used as the carrier for the test film, even temporarily, may affect the property measurements, as well.

The primary concern in making films for tests is that the film prepared be homogeneous and consistent with previous or future films for the same test. The jargon of the trade calls the art of making films "casting," but many film formation methods are used to form the film, and each method has its own set of advantages and drawbacks.

TEST REQUIREMENTS OF FILMS

Test requirements come in two classes, appearance and physical properties. Choice of application method for the film may affect the appearance in some cases. For instance, the "multicolor" paints must be applied by dip or spray techniques for laboratory testing, or the appearance does not give the desired mottle of nearly circular spots. Roller, brush, or even drawdown bar will cause these spots to become streaks. Choice of application method for appearance includes drying technique, as some films require special drying conditions to attain their desired special appearance. Examples include leafing aluminum flake "metallic" look paints, hammertones, and wrinkle finishes.

Choice of application method driven by physical property testing is also necessary. Think carefully of the three kinds of stresses (tensile, compression, shear) and recognize that all are blended in a hardness or adhesion evaluation by indenter, pencil, mandrel bend, or dart impact test on a coating. Recognizing these stress combinations can make one aware of film preparation needs. In cases where adhesion is stronger than cohesion of the film, one should be able to distinguish between adhesive failure and cohesive failure. Film preparation should not conflict with these objectives.

The physical properties to be tested in specific ASTM methods have a "significance and use" section in the method to ascribe the relation of the test value to some "in use" performance criterion. The preparation of the test film should thus correspond to the standard field application of the material, as well.

Another portion of film influence on the test is film thickness. The presentation by the Technical Committee from Toronto in the 1990 National FSCT meeting and Paint Show [*1*] dealt with hardness measurements in films of varying thickness. However, the control of film thickness was not as straightforward as might have been thought. Hardness values turned out to be dependent on film thickness along with other equally important variables [*2*].

Fluid rheology, concentration, and other factors govern the amount of coating left after the application process. Knowing the process variables associated with a film-casting technique are essential to getting what is needed for the ultimate test and results therefrom. Certain other properties of the film (opacity, permeability, erosion rate by some attacking mode, etc.) will depend on the thickness of the film. So, understanding thickness control in the casting process is crucial to obtaining meaningful results in terms of meeting specifications in reproducibility.

In instances where fluid or gas permeation resistance or corrosion barrier properties are to be tested, a "pinhole," "holiday," or "mudcrack" in the film is a fatal flaw. The film preparation technique must eliminate (as much as possible) any such fatal flaw, or the test method should prescribe what is to be done (for example, replications) in cases where an unseen fatal flaw is detected by the test.

FILM CASTING TECHNIQUES

Free Films

Free films, that is, films not applied permanently to a substrate, are used for a wide variety of tests and accordingly vary in thickness and size. The most common castings of free films are used for permeation or strength and elongation testing. They can also be used for cold flex tests or moisture/solvent absorption studies related to permeation. Free film thickness can be measured as described in ASTM D 1005: Test Method for Measurement of Dry-Film Thickness of Organic Coatings Using Micrometers.

Probably the most common free film castings are laid down on a "nonstick" surface, such as the silicone-coated papers (available through Leneta and other suppliers) or TEFLON™ or polyethylene sheets. Release substrates are described in ASTM D 823: Test Methods for Producing Films of Uniform

[1]Athey Technologies, P.O. Drawer 7, El Cerrito, CA 94530-0007.

Copyright© 1995 by ASTM International

Thickness of Paint, Varnish, and Related Products on Test Panels. Lack of release-substrate wetting is the most common problem encountered when trying to obtain a continuous film. Water-borne coatings are especially difficult to formulate for good wetting of these substrates. One trick to use with such formulations is to prepare the sample at higher than normal solids content, which results in increased viscosity, and resistance to beading is improved. An alternative is to apply several coats until the dried "beaded-up" portions merge to form a continuous film.

A vacuum plate makes it easier to hold down the paper or polymer film for film casting and is an aid to good results. Figure 1 is a diagram of the vacuum plate formed from aluminum. Older versions had eyes at the bottom surface through which screws could affix the plate to a table top. If this system is to be vacuum supplied from a sink faucet aspirator, a liquid trap (vacuum side-fitted Erlenmeyer flask) should be placed in line between the vacuum plate and the aspirator. This will ensure that any liquid coming from the aspirator will not get to the vacuum plate or coating substrate.

Grenko [*3*] suggested several coated paper techniques for obtaining free films, such as decal paper coated on the face side or outdated matte or semimatte photopaper. The decal paper could be floated on water and the paper peeled off. Grenko did not describe the removal of photopapers from the film. He also cited Sager [*4*] for a technique using an embroidery hoop for holding a nonmoisture proof cellophane. After the coating film had been applied, one simply poured water on the inverted cellophane and the coating film dropped off. These techniques are likely to be most appropriate for solvent borne or 100% reactive formulations. Water-borne coatings may be inappropriately leached or weakened by the water used to loosen and isolate the films.

Grenko [*3*] also mentioned the use of metal substrates for free film isolation. Brightwell [*5*] used glass onto which a thin silver film had been vacuum deposited. Bayor and Kempf [*6*] used thin aluminum foil that was later dissolved from most of the back with hydrochloric acid doped with a minute amount of platinum chloride. The latter dissolved off only enough aluminum foil to leave a foil "frame" at the edges of the film to support it and to facilitate handling. This technique with aluminum foil dissolution in an acidic, aqueous medium presumes no sensitivity of the coating components to acid or water.

For thicker films (1 cm or more), a PYREX™ or TEFLON™ coated baking pan can be used with some success. For instance, about 300 mL of a latex formulation in a 9 by 12 in. (23 to 30 cm) Pyrex™ baking dish will yield plenty of thick film for testing. Occasionally, there is a "mudcracking" problem, but it can be reduced periodically by releasing the edges of the film from the vertical sides of the dish with a spatula to allow uninhibited shrinkage. This way usually results in increased size pieces, and 1 in.^{2} (6.25 cm^2) is all you need for the moisture absorption or solvent swell test. Using this technique, it is possible to obtain large enough pieces for moisture vapor transmission tests at application thicknesses that are common for roof coatings.

The "mudcracking" problem is serious for any coating. The cause is the lack of "wet gel strength" to resist the tensile stresses within the shrinking membrane. Strictly speaking, unless the coating cross-links, it is not a gel, but simply a high-viscosity fluid or "pseudogel." The problem may be alleviated by assuring that the upper surface does not "skin over" through controlling the humidity or solvent-vapor environment over the drying surface.

The literature describes mercury pool casting [*7,8*] or tin foil casting [*9*] with mercury amalgamation used to remove the tin without stressing the coating film. ASTM D 4708 Practice for Preparation of Free Films of Organic Coatings also describes the tin foil amalgamation technique. These techniques are no longer in common use, as the mercury vapor is deemed a health hazard.

Rarely, but occasionally, a free film of a polymer or binder material is needed for testing water vapor permeation or absorption, for instance. Some of these tend to be tacky, and powder applied to the surface will make them easier to handle. Although pearl cornstarch is preferred over the powdered talcs, baby powders and similar talcum powders are often used.

Rotational casting is a means of obtaining nonporous, nonmudcracked free films. The standard jar-mill roller (see Fig. 2) may be used with a variety of open containers (quart or gallon jars, earless paint cans with a 4-in. (10-cm) circle cut out of the bottom, . . .) to centrifugally cast the film with good thickness control. An alternative device, the Caframo REAX 2

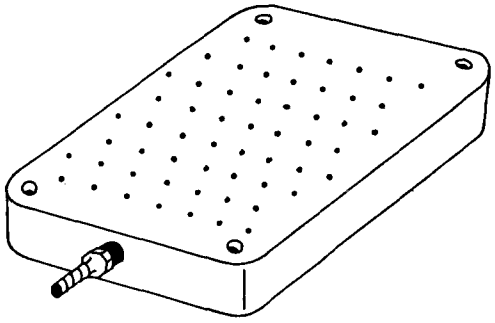

FIG. 1–*Vacuum plate*—pulling a vacuum through the side nozzle holds paper or paperboard substrates tight for drawdown film casting. (Courtesy P. N. Gardner Co.)

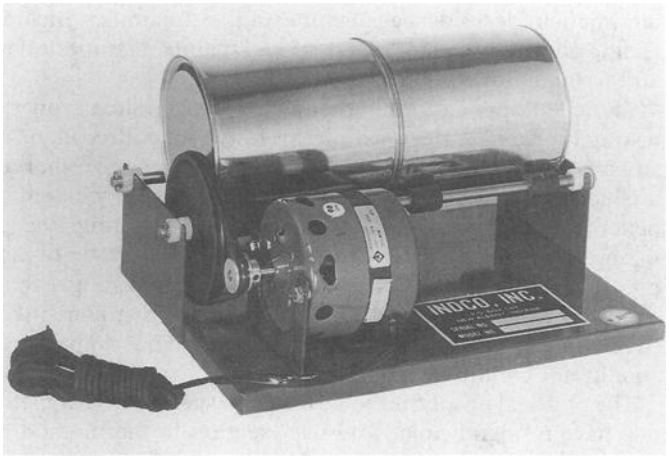

FIG. 2–*Lab roller mill*—Although this device is most often used for pebble milling, an empty earless paint can on the rollers may be used to cast films. (Courtesy of Indco Inc.)

rotating mixer [*10*], may be used to hold the paint can with its main axis along the rotation axis of the clamp (see Fig. 3).

This rotational casting technique was used successfully in a study by the Los Angeles Society for Coating Technology Technical Committee to obtain tensile and moisture vapor permeation film samples from acrylic latex compounded with silane modified talcs [*11*]. It is derived from an older practice at the Thiokol Rubber Co. to form films of castable elastomers in a rolling pipe [*12*].

Equipment for this technique is easy to set up and use. Introduce 100 mL of coating into a 1-gal can and let it roll overnight. This will result in a film approximately 6 by 18 in. (15 by 46 cm). That is a sufficient amount for 6-in. (15-cm) tensile bars and 2-in. (5-cm) permeation circles. Close control of film thickness is achieved by knowing the area of the cylinder and concentration. From these, the weight of coating needed can be calculated. Films of tacky coatings or pressure-sensitive adhesive formulations can be made by this technique. After the film is formed, the can is placed in a refrigerator or freezer to facilitate film removal.

To obtain a centrifugally cast powder coating film, a sample of the powder is introduced into the can. Then, a hot air gun is held at the outside of the rolling can, and the powder coating will melt to coat the inside. Care is needed to eliminate scorching, and practice is needed to determine how close the flame should be to the can to get a good film. Other techniques to obtain a film include melting on a Teflon™ sheet on a hot plate or in between Teflon sheets in a heated (Carver, PHI, . . .) press.

Spraying is occasionally used to make free films (e.g., onto a silicone-coated paper). There is no problem with this technique when it is done by a skilled practitioner. However, films made with this technique may not give as good permeation test results as from one made by a film from a fluid-flow technique.

A note of caution should be added about handling free films made for physical testing. Any undue stresses may chip or crack the film. This is especially important for permeation or physical property tests. In the case of the latter, some materials are "notch sensitive," that is, the results of a tensile or other physical test may be reduced by the presence of a notch, scratch, or crack in the film [*13*].

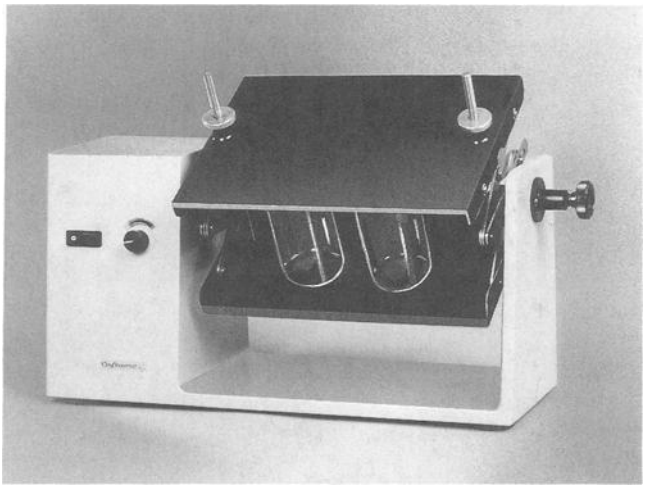

FIG. 3–*Caframo "REAX 2"*—This device was designed as a rotational mixer for fluids, but a gallon paint can will fit in it for rotational film casting, as well. (Courtesy of Caframo Ltd.)

Dry Coatings on Substrates

Test coatings on a substrate are generally applied for a wide variety of appearance and physical property tests. Color and opacity are commonly evaluated on coated paper charts, though unsealed paper charts with a porous surface are available, as well. Coating on substrates to simulate actual use is common so the paint lab has many kinds of steel, aluminum, wood, or other substrates in stock as needed by the customer or the paint company.

Plastic panels are rarer, but can be made available when needed. Several companies now offer such products. Plastic panels may need special surface preparation techniques to assure wetting and adhesion (solvent washes, chemical etchs with alkali or acid, low-temperature plasma, or corona discharge or chemical oxidation, etc.). As painting plastics become more and more important for automotive, computer, sign, and other industries, the manufacturers will make panels available to potential paint suppliers.

Panels of metal are a special case for the preparation of test films for paint. One may have to do a precoating surface preparation on the metal, and consultation with appropriate specifying agencies may be necessary. The Steel Structures Painting Council has many grades of hot-rolled steel preparation techniques that vary from wire brushing through sand blasting to expose "white metal" [*14*]. Other preparations such as phosphatizing, galvanizing, anodizing, etc., are unique to specific industries or industry segments and will require lab preparation of panels or freshly treated panels from the customer or a commercial source. An annual handbook contains descriptions of some of these techniques for lab usage [*15*]. Preordered steel panels that are subsequently stored in special corrosion-inhibitor-treated packaging may skew exposure tests if they are not rigorously cleaned of corrosion inhibitor just prior to the coating steps. Cleaning procedures may require rinsing with hydrocarbon solvent or acetone and hot-air drying just before paints are applied. Exposure panels made of metal must also have special edge protection to ensure that only the coated face has the exposure test applied.

The casting technique on a paper or paperboard substrate is a skill one learns through apprenticeship. First, the panel needs to be clean and dust free. For horizontal castings, which is a way to obtain good flat films, it is necessary to ensure that the surface is level during casting and drying. Tape the chart or panel to the level surface so it doesn't curl as the film loses solvent or dispersing media and tries to shrink. Unsealed paper charts will curl in a convex manner since any water in the coating swells the paper fibers, and the substrate may try to curl the sheet in a concave manner when the film tries to shrink across the top surface from which evaporation is taking place. Vacuum plates are available, as noted earlier, to hold down the paper, foil, or cardboard chart during the film-casting process. The paper board chart should be stored in the same humidity environment that will be used in drying/curing the coating as the wood-pulp fibers are hygroscopic.

Concrete, plaster, and asphalt/gravel test blocks or panels may be prepared in the lab or may be purchased. However, whenever possible such blocks should be obtained from the customer since paint-lab results may not compare well with the customer's results if details such as porosity, surface salinity, surface pH, soluble calcium or sodium ion content, etc., are not equivalent. These materials may be hygroscopic and will need equilibration in the drying/curing environment prior to coating. In addition, some concrete castings, that is, tilt-up wall constructions, often have surface residues of form coatings that had been used to aid release from the forms. Surface characterization for such release aids or rigorous cleaning may be needed. There is an ASTM standard practice for preparation of mortar panels for testing paints: ASTM Method of Making and Preparing Concrete and Masonry Panels for Testing Paint Finishes (D 1734).

Grenko [*3*] has described press coating of bitumens on aluminum or felts, with shims placed in the press to attain appropriate thickness. His work was based on earlier work by Greenfield [*16*].

Wet Films for Testing

There are a variety of reasons one may want to have a close look at the wet film. Simply watching the drying process may make any problems with moisture condensation on the film, pigment float, etc., apparent. There are test films made to assess wet hiding or sag resistance (ASTM D 4400: Test Methods for Sag Resistance of Paints Using a Multinotch Applicator). Good film casting practice, for example, a level surface for casting, consistent technique, etc., is a requirement for reproducibility of results. Equipment needed for special tests will be included in the following section.

EQUIPMENT FOR FILM PREPARATION

Drawdown Bars

The drawdown bars are the simplest of the film casting devices to use. One simply makes a puddle of coating on the desired substrate and moves the drawdown bar over the puddle to make the desired wet film thickness. Application of the film with a drawdown bar nominally gives a good continuous film, but the spacing between the bar and the substrate may have little to do with the film thickness obtained. Speed of pulling the drawdown bar over the fluid will affect the film thickness since fluid rheology influences film thickness. High-molecular-weight polymers may cause the edges of the film to draw in and increase the wet-film thickness. The formulation may not wet the drawdown bar, and this adds another factor to the control of film thickness. Wetz and coworkers [*17*] showed almost 100% deposition of the wet film and found a relationship between wet-film and dry-film thickness.

$$T_{df} = 0.057 + 0.588GS(\rho_l/\rho_f), \text{ or}$$

$$T_{df} = 0.057 + 0.955T_{wf}(\rho_l/\rho_f),$$

where:

T_{df} = dry film thickness, mils
T_{wf} = wet film thickness, mils
ρ_l = density of liquid
ρ_f = density of dry film
G = clearance of drawdown bar(mils), and
S = weight fraction of solids in liquid.

Grenko [*3*] makes the point that these relationships are only true for drawdown blades having substantial flat surface between the leading edge of the bar and the trailing edge. The Byk-Gardner information [*18*] suggests the following expectations for varying film thicknesses cast:

TABLE 1—Drawdown bars for film casting.

Type	Design Details	Supplier[a]	Reference
"Bird" knife	Permanent fixed gap	P. N. Gardner	[*3*]
Two-path applicator (Wasag [*11*])	Bar has two cuts of different depth machined into top and bottom	P. N. Gardner	[*20*]
Eight-path applicator	Stainless steel square tube with eight different depth cuts in each of top and bottom edges	P. N. Gardner	[*20*]
Gardner "Microm" applicator (also Hercules-Gardner adjustable [*3*])	Micrometers on each side lower or raise blade of "U" shaped deviced	P. N. Gardner	[*20*]
"Universal" blade applicator	Blade forms "U" shape with sides having slots and thumb screws to raise or lower	P. N. Gardner	[*20*]
Dow latex film applicator	"U" shaped blade with wider cut for larger gap so second cast film covers first	Byk-Gardner	[*3*]

[a]There may be many other suppliers, but only one is cited herein as a space savings technique.

15 to 100 μm	50%
100 to 300 μm	60%
300 to 500 μm	80%
over 500 μm	90%

The hand-held drawdown bars are covered in an ASTM specification: Method E in ASTM D 832, Practice for Rubber Conditioning for Low-Temperature Testing.

A wide variety of drawdown bars are commercially available, though your local machine shop can make special orders of any design, if needed. Table 1 lists a few of the available types of drawdown bars, with commercial sources reports on them. Some rectangular design devices have differing gap depths on the sides so one may choose the film thickness needed for casting (see Figs. 4 and 5).

Stainless steel or aluminum are the preferred materials of construction, as corrosion can damage the region of the drawbar controlling thickness of applied film. Good laboratory practice dictates immediate cleaning of the paint contact surfaces after every usage to minimize the threat of corrosion or other damage. A caution on marking the drawdown bars, as some manufacturers label them not with the gap spacing, but a number half the gap spacing since that is the expected wet film thickness to be obtained.

Some drawdown bars have film thickness adjustment choices by micrometers or other techniques (see Table 1 and Fig. 6). When these are used, the settings should be checked with feeler gages to make certain user wear has not made them inaccurate. These also require dismantling and cleaning after every use. If oil is used to inhibit corrosion and make the mechanics move smoothly, make sure they are rigorously cleaned of oil prior to usage.

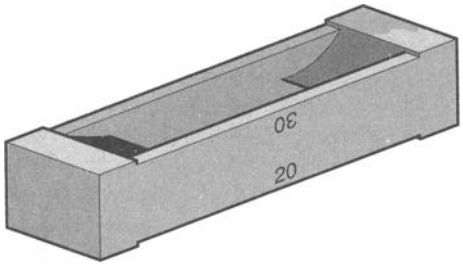

FIG. 4–*Applicator frame/step gap applicator*—Two film thickness choices are available with this device. (Courtesy of Byk-Gardner Inc.)

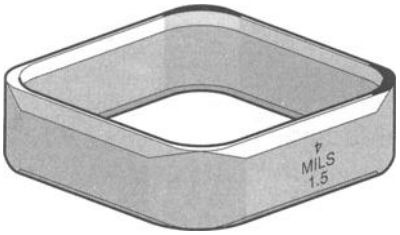

FIG. 5–*Multiple clearance applicator*—Eight film thickness choices are available on one device. (Courtesy of Byk-Gardner Inc.)

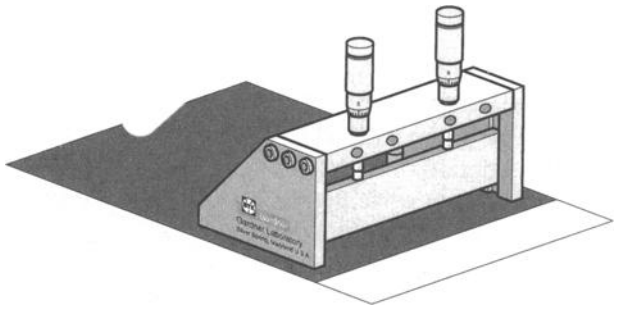

FIG. 6–*Film casting knife*—Micrometers adjust the blade clearance. (Courtesy of Byk-Gardner Inc.)

Several drawdown bars have gradations of cuts into the wet-film thickness controlling surfaces. For instance, the Erichsen suppliers offer the Kruse Multi Clearance applicator, having six to ten adjacent film strips of 10 to 200 μm in thickness for assessment of color yield, opacity, . . . (see Fig. 7) [*19*]. A similar device, the Leneta TG19 Logicator, is intended for hiding power and spreading rate measurements. It is available from P. N. Gardner [*20*] and has eight "gates" ranging from 2.65 to 10.4 mil in depth.

There are motorized film application devices specified in ASTM D 823, Test Methods for Producing Films of Uniform Thickness of Paint, Varnish, and Related Products on Test Panels, as Method C. The Model 509/1 Film Applicator from Erichsen [*19*] may be fitted with any sort of drawdown bar or blade (see Fig. 8). Speed of the motion of the applicator may be preset, so the variation among several samples may be minimized.

Two devices Grenko [*3*] included with drawdown bars are more like bulk coating devices as they do not require putting down a puddle of coating before applying the blade. Indeed, these devices contain the coating and apply it to a stack of

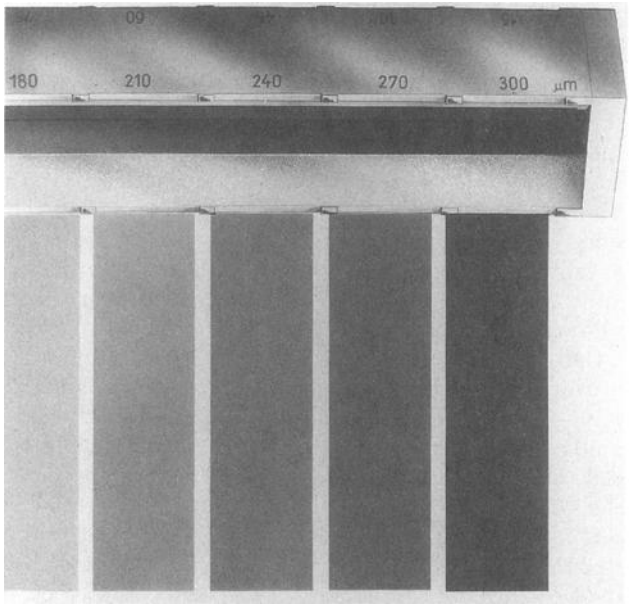

FIG. 7–*Multiple gap drawdown bar*—Six or eight gaps are machined along the same edge for casting side-by-side films for comparison. (Courtesy of Erichsen GMBH & Co.)

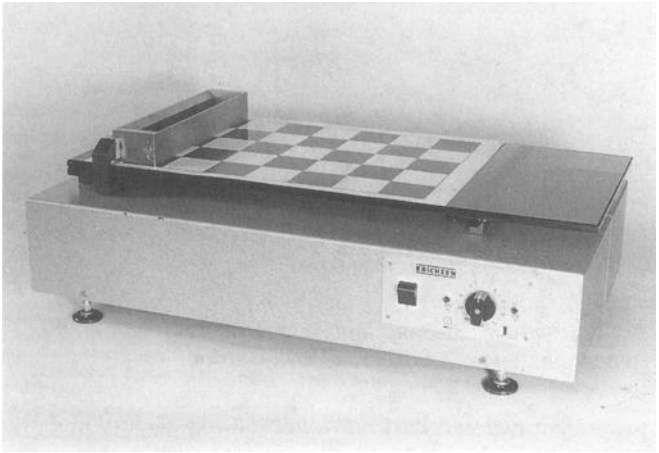

FIG. 8–*Electrically driven drawdown device*—Four speeds may be chosen to control drawdown rate. (Courtesy of Erichsen GMBH & Co.)

sheets, one sheet at a time as the sheets are pulled out from underneath the device. One such device is the Parks Film-O-Graph cylinder. One puts the cylinder on a stack of Leneta charts or metal panels, fills the cylinder with the coating, and pulls each sheet from underneath the cylinder. A portion of the rim edge of the cylinder is milled out to act as the gate to allow coating at a desired thickness. One may even use it for very viscous coatings (even putty) by forcing the fluid through the tube with a loose-fitting plug from the top and wiping the bottom of the tube over the substrate to be coated.

The second of the devices discussed was the Parks Rapid coater. Paper sheets were stacked in the bottom of a box with their ends out of a side slot at the bottom. The box was then filled with coating fluid, and each sheet was withdrawn individually. Grenko [*3*] noted this was not a precision device, but it was adequate for some purposes.

Grenko [*3*] also described the flat Parks Film-O-Graph, which used a flat plate with spring clips to hold shims along the sides of the sheet of substrate. One poured the coating onto the substrate between the shims and used a bar such as a ruler or other straight edge to doctor off the excess and make the coating as thick as the shims. Bending of the scraper bar by the very slightest amount would make very thin films almost impossible, but for thick films (for example, roof coatings), this technique worked well.

Some applicators are meant only for the wet film tests. Two especially useful applicators for these are the sag test devices and the wet hiding test devices. The latter, most frequently the Pfund Cryptometers (available from Erichsen [*19*] and Byk-Gardner [*20*]), have black or white glass (ceramic) beds over which a transparent wedged cover levels the coating film (see Fig. 9). Although these devices are quite hard, care in cleaning will assure they do not get scratched. They must be stored carefully, wrapped, and covered.

The sag test film casters essentially drawdown several narrow films in gradations of film thickness. Many are simply slotted U-shaped drawdown bars with variations in slot depth from 1 to 6 mil, 3 to 12 mil, and 14 to 60 mil. However, the New York Paint Club Technical Committee designed a special "leveling test blade" that had double slots for each depth

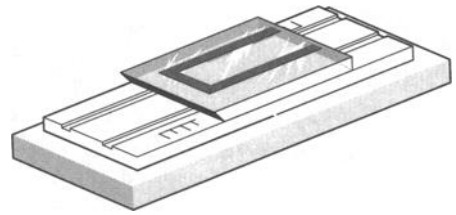

FIG. 9–*Pfund crytometer*—The white style shown is for black/dark paints, while a similar black style is used for white/light paints. (Courtesy of Byk-Gardner Inc.)

with a wide space between each set of double slots [*21*]. Their slots are 1, 2, 4, 8 and 16 mil in depth (see Fig. 10).

As paint film drip or sag depends on the rheological characteristics, the thickness of the coating that first sags may be related to the gravity-applied shear stress by the outer elements furthest away from the substrate on that film. Other rheological factors (high shear viscosity, ca. 10 000 s^{-1}, for instance) are also important in sag and leveling. Sag test devices complying with ASTM D 3730, Guide for Testing High-Performance Interior Architectural Wall Coatings, and several federal specifications and the New York leveling test blades are available from P. N. Gardner [*20*] and Byk-Gardner [*18*].

Wire-Wound Rods

For very thin films, the wire-wound rods are quite useful for quickly and easily applying films. The wire-wound rods are simple rods of 12 or 16-in. (30 to 40-cm) length, of ¼, ⅜, or ½ in. (0.63, 0.45, or 1.27 cm) diameter, with a sprial wind of wire tight about 75 to 80% of the rod. Table 2 shows a selection of wet film thicknesses obtained from the rods with different wire diameter.

The film laid down with a wire-wound rod is almost exactly a tenth the thickness of the wire winding. Strictly speaking, as the film has the rod depart, there are ridges in the film in the direction of travel of the rod. However, these collapse to make a quite smooth film unless there is rheological inhibition in the formulation or the coating is very fast drying. This technique is quite effective to simulate paper or can coating end products. There are industrial production systems that em-

ploy wire-wound rods to meter coatings onto roll substrates, as well.

A similar device called the "spiral-film applicator" is available from Erichsen [*19*]. It is a wire-wound rod with a perpendicular handle (see Fig. 11). It is available to apply film thicknesses from 10 to 200 μm in widths of 80, 150, or 220 mm. Byk-Gardner offers a handle that attaches to the ends of the wire-wound rod for lab film preparation as well [*18*]. The Accu-Lab™ Lab Drawdown Machine has a rod holder and substrate holder to assure precision in laboratory manual film preparation [*22*].

There are also two-wire rods in which a second, smaller wire is wound in the grooves made by the first winding wire. These yield higher application rates than do the single-wound wire rods. There is potentially an advantage to the two-wire rods since they leave a different pattern in the coating. The ridges left are larger and may level faster and uniformly.

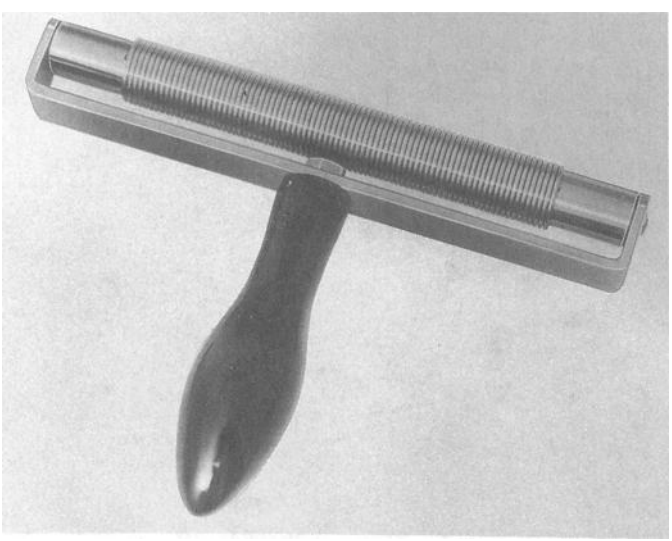

FIG. 11—***Spiral wire drawdown applicator***—**The handle shown grips the end of the wire-wound rod for application with one hand. (Courtesy of Erichsen GMBH & Co.)**

Spray Outs

Spray application, including by weight on a panel hanging on a balance in a spray booth, can be done with good precision. Good spray out application on panels can be done by those skilled in the art. To control the weight applied in a spray booth, a triple beam balance may be attached to a beam 5 or 6 ft. (1.5 or 1.8 m) above the floor, and a hanger-wire panel holder is hung from it as the spray target. A cardboard shield over the balance will keep off overspray. Tare the balance and preset weight needed to apply. Take off a few tenths of a gram to give a pointer indicator warning when the spray has almost reached the desired weight. Spray quickly to minimize evaporation.

There are automated spray devices. Grenko [*3*] related the automated spray device design from Bell Labs [*23*] to Method A of ASTM D 823. The Bell Labs design has the gun travel over stationary panels, while an alternative design has the panels on a moving belt under a stationary spray gun, similar to a design reported from Battelle [*24*]. In either case, the amount of coating applied to the panel is controlled by the speed of the moving belt and by nonvolatile content of the sprayed fluid. Grenko [*3*] notes the sample panels on the moving belt may be held to the belt with magnets or suction cups. Erichsen [*19*], Gardner [*20*], and others offer automated spray applicators for lab sample preparation (see Figs. 12 and 13).

The spray technique is particularly important, but precautions are necessary to assure evenness of coating on the substrate. The spray pattern should extend beyond the edges of the substrate when the nozzle is aimed at the center of the target. The spray pattern—be it flat, fan, or circular—has less paint at the edges than at the center. Moving the spray nozzle across the target or the target under the center of the nozzle makes the deposition more likely to be consistent in thickness.

Dip Coating

Dip coating is particularly important in some special cases. For instance, the edge protection of corrodible panels in preparation for the application of a test coating is a common practice. The Golden Gate Society for Coatings Technology Technical Committee use a red lead vinyl ½-in. (1.27-cm) dip for edge protection of their exposure panels quite successfully, as attack corroded only the desired exposure surfaces [*25*]. The point is that dipping assures film thickness without holidays that other techniques do not. This is particularly true for odd-shaped test specimens such as fragments of a pressurized gas cylinder in an unpublished Mellon Institute corrosion study.

Grenko [*3*] briefly reviewed two-dip coaters. Bruins [*26*] first designed one using a tire pump and needle valve to control the rate of panel withdrawal from the coating, while Payne designed an electric motor-driven device adopted for ASTM D 823 Method B. A commercial lab device is available from P. N. Gardner [*20*], with variable withdrawal speeds at 2 to 20 in. (5 to 50 cm) per minute. It can dip a panel of up to 2 lb (0.9 kg) and 1 ft^2 (0.3 m) in area (12 by 12 in. (3.65 by 3.65 cm).

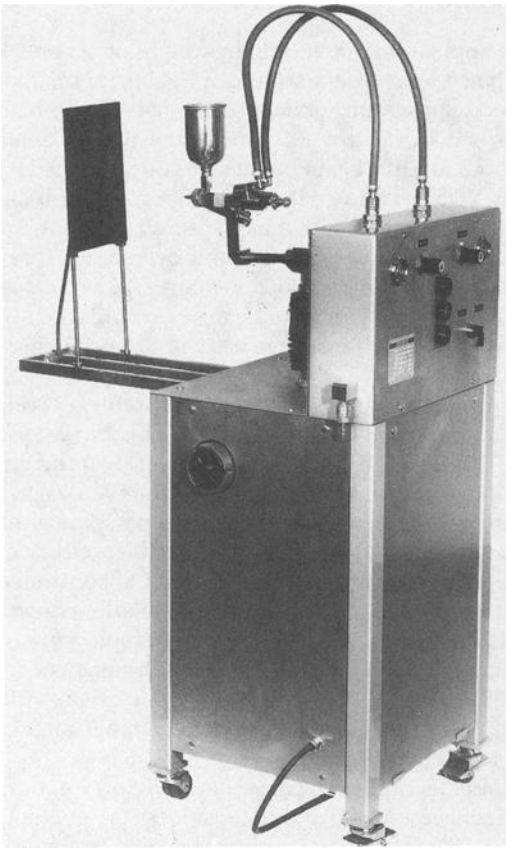

FIG. 12–*Single setting lab spray applicator.* (Courtesy of Erichsen GMBH & Co.)

FIG. 13–*Programmable lab spray applicator.* (Courtesy of Erichsen GMBH & Co.)

Again, care must be taken while dip coating. Film thickness control is a battle between wetting surface forces and the shear forces of drainage through the thickness of the film. Drip edges on the bottom edge may be avoided to some degree by having the panel holder inverted to hold the bottom edge upward for a portion (or intermittent portions) of the drying period.

Spin Coating

Grenko [*3*] described the work of Walker and Thompson [*27*] attaching a panel to a turntable and rotating for 1 min at 300 rpm to obtain a 25-μm varnish film thickness. He also described the Sward-Gardner [*28*] relation of film thickness (F) to viscosity (V, in poise) and nonvolatiles, % N, as

$$F = 0.4N + V^4 + 3$$

where spin rate was 290 rpm for 60 s. Their work had a precision of 5 to 10%, and corrections for time or rpm variations were offered. Parker and Siddle [*29*] suggested modifying the method by adjusting viscosity to equivalence for all fluids to be compared and using volume solids rather than weight percent nonvolatiles. Plots of film thickness versus volume percent nonvolatile were straight lines for non-thixotropic fluids, but curvature existed for thixotropic fluids.

A commercial lab spin coating device is currently available from Erichsen [*19*]. There are two versions, one with 600 rpm speed set, and another adjustable from 50 to 2000 rpm (see Fig. 14).

OTHER TIPS ON PRACTICE OF THE ART

Dust is always a problem, especially in formulation labs that have pigment dusting in the lab and plant. Cover cast

FIG. 14–*Lab spin coating device.* (Courtesy of Erichsen GMBH & Co.)

films immediately to keep the dust off. The easiest cover is the top of a box from a typewriter paper or file folder shipment container. Simply cut out ½ in. (or 1 cm) strip from two, three, or four sides for free flow of air. Of course, a similar cover can be made from this plywood. Keep the cover on top of the lab refrigerator or book shelf so it's always at hand.

Make sure the film is drying under appropriate temperature and humidity conditions. Something in the formulation may respond in an adverse manner to condensing moisture that can form droplets on the surface as evaporating solvent rapidly cools the system. In moisture-cure and reactive two-package urethanes, the condensing moisture may react with the isocyanates to modify degree of cure, which can reduce strength, solvent resistance, etc. In systems that do not react with the condensing water, one may still get pits, pinholes, or haziness from the condensing water droplets on the surface. Paint applicators are learning to pay attention to humidity variation and its effects on the end product surface.

CONCLUSION

How the film is prepared for testing can have a dramatic effect on the test results. The thought put into film preparation prior to preparation and the care used in casting can be crucial factors in obtaining meaningful and reproducible results.

Measurement of Film Thickness

by C. M. Wenzler[1] and J. F. Fletcher[1]

ONE OF THE MAJOR REQUIREMENTS OF PAINT and coating testing is the measurement and control of film thickness. Ensuring that a specification is achieved is important in laboratory tests, paint application, automatic spraying, and other coating application methods.

A number of test methods are available, and the choice is dependent on: (1) the location—laboratory or site; (2) the material coated—metal (ferrous or nonferrous), wood, plaster, brick and plastic; (3) the condition of the coating—wet or dry; and (4) the condition of the surface—rough or smooth, flat or shaped, thick or thin, etc.

WET FILM THICKNESS

The measurement of wet film thickness provides the first opportunity to check the coating and its application process. It also offers an assessment of the spreading rate when a paint is applied. It is very important that wet film measurements are made as soon as the coating is applied to avoid error due to solvent loss during the curing process.

Reference to the technical data for volume solids in the coating is required to establish the wet and dry ratio so that wet film thickness values can be converted to dry film equivalents. In most cases wet film thickness gages can be cleaned with solvents and reused.

ASTM Test Methods for Measurement of Wet Film Thickness of Organic Coatings (D 1212) standardizes the Inmont wet film gage (formally known as Interchemical and commonly known as the wet film wheel) and the Pfund wet film gage. These two gages are detailed in the following sections, and two nonstandardized methods are also described.

Inmont Wet Film Gage (Wet Film Wheel)

The Inmont wet film gage consists of two concentric outer disks with an inner eccentric disk with a smaller diameter positioned between them as shown in Fig. 1. The outer disks are scaled, with the clearance between the inner disk and the outer disk from zero to a maximum value as shown.

The gate is used as follows. The disks are placed with the maximum clearance on the specimen of coating and rolled toward the minimum clearance in either direction. The paint will coat the inner disk until the clearance is greater than the wet film thickness. The point at which the coating stops on the inner wheel is referenced to the scale on the outer wheel and the value noted.

Starting from maximum value avoids the possibility of pushing paint ahead of the inner disk, creating an error condition when the gage indicates a value higher than the true wet film thickness.

A number of ranges are available.

Pfund Wet Film Gage

As shown in Fig. 2, this gage consists of a convex lens, L, whose radius of curvature is 250 mm, at the lower end of tube T1 that slides in the outer tube T2. Compression springs, S, keep the lens out of contact with the paint film until pressure is applied on tube T1. In making a measurement, the gage is placed on the painted surface and the lens is pushed slowly through the film until stopped by the substrate. The pressure is released, and the diameter of the spot of paint transferred to the lens is measured. A 1 to 1 ratio for the thickness added by the paint displaced by the lens to the actual thickness has been assumed and is accounted for in the equation

$$t = D^2/16R \tag{1}$$

where

D = diameter, mm, of spot, and
R = radius of curvature, mm, of the lens.

Table 1 gives film thickness and the corresponding spreading rate in square feet per gallon for spots from 3 to 38 mm in diameter.

It has been observed that a substantial proportion of paints do not obey the 1 to 1 relationship. The actual thickness, obtained by independent methods, may be several times, or only a fraction of, the thickness calculated by the equation. A small amount of thinner added to a paint may increase the diameter of the spot on the lens and give a corresponding increase in the calculated thickness. This phenomenon has been ascribed to the effects of surface tension. Hence, for best results, a correction factor should be established for each type of paint based on the known thickness of a freshly prepared film measured by the Inmont gage.

Reproducibility is within about 2% for films 2 mils (50 μm) thick, decreasing to about 10% for films 5 mils (125 μm) thick, then becoming better as thickness increases.

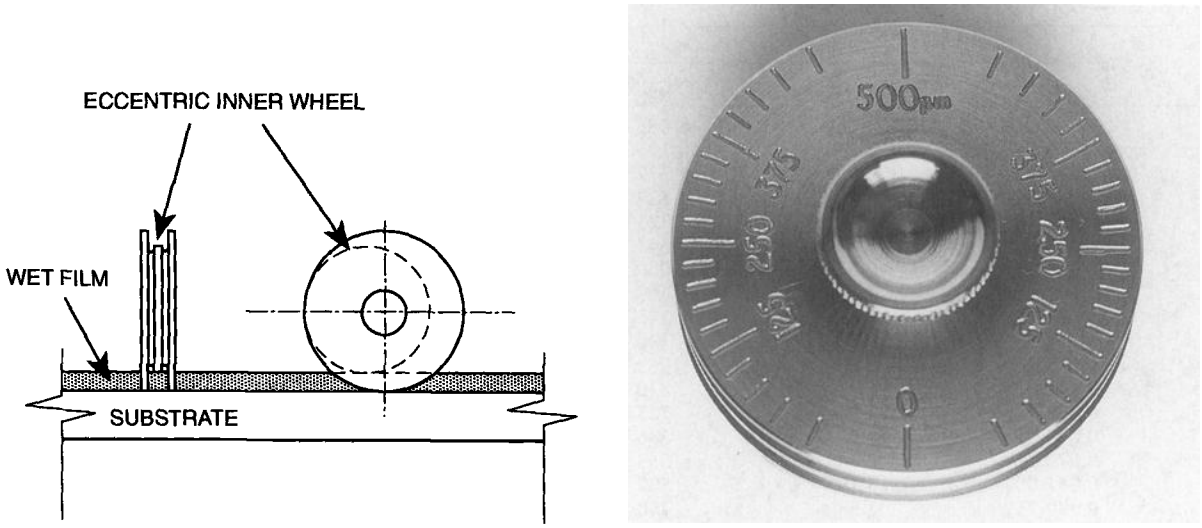

FIG. 1–Inmont gage (Interchemical) wet film wheel *(left)* and 120 photo *(right)*.

Notch Gages (Wet Film Comb)

Notch gages are formed on the edge of a piece of material so that each notch has a different clearance from the reference shoulders to its neighbors (Fig. 3). Many different materials are used, such as stainless steel, aluminum, and plastic in a variety of shapes: square, rectangle, triangle, hexagon, etc. It should be noted that combs made of aluminum are known to wear on rough surfaces. It is a simple low-cost device which is useful when approximate values are satisfactory as the notches have discreet values and are not continuous. The gage is dipped vertically into the film until the reference shoulders are resting firmly on the substrate. The thickness of the film is between the highest coated notch face and the next highest notch value.

Several different methods of manufacture of these gages exist from spark-eroded stainless steel precision combs, through punched aluminum sheet, to plastic flow molded combs. The stainless steel combs can be certified with measurements of the tooth displacements, which are traceable to national standards. As the stainless steel is hard wearing, this certificate can be valid over a period of up to one year. On the other hand, plastic combs, although manufactured from solvent-resistant ABS plastic, should only be used once as the solvent in the coating may soften the plastic. Plastic combs can be tagged and kept as a permanent record of wet film measurement.

Aluminum combs are prone to wear, and the condition of the gage should be monitored before use.

Gages are available in many ranges, from 0.5 mil (2.5 μm) to 160 mils (4 mm/4000 μm) (for high-build, low-solvent-content coatings). The teeth are normally square ended, but for thicker coatings pointed teeth are often used.

Notch gages are supplied by various coating equipment suppliers, e.g., Nordson, Elcometer Inc. and are described in ASTM Practice for Measurement of Wet Film Thickness of Organic Coatings by Notched Gages (D 4414).

Needle Micrometer

This method was used to study the relationship between the clearance of a doctor blade and the thickness of the wet film left by the blade [*1*]. A needle is attached vertically to the objective holder of a microscope. The barrel is lowered until the needle just touches the film that has been spread on a plain metal panel. The contact is observed through a horizon-

tal microscope (Fig. 4). When contact is made, the needle and its image reflected by the film just meet. The needle is then lowered into the film until it just touches the metal panel. This contact is noted by the deflection of a galvanometer in series with the panel, a dry cell, and the needle. The thickness of the film is calculated from the number of turns made by the focusing screw of the vertical microscope between the two points of contact.

It should be noted that this technique is only applicable to measurements made in a laboratory as it is impractical for work on site.

DRY FILM THICKNESS (DESTRUCTIVE METHODS)

As there are many circumstances under which coatings and paints are used, no single method of dry film thickness measurement is universal. Some methods are destructive, and these are most often used when nondestructive methods are not applicable. The nondestructive methods are limited to coatings on metals.

Micrometers and Dial Gages

When a chip or flake of coating is freed from the surface of the coated object, its thickness can be measured directly using a micrometer. Alternatively, the total thickness of the substrate and coating can be measured; the substrate can then be remeasured after removing the coating with a scraper or solvent. The coating thickness is then the difference between the two measurements.

ASTM Test Method for Measurement of Dry-Film Thickness of Organic Coatings (D 1005) details a preferred procedure using a dial micrometer mounted on a support with a clamp to hold the specimen (see Fig. 4). This method is recommended only for thicknesses over 0.5 mil and is accurate ±0.1 mil.

A hand-held dial gage, the Elcometer Model 126 (Fig. 5), may be used. In this case the dial records the difference in position between the foot that sits on the surface of the coating and the stylus with its ball end, which passes through a hole prepared in the coating to the surface of the substrate. This is particularly useful for site work. However, for best accuracy and precision, the firmly mounted dial gage specified in ASTM Method D 1005 is preferred.

Gardner Needle Thickness Gage

This instrument is designed to measure the thickness of electrically nonconducting films on metal (conducting) substrates. It is small enough to be used in the field where the substrate can be made part of the electric circuit. The needle makes only a minute puncture in the film. In many instances, particularly in a go no-go determination, the damage is so slight that the method may be considered nondestructive for many end users.

The case aluminum housing contains the needle screws for forcing the needle through the film and a lamp to signal when the needle contacts the substrate. For use in the field and for occasional use in the laboratory, the electric circuit comprises the needle, the substrate, a dry cell, the lamp, and a cord that connects with the substrate. In the laboratory, if many measurements are to be made, it is advisable to use a step-down transformer and to connect to a 110-V source.

The thickness is read on a dial attached to the screw. One turn of the dial raises or lowers the needle by 2 mils. The dial is graduated in steps of 0.05 mil. Range is 0 to 15 mils.

The zero setting of the needle is obtained by retracting the needle within the housing, placing the gage on a plane metal block, and lowering the needle until the lamp signals contact. The block is replaced by the specimen, and the needle is lowered until the lamp again signals contact. The difference between the two readings is the thickness of the film.

Gardner Carboloy Drill Thickness Gage

In many instances films are so hard that they successfully resist penetration by the needle penetrometer described above. This difficulty has been overcome by substituting a Carboloy drill for the needle. The drill is a needle terminating in a pyramid having three faces. The drill is secured in a chuck that can be rotated and advanced independently. The rotation is controlled by finger action on a knob at the upper end of the chuck shaft. In all other respects, the operation is the same as that of the needle gage.

This method has been standardized by ASTM as Procedure B in Test Method for Measurement of Dry Film Thickness of Non-metallic Coatings of Paint, Varnish, Lacquer, and Related Products Applied on a Non-magnetic Base (D 1400).

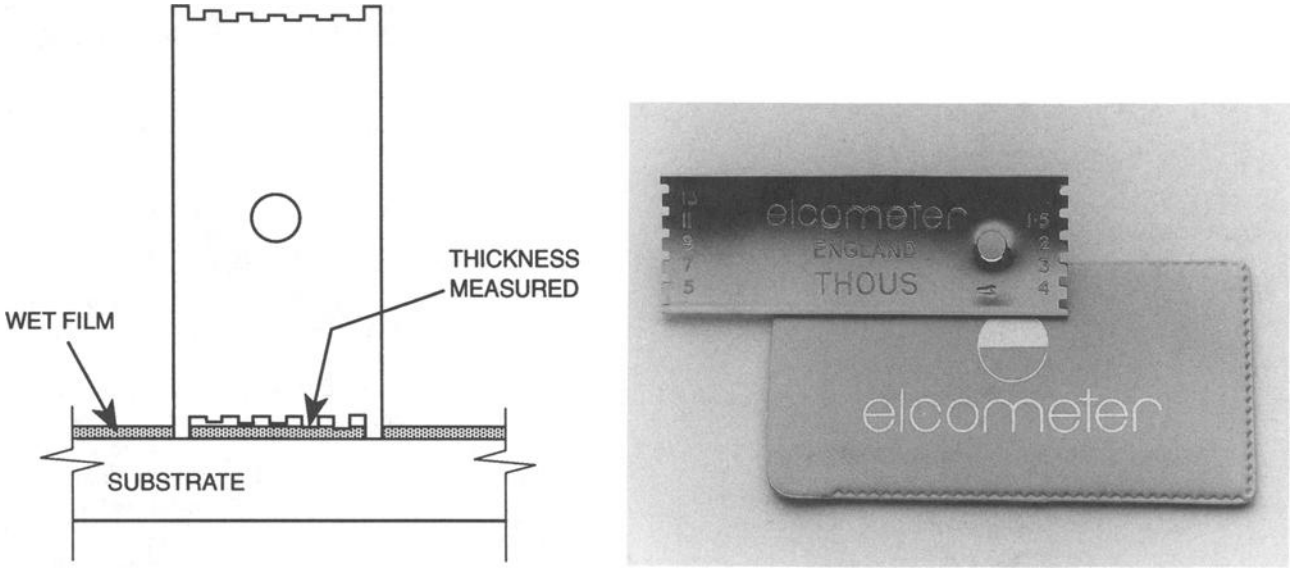

FIG. 3–Wet film comb 115 and photo.

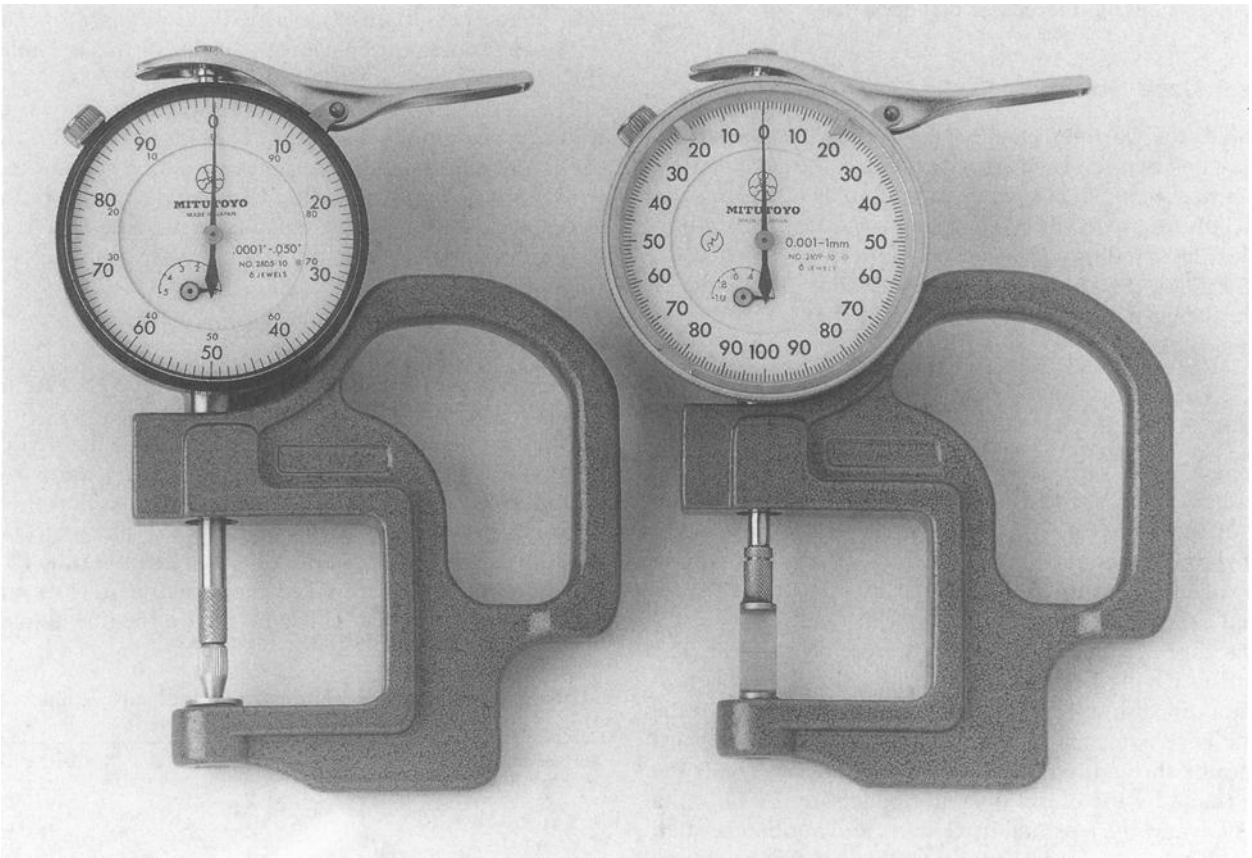

FIG. 4–Dial micrometer.

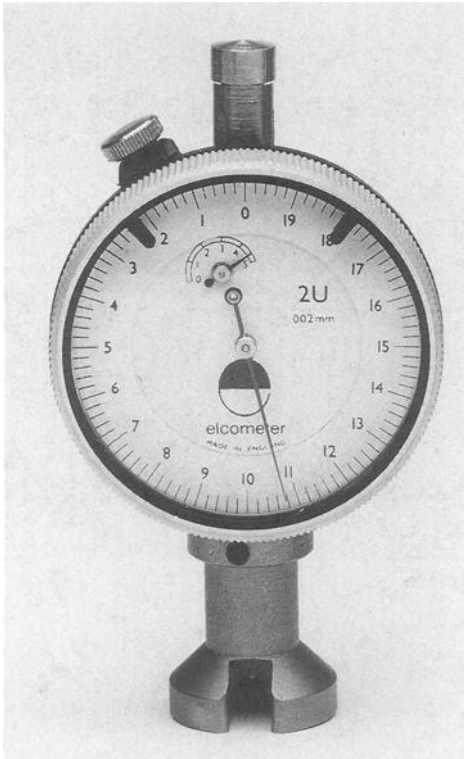

FIG. 5–Elcometer dial gage 126.

Gardner Gage Stand

Although the Gardner needle gage and the Carboloy drill gage may be operated by manually holding the gage against the specimen, using the Gardner gage stand is less tiring and more accurate, especially when many measurements are to be made. The stand provides constant known pressure [up to 10 lb (5 kg)] on the specimen and ensures that the needle or drill are always perpendicular to the specimen.

Gardner Micro-Depth Gage

Although in outward appearance this gage resembles the gages described in the last two subsections, only the establishing of the zero setting is the same. Measurement is not restricted to nonmetallic films on metal—any type of film on any type of substrate may be measured, and the film is always damaged.

In this gage, a chisel replaces the needle of the gage. The zero setting having been established, the chisel is advanced by an amount estimated to be less than the thickness of the film. The gage is placed on the specimen and drawn toward the operator through a distance of a few millimetres. If the scratch made by the chisel does not penetrate the film, the chisel is advanced by a small increment, and another scratch is made. The procedure is repeated until the substrate is reached and exposed. Inspection is best made with the aid of a low-power magnifier. The range is 0 to 40 mils (1000 μm). Repeatability depends on the magnitudes of the increments and the compressibility of the film and substrate. For example, specimens with poor adhesion may be torn off, exposing the base, even if the chisel does not penetrate the film.

Microscope for Film Thickness

Classical Method

To use a microscope to assess film thickness, a section is prepared and the width of the coating is measured using a graticule in the eyepiece of the microscope. For an approximate assessment, a flake of the coating can be used, but for best results from this method the specimen should be prepared as follows.

The specimen is mounted in a block of wax. The face of the mount is cut or ground to a smooth surface. The prepared specimen is then inspected under the microscope. ASTM Method for Microscopic Measurement of Dry Film Thickness of Coatings on Wood Products (D 2691-88) is based on this method; however, as paints are often hard and brittle, a grinding and polishing method is preferred to the blade method indicated in D 2691.

Brightwell Method [2]

This method does not require removal of a chip and elaborate mounting and preparation. A tiny furrow is made in the film or a small chip is removed. A prism or ribbon of light is projected on the selected area at an angle of 45°. The distortion of the beam is examined with a microscope equipped with a micrometer eyepiece. Apparatus for this is available in the Schmaltz optical surface analyzer (Carl Zeiss).

The apparatus is calibrated by measuring known depths milled in a smooth metal block. The ribbon of light is focused on line A, and the filar micrometer reading is recorded. The procedure is repeated on line BC. The difference multiplied by the calibration factor equals the thickness of the film. Table 2 compares results by this method with results with a micrometer.

Stopped Method [3]

A cut is made in the film with a sharp knife. The microscope is focused, in turn, on the upper and lower edges of the cut. The thickness of the film is computed from the vertical adjustments of the microscope. If the value is not known, it may be found as follows: Put a piece of plate glass on the stage. Lower the tube until it just touches the plate. Record the reading of the fine adjustment. Now raise the tube as far as possible and again record the fine adjustment. Now raise the tube as far as possible and again record the fine adjustment.

TABLE 2—Film thickness (mils) by optical surface analyzer and dial micrometer (Brightwell).

Surface Analyzer	Dial Micrometer
0.39	0.4
0.46	0.5
0.71	0.8
0.98	1.0
1.30	1.3
1.51	1.4
2.28	2.1
3.58	3.5

The distance of the tube from the plate divided by the number of turns of the adjusting screw gives the value for each turn.

Tooke Inspection Gage (Paint Inspection Gage P.I.G.) [4]

This gage (shown in Fig. 6) provides for estimating the thickness of a film from the geometry of a V-groove cut in the film by a special tool. With the aid of a ×50 illuminated magnifier equipped with a reticle in the eyepiece, the operator measures the lateral distance from the top edge of the cut and the projection of the intersection of the cut and the substrate. To make a measurement, a "bench mark" of ink applied to the surface of the film serves to make the top edge of the cut readily visible. A short cut is then made at a right angle to the bench mark with the selected cutting tip. Film thickness is then obtained by counting the scale divisions as described previously.

The relationship among the tips is summarized in Table 3.

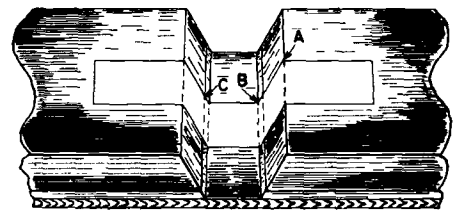

FIG. 6–Groove in paint film.

TABLE 3—Tooke inspection gage tip specifications.

Tip	Maximum Coating Thickness, mils	Precision of Thickness Determination Represents, mils	One Division on Reticle Scale, mils
×1	50	±0.25	1.0
×2	20	±0.13	0.5
×10	3	±0.025	0.1

Saberg Drill

This method is similar to the Tooke inspection gage described in the previous subsection; however, a circular drill is used to penetrate the film. The hole can then be inspected using the ×50 magnifier with graticule, and the width of the cut from the outer edge to the print where the drill penetrates to the substrate is a measure of the coating thickness. For the instrument kit supplied by Elcometer Inc., Rochester Hills, MI 48309 (Model 195), the calculation of coating thickness is as follows:

1. For measurement in mils, multiply graduations by 0.79.
2. For measurement in micrometers, multiply graduations by 20.0.
3. This method is now described in ASTM Test Method for Measurement of Dry Film Thickness of Protective Coating Systems by Destructive Means (D 4138).

DRY FILM THICKNESS (NONDESTRUCTIVE METHODS)

Permanent Magnet Thickness Gages

Permanent magnet coating thickness gages can be used to determine the thickness of films applied to magnetic substrates such as steel, iron, magnetic stainless steel, etc., providing that the coating is nonmagnetic. Materials such as nickel and cobalt, that are naturally magnetic have to be treated with care, while paints containing magnetic particles, such as some ferrous micaceous iron oxide (MIO), can cause errors when using magnetic gages.

Simple magnetic coating thickness gages or mechanical gages use the principle that the attractive force between a permanent magnet and the magnetic metal substrate is inversely proportional to the distance between them.

The principal limitations are (1) the film must be sufficiently hard to prevent indentation, and (2) the film must not be tacky causing the magnet to be held by the surface of the coating.

Electronic magnetic coating thickness gages are also available, but these will be described in a separate section entitled **Electromagnetic Thickness Gages;** however, this section does include the electronic gage based on the magneto-resistor probe.

Magne-Gage [5]

This instrument (Fig. 7) consists of a small permanent bar magnet, 2 mm in diameter, suspended from a horizontal lever arm. The arm is actuated through a spiral spring by turning a dial. The tip of the magnet is brought into contact with the paint film (on iron or steel), and the dial is then turned until the magnet is detached. The attractive force between the magnet and the film support is indicated on the dial, and the thickness of the nonmagnetic paint film is obtained from a calibration curve relating thickness to dial reading.

The gage can be used to measure coatings on convex and concave surfaces as well as on flat ones provided the radius of the curvature is not too small. Unless special calibrations are made, cylinders should not be less than ½ in. (1.27 cm) in diameter, spheres not less than ¾ in. (1.9 cm), and flat pieces should be at least ¾ in. (1.9 cm) square.

Magnets for thicknesses in the following ranges are available: 0.0 to 0.002, 0.002 to 0.007, and 0.007 to 0.025 in.

ASTM Method for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Organic Coatings Applied to a Ferrous Base (D 1186) has standardized the operation on the magne gage.

Hand-Held Magnetic Gages

These gages are being superseded by electronic gages, and some—such as the Tinsley gage and the chemigage—are no longer manufactured. However, many thousands of these types are still in use, so it is appropriate to describe them.

The simplest form of these gages contains a magnet suspended from a coil spring housed in a pen-style body manufactured from aluminum or plastic. A scale is drawn on the body and a marker used to indicate the extension of the spring on the scale. The reading on the scale when the magnet lifts off the surface corresponds to the thickness of the coating.

The scale on these instruments is nonlinear, leading to poor resolution at the maximum range, usually 20 mils (500 μm),

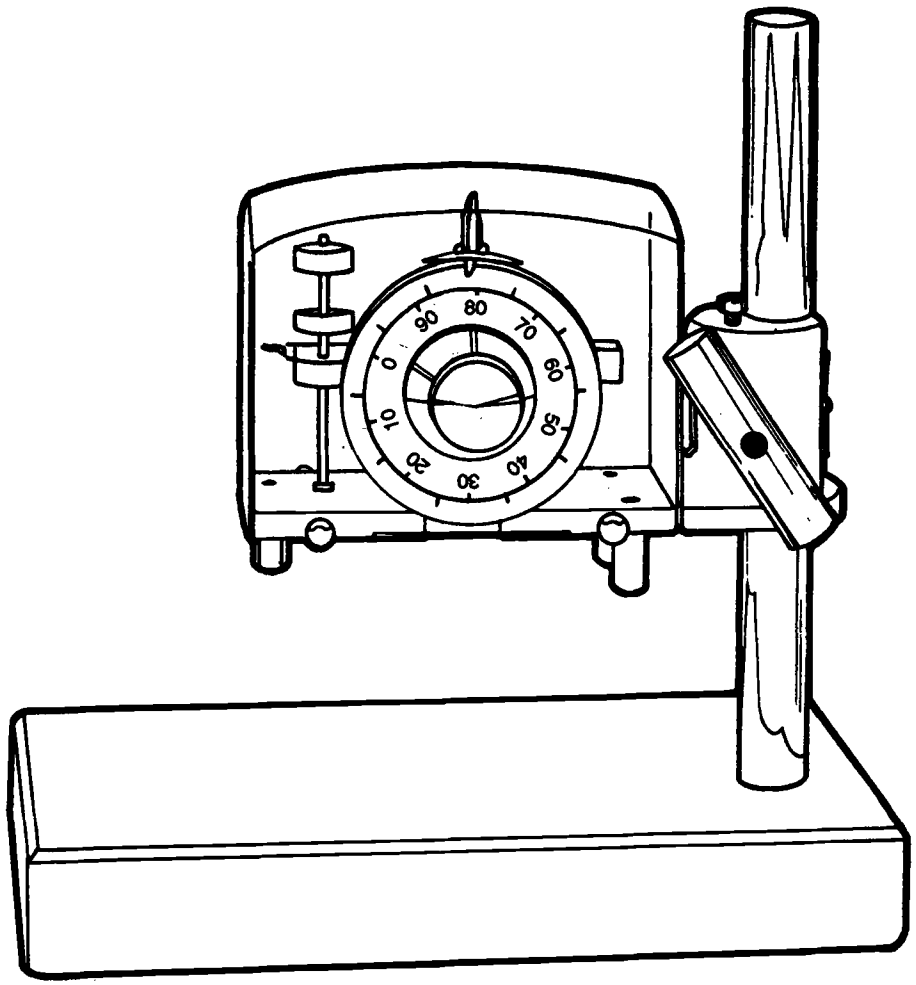

FIG. 7–Magne gage (courtesy of American Instrument Co.).

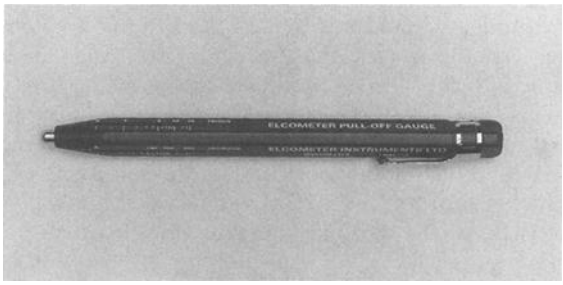

FIG. 8–Elcometer pull off gage 157.

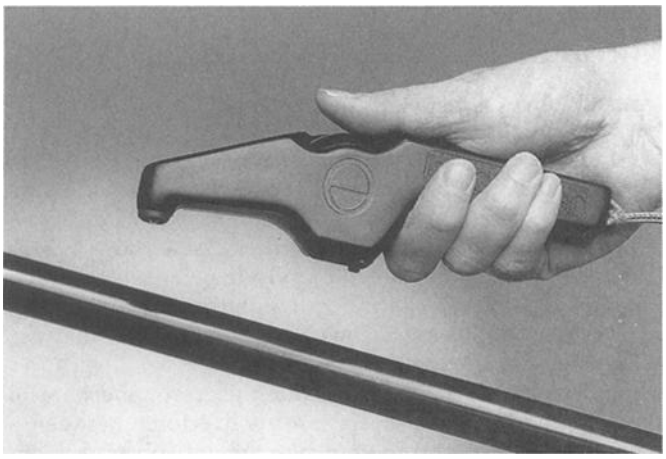

FIG. 9–Elcometer magnetic coating thickness gage 211.

and great care must be taken to ensure that they are used vertically to avoid the influence of gravity on the spring-magnet combination. Some of these types of gages have design features to overcome the gravity effect when the gage is used horizontally. An example of this type of gage is the Elcometer Model 157 (Fig. 8).

A common form of the hand-held magnetic gage is shown in Fig 9, and its principle is illustrated in Fig. 10. A balanced beam with a magnet fitted to one end and counterbalanced by a brass weight at the other is attached at the pivot to a helical spring. The other end of the spring is attached to a ring holding the scale. Rotation of the ring raises or lowers the magnet.

The gage is placed on the surface to be tested in any orientation as the balance weight ensures that gravity effects are neutralized. The ring or scale wheel is pushed forward

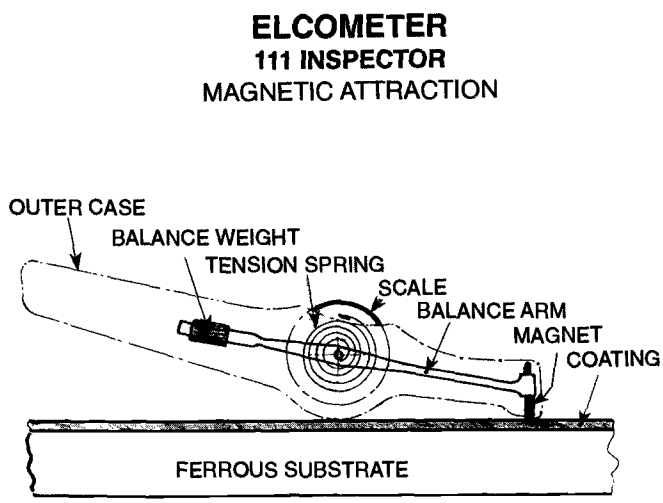

FIG. 10–Magnetic coating thickness gage principle.

(anticlockwise rotation) to bring the magnet in contact with the coating and to set the scale to a maximum reading. The ring or scale wheel is then rotated clockwise until the magnet breaks free, the thickness of the coating being indicated by a pointer.

This type of gage is calibrated against plated standards available from NIST, and accuracy against these standards of ±5% of reading are achieved. It should be noted that the steel used to make NIST standards is not always representative of engineering steels, and therefore a practical operating accuracy of ±10% is obtained in the field.

Elcometer (Model 101)

The Elcometer is one of the first magnetic thickness gages to be commercially available, being patented in 1948. Based on magnetic permeability, the magnetic flux acts on an armature suspended in between the two magnetic arms of the unit (Fig. 11) north and south poles. The turning moment of the magnetic flux is countered by a helical spring, and the magnitude of the magnetic flux changes with the distance between the ends of the magnetic arms (ball feet) and the substrate beneath the coating. A pointer attached to the armature indicates the thickness of the coating. Instruments covering ranges from 0 to 3 mil (0 to 80 μm) to 0 to 0.75 in. (0 to 18 mm) are available.

Magneto Resistor (Electronic)

This instrument combines a permanent magnet with a magneto-resistor in a probe to provide a signal which varies with the intensity of the magnetic field, which in turn is influenced by the distance of the magnetic substrate from the tip of the probe (Fig. 12).

The scale of the instrument is nonlinear and uses an analogue meter movement to indicate the thickness. In operation it is necessary to set zero on the uncoated metal and calibrate to a thickness of known value to obtain the best accuracy.

These instruments have been superseded by the electromagnetic induction types and by digital electronics, but again many instruments are in use and the principle embodied in the probe is still used for ferrite detection in stainless steel

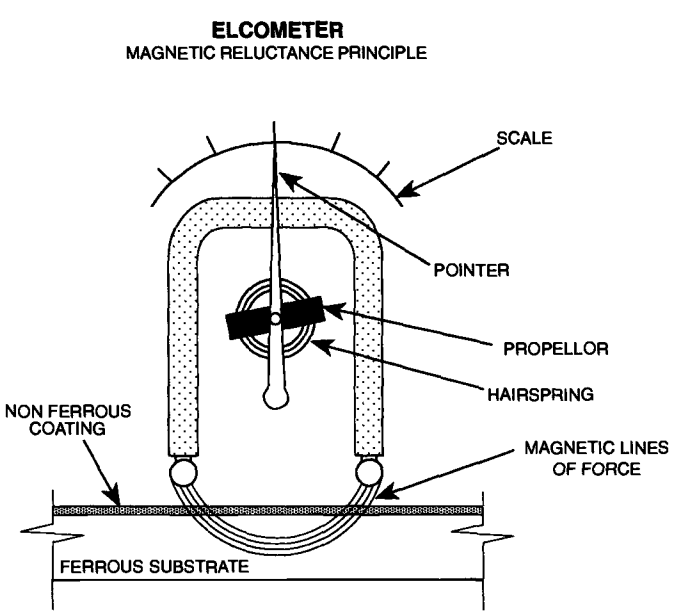

FIG. 11–Elcometer 101 principle.

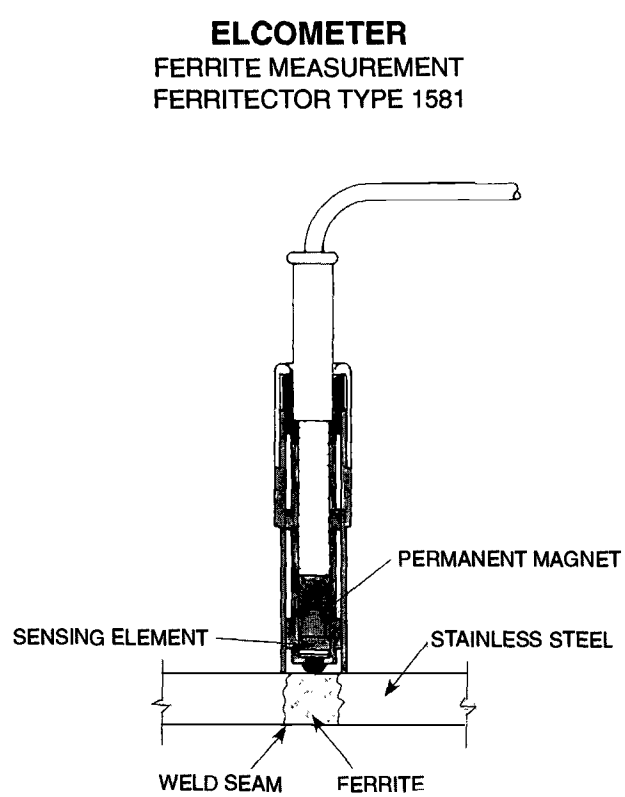

FIG. 12–Magneto resistor principle.

weld materials. In this application the magnetic properties of the substrate change with the ferrite content and the gage is calibrated in reverse, that is to say, zero, with the probe away from the influence of the magnetic material (free air) and maximum (Ferrite Number 28) on a 20 mil/thou in. (500-μm)-thick coating on a mild steel base.

For ferrite measurement, the probe is applied to an uncoated weld.

Electromagnetic Thickness Gages

The electromagnetic induction method for measuring film thickness is based on the effect of a magnetic metal substrate on the balance of the alternating magnetic field in the probe tip, generated in the probe (Fig. 13) by a signal applied to the central coil.

When the probe is away from the influence of the substrate (free air condition), the net voltage output from the two outer coils tends to zero. As the substrate is brought towards the tip, the field is increasingly out of balance between the two outer coils until, with the uncoated substrate in contact with the tip, the net voltage output from the coils tends toward V max.

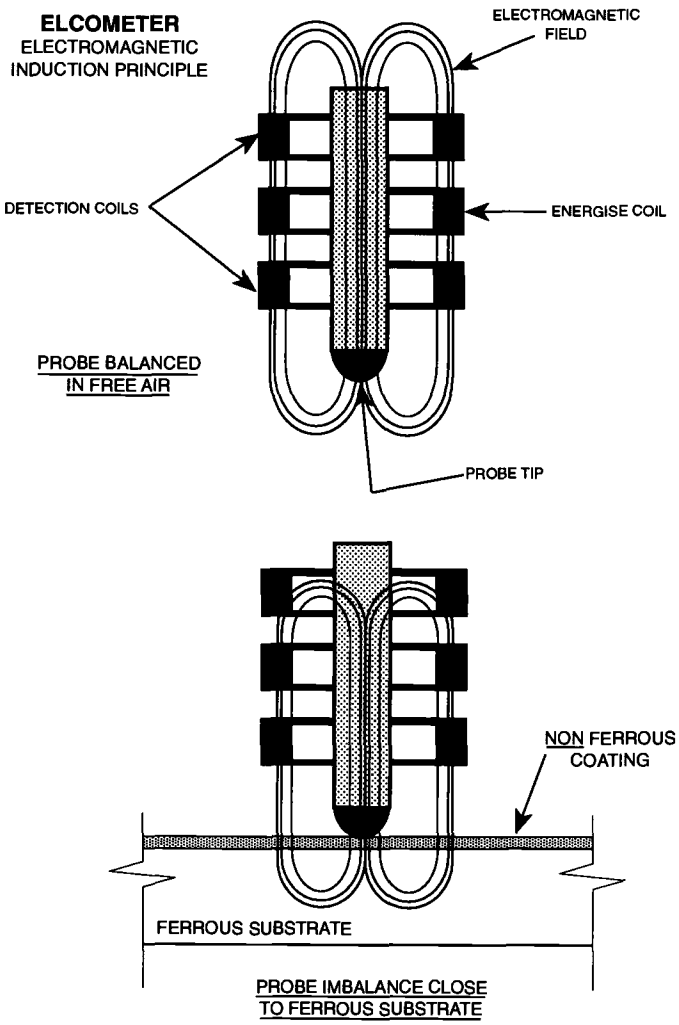

FIG. 13–Electromagnetic induction principle.

The voltage output from the probe can be amplified and calibrated and then used to display a thickness value. Three types of electronic coating thickness gages have been developed on the basis of this probe technology using analogue, digital, and microprocessor electronics. These types of gages have been standardized by ASTM as Test Method B of D 1186.

Analogue Electromagnetic Thickness Gages

The simplest form of instrument uses a nonlinear scale on a meter movement to display the voltage output from the probe in thickness terms. The Elcometer Model 145 (Fig. 14) is an example of this type of unit.

In common with most electronic coating thickness gages, the instrument must be calibrated by setting the needle to zero with the probe on the uncoated magnetic metal substrate and then setting the upper scale point using the calibration control with the probe on a known thickness of coating.

Two forms of thickness standard are in common use: (1) the plated type, as illustrated by the standards available from NIST and other sources, and (2) the measured and unmeasured plastic shims available commercially from gage manufacturers. In many applications the plastic shims are preferred as calibration on the work to be measured reduces the errors of calibration due to surface finish, curvature, and substrate composition. More details of this are given later in this chapter under **EFFECTS OF SURFACE FINISH, CURVATURE AND SUBSTRATE COMPOSITION ON ELECTROMAGNETIC AND EDDY CURRENT MEASUREMENTS.**

Digital Electromagnetic Thickness Gages

Advances in electronic components and instruments design techniques have made it possible to significantly reduce the size of coating thickness gages while returning and enhancing the features users find necessary. The use of digital electronics means that the voltage output from the probe can be converted to a numerical value early in the processing of the signal, thus reducing the effects of instrument temperature changes and component drift on the accuracy of the result. It is also possible to use a linear scaling, making it possible to have a fixed resolution over the full range of the instrument scale although resolutions are often enhanced in the 0 to 10 mil range (0 to 100 μm when scaled in metric units). An illustration of this type of instrument is shown in Fig. 15, but it should be noted that this type of product is already being superseded by microprocessor-based designs. The same principles of calibration apply to digital electromagnetic coating thickness gages as apply to the analogue types, and accuracy capabilities of ±5% of readings are achieved in the field.

Microprocessor Electromagnetic Thickness Gages

The development of microprocessor electronics and their application to portable coating thickness gages has made it possible to improve the accuracy and reproducibility of these instruments as well as allowing developments in range, special calibration techniques for rough surfaces, memory of readings, statistical calculation, and printouts.

In a microprocessor design, the characteristic of the probe voltage output against coating thickness value is stored in the

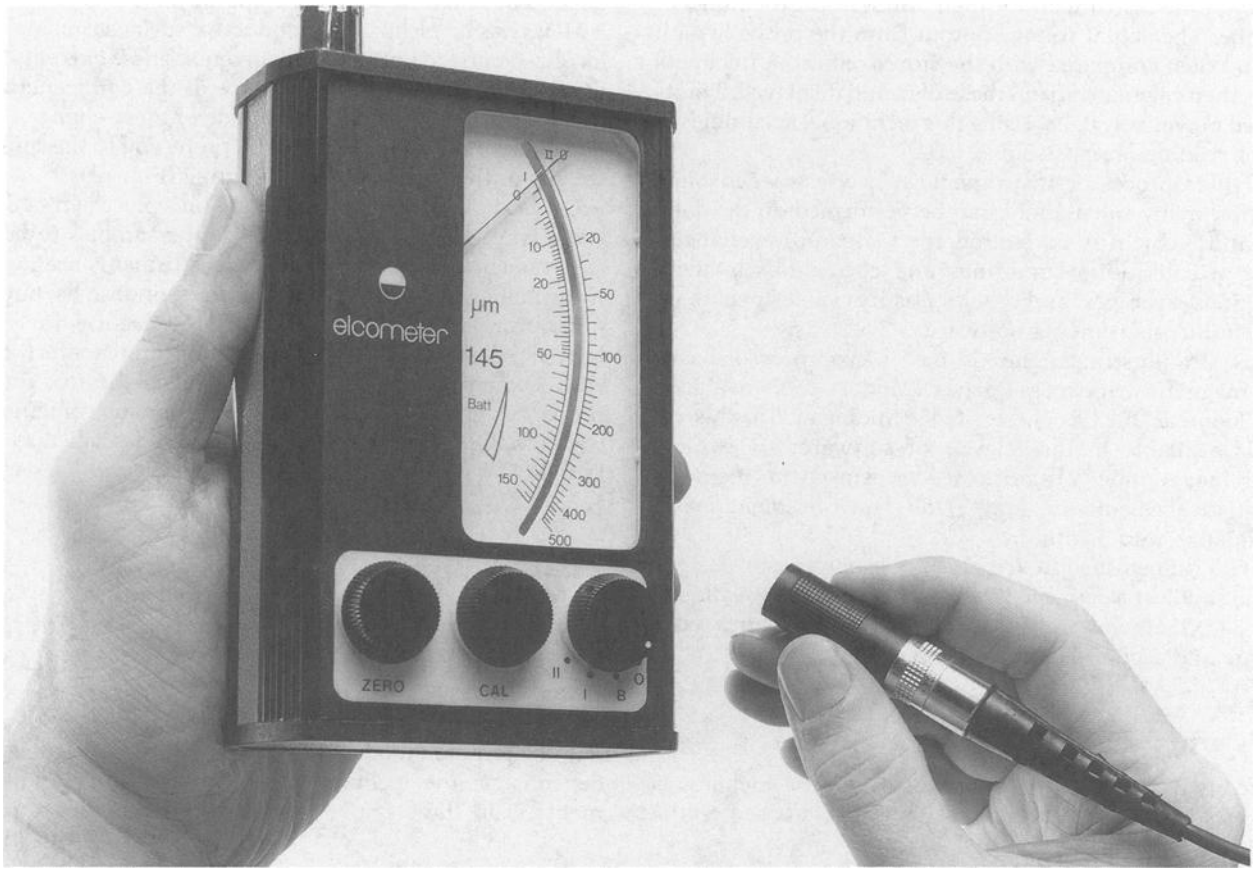

FIG. 14–Analogue electromagnetic thickness gage 145.

FIG. 15–Digital electromagnetic thickness gage 245.

memory of the instrument for many values over the range of the probe. The actual voltage output from the probe is digitized and then compared with the stored values. A thickness value is then calculated from these data and displayed. This is achieved in typically 0.3 s. Using this technique, accuracies of ±1% of reading are possible.

As a microprocessor instrument is in effect a dedicated computer, many calculations can be performed on the data, and features such as correction for temperature changes, storage of calibration conditions and corrections to these calibrations, averages, and other statistical values can be included in the instrument's software.

Figure 16 illustrates one of the microprocessor-based electromagnetic thickness gages Model 256, available from Elcometer Inc., Rochester Hills, Michigan. This instrument is available in three levels of software: (1) *basic*—measurements only; (2) *statistical*—measurement, memory, and statistical calculation; and (3) *top*—measurement, memory, statistics, and printout.

Figure 17 illustrates the trends in microprocessor designs with the smallest electronic coating thickness gage available, Model 345, Launched in October 1991, the unit supersedes analogue and digital designs at a lower cost.

Eddy Current Thickness Gages

The eddy current method for measuring film thickness is applied to coatings on nonferrous metals. It is based on the effect that a high-frequency alternating field (3 000 000 Hz or 3 MHz) has an electrically conductive surface causing highly localized current flow or eddy currents. These currents generate their own magnetic impedance of the coil, generating a high-frequency field. The magnitude of these changes is proportional to the distance from the probe coil to the substrate, that is, to the thickness of the coating (Fig. 18).

Calibration by adjustment to zero on a piece of metal of the same type, shape, and thickness as the samples to be measured is vital to ensure accuracy. Instruments are available using analogue, digital, or microprocessor designs, but many microprocessor instruments offer the facility for a dual ferrous (F) electromagnetic induction and nonferrous (N) eddy current principle instrument using the two different probe designs such as the eddy current instruments illustrated in Fig. 19. This type of gage is also described as ASTM D 1400.

EFFECTS OF SURFACE FINISH, CURVATURE, AND SUBSTRATE COMPOSITION ON ELECTROMAGNETIC AND EDDY CURRENT MEASUREMENTS

The accuracy of coating thickness measurements carried out using the methods described in the last two subsections depends on the technique used in calibrating the instruments. The three major influences on the calibration are

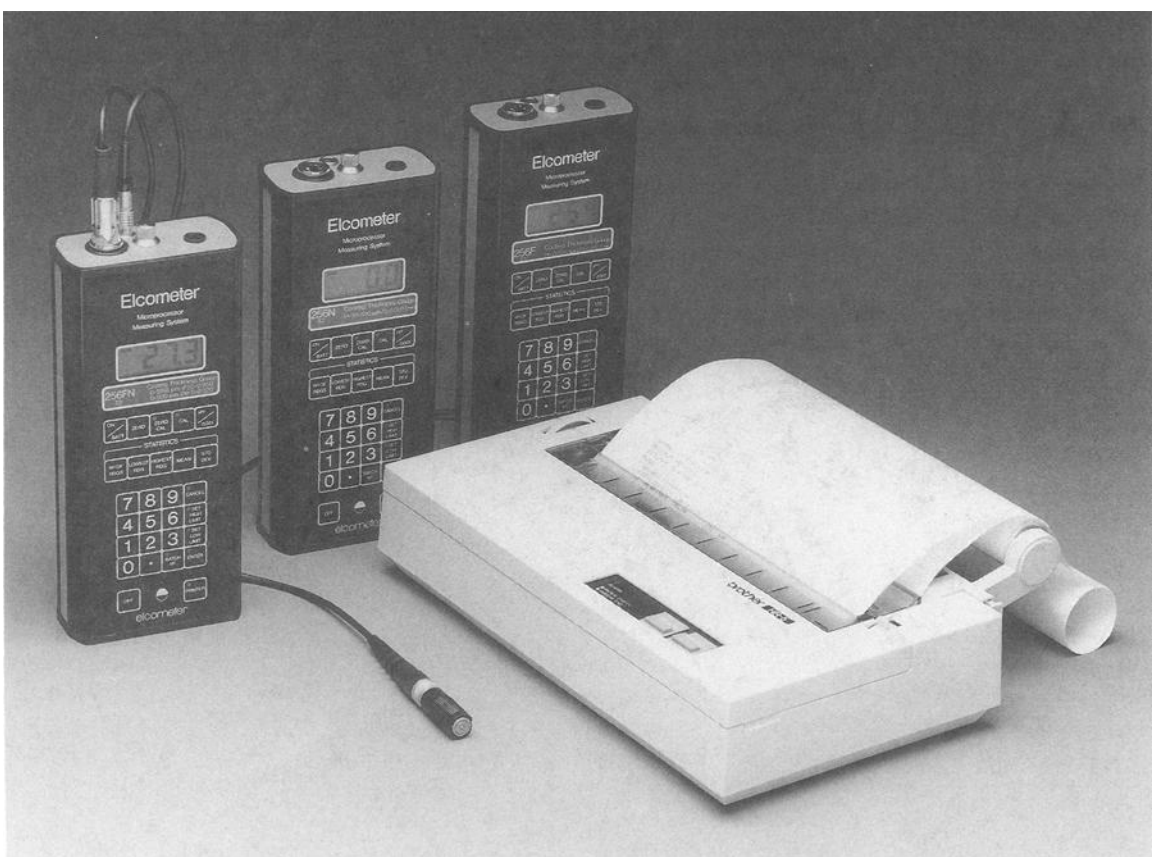

FIG. 16–Microprocessor electromagnetic thickness gage 256.

FIG. 17–Smallest microprocessor electromagnetic thickness gage 345.

surface finish, curvature, and shape of the substrate composition.

Surface Finish

A variety of surface finishes are to be found on metal to which a protective or decorative coating is to be applied. In some cases the coatings used require an anchor pattern of profile depth which forms a part of the specification. Comparators such as the Keane-Tator Surface Profile Comparator or the International Standards Organization ISO 8503 are used to determine the surface finish after shot or grit blasting. Also Testex Tape and the Elcometer Surface Profile Gage can be used to measure peak to valley heights of profiles. These instruments are shown in Fig. 20 along with the photographic standards for cleanliness ASTM Pictorial Surface Preparation Standards for Painting Steel Surfaces D 2200-1989 and SSPC-VIS1.

Surface finish also influences calibration as the quantity of metal directly beneath the probe is reduced by the effects of shot and grit blasting as the probe tip sits on the highest peaks. This has the effect of increasing the value of thickness indicated using a gage calibrated on a smooth surface by as much as 1.5 mils (35 μm) at 4 mils (100 μm) coating thickness for the highest values of profile.

It is possible to use a rough surface calibration technique to eliminate this error and make the instrument read the correct value of coating thickness over the peaks by using the statistical power of the microprocessor type gages to calibrate on the profile. This is achieved by using a thin foil 1.0 mil (25 μm) over the profile to set the lower calibration point and a thicker foil 5.0 mils (125 μm) or 10.0 mils (250 μm) to set the upper value over the profile. The instrument will then indicate the thickness over the peaks for the coating between the values of foil chosen.

This method is most accurate and reproducible when 15 to 20 readings are taken on each calibration foil to establish a mean value and the mean value is then reset to the correct value of the foil. Trials have shown that the mean of 15 to 20 readings taken over an area of coating give a mean value within a few percent of the actual value over peaks determined by sectioning.

The method does not, however, take into account situations where access to the substrate is not possible for calibration purposes. In this case, the method described in SSPC PA2 where a correction factor is applied to readings taken using a smooth surface calibration in the instrument is more appropriate. In either case it is important to agree with the method before measurements start to avoid discrepancies in reporting.

Curvature

The shape and metal wall thickness can also influence the accuracy of the calibration. The degree to which a particular instrument is affected depends on the design of the probe. Many modern instruments exceed the limits identified in SSPC PA2 of 1 Nov. 1982.

The effect of shape is most evident when taking readings on an uncoated sample. With an instrument calibrated on a smooth piece of metal 0.125 in. (3.175 mm) thick, changes of more than 0.2 mil (5 μm) in the reading at zero will be seen on curves with a radius below 0.12 in. (3 mm) convex or 0.96 in. (25 mm) concave on a typical electromagnetic induction probe. Values will vary between manufacturers and from different probe types.

This error can also be eliminated by calibration on a shape closely representing the specimen to be tested. However, it should be noted that once below the values of curvature indicated in the manufacturer's literature, changes in curvature have a significant effect on calibration, i.e., the calibration on a shape will not be applicable to another shape.

Substrate Composition

In the case of electromagnetic induction probes, most are insensitive to the majority of steel specifications in general engineering use. However, when high-carbon steels are coated, the carbon content sufficiently alters the magnetic properties of the steel to cause the normal calibration curve applied within the instruments to be in error with respect to linearity. Thus, an instrument calibrated at zero and say 5 mils (125 μm) may have an error at 2 mils (50 μm) of more than 0.2 mil (50 μm) or 10%. A similar effect can be seen with some cast irons.

This error can be overcome by calibrating as for the rough surface described in the section earlier in this chapter entitled **Surface Finish.** For best accuracy, choose a foil just below the expected coating thickness value for the lower calibration

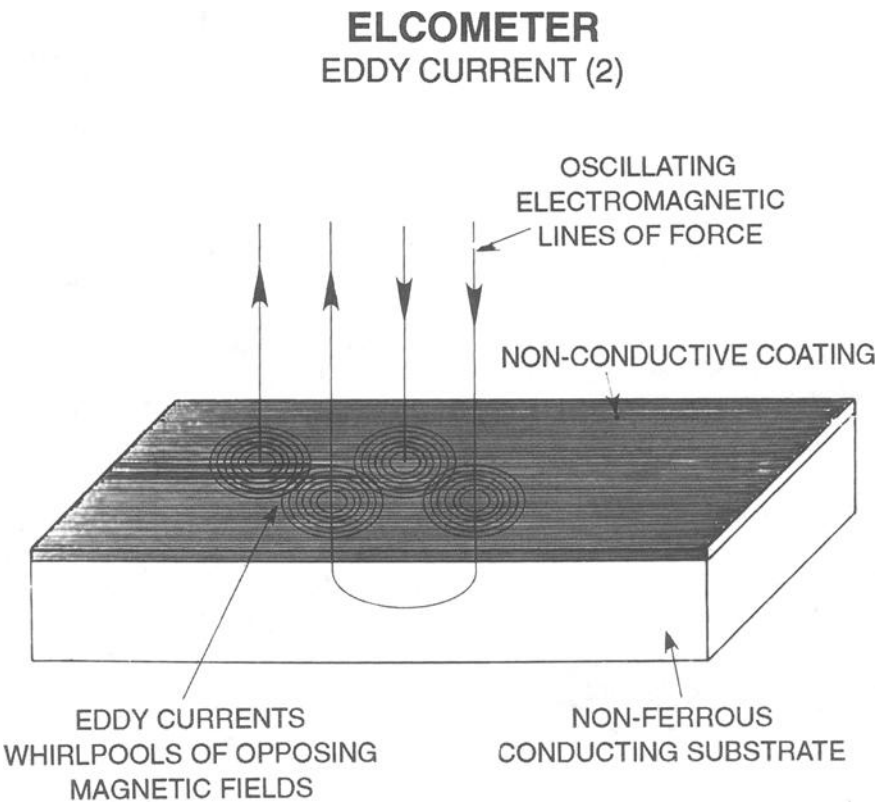

FIG. 18–Eddy current principle.

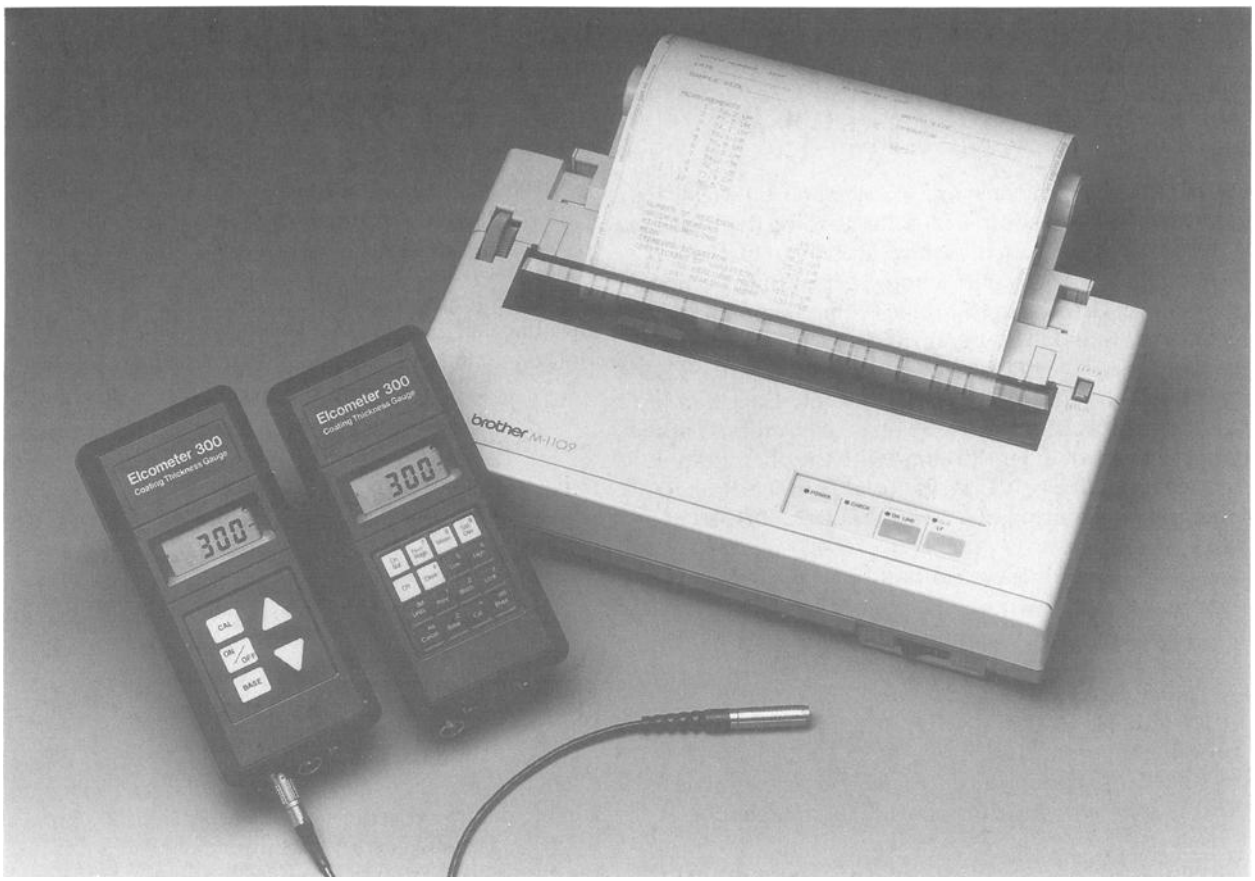

FIG. 19–Microprocessor eddy current gage model 300.

FIG. 20–Surface profile instruments (group) with model numbers as brochure.

points and a value well above the expected coating thickness value for the upper calibration point.

When coatings applied to nonferrous metals are being measured using eddy current techniques, the composition of the substrate and its effect on electrical conductivity are the important factors with respect to calibration. Materials such as aluminum and copper have very similar characteristics and similar calibration values. However, zinc, brass, and other nonferrous metals and alloys have different characteristics, and calibration on an uncoated sample is essential. Differences of up to 2 mils (50 μm) can be seen between "zero" with an aluminum calibration and zero on a brass component.

TABLE 4—X-ray fluorescence can be used for these applications.

Coating	Substrate
Chromium	Steel, copper
Cadmium	Steel, copper
Copper	Steel, zinc, brass
Nickel	Steel, copper, Kovar, aluminum, Alloy 42, inconel
Nickel-phosphorous	Steel, copper, Kovar, aluminum, Alloy 42
Zinc	Steel, copper, brass
Zinc-nickel	Steel
Gold	Nickel, aluminum, Kovar
Rhodium	Nickel, gold
Palladium	Nickel
Silver	Steel, copper, Kovar
Tin	Steel, copper, Kovar, aluminum
Titanium nitride	Steel
Ferrous oxide	Aluminum, plastic

STATISTICS IN FILM THICKNESS MEASUREMENT

As many random variations can be expected in a coating process, it is appropriate to classify the thickness of the coating using a statistical analysis. In fact, many national specifications utilize a statistical approach in recognition of these variations, e.g., SSPC PA2.

The sources of these variations are many, and only a few examples can be cited here—operator error in taking the measurement, recording error, variation due to surface or curvature or composition, local variation in substrate due to local heat treatment or due to forming or working the metal, inclusions in the metal or in the coating, etc.

The influence of these factors can be greatly reduced by taking a statistically significant number of readings for each area of the coating to be tested. This group of readings can then be summarized using mean and either standard deviation or range to show the average and the spread of readings about the average.

A statistically significant number of readings would be 20 to 50; however, if the process is under statistical control as defined, five readings in each group or subgroup is sufficient.

Many of the microprocessor-based coating thickness instruments are capable of calculating and recording mean

values ($\bar{x}$), standard deviation (σ), and highest and lowest values (range) within a batch of readings.

It is important to establish the method of evaluating the information before embarking on an evaluation of a coating system so that the correct disciplines are applied to collecting the data and evaluating it for further decisions.

X-RAY FLUORESCENCE (XRF)

Over recent years, developments in performance and reductions in cost have pushed X-ray fluorescence to center stage, particularly for metal-on-metal applications and ever smaller parts. Beta-ray backscatter (BBS) techniques had been widely used to measure plated coatings; however, limitations in performance—e.g., a minimum of 20% difference in atomic number between the coating and the substrate is required—mean that while gold over nickel, copper, or Kovar can be measured, nickel over copper or Kovar cannot be measured using BBS techniques. Other disadvantages exist, such as limits in the aperture/component geometry, and measurement times have led to the further development of XRF techniques and technology.

Principle of XRF Measurement [6]

If sufficient light energy collides with an electron, it is possible for the electron to be driven out of its atomic orbit, a process known as the photoelectric effect. An atom with an electron removed from its orbit is unstable, so to restore equilibrium, an electron from a higher shell must drop into the vacant orbit. This transition causes an emission of energy in the form of a light wave or photon.

When the inner shell electrons are ejected from an atom, the emitted photon has high energy, and they fall into the region of the electromatic spectrum called X-rays. X-rays have characteristic energy levels determined by the element which is emitting and can therefore be used to identify the elements in a sample.

In XRF instruments an X-ray source or tube is used to produce photon emissions as they have an energy distribution capable of fluorescing all elements commonly used in plating. The X-ray beam can be accurately illuminated to provide a small focal spot and high-intensity energy suitable for noncontact measurement of complex layers on small components. The characteristic X-rays emitted by the target materials are detected using a gas-filled "proportional counter" in which the passage of the X-ray ionizes the gas and produces a pulse of electrical charge proportional to the energy of the X-ray.

The XRF instruments' electronics convert the charge pulse into a digital signal that can be interpreted as thickness or analyzed for composition and produce the measurement information by comparison with standards of known thickness. XRF instruments have developed with optical alignment systems and motor-driven sample stages to position the sample and computerized analytical equipment to store calibration data to calculate and present data to the user in a suitable format. Table 4 shows some of the applications which can be successfully measured using XRF.

Drying Time

by Thomas J. Sliva[1]

THE PROCESS OF DRYING INVOLVES several physical and/or chemical changes, such as solvent evaporation, oxidation, and polymerization, all of which are time dependent. The various stages of drying that occur in organic films may be subjective, difficult to measure reproducibly, and are influenced by many factors such as film thickness, substrate, temperature, humidity, light, and air circulation. Therefore, it is essential that most of these variables must be minimized in order to make drying time determinations more quantitative.

PREPARATION OF SPECIMENS

Substrate Preparation

It is essential that the substrate to be used and the applied wet film thickness be agreed upon in advance, preferably to conform to the intended use of the coating. Flat glass panels are typically the substrate of choice. Ground and polished glass plates are more suitable for low-viscosity coatings that may tend to crawl. All panels must be thoroughly cleaned, dried, and placed in a horizontal position on a level surface.

Application

The test coating should be filtered to remove any dirt or contamination. Test films are typically prepared, in duplicate, using a drawdown or doctor blade adjusted to obtain a uniform film thickness. Films should be drawn down at a uniform rate of application to avoid drag on the coating. It is recommended that all test films should be prepared and tested by one operator properly skilled in the method to be used and that a control (known) coating be run alongside the test coating. All testing should be done within an area, any point of which is not less than ½ in. (15 mm) from the edge of the test film.

Table 1 can be used as a general guide for film application when nothing more specific is agreed upon between the purchaser and seller. The dry film thicknesses shown in Table 1 are suggested.

Other methods of application, such as spraying, dipping, or flood coat, may be used provided the film thickness obtained is consistent with that recommended under actual usage. Other substrates, such as metal, may be used provided they are smooth and flat.

[1]Assistant technical director, DL Laboratories, 116 East 16th St., New York, NY 10003.

ENVIRONMENT

When determining drying time, a controlled environment is essential. Variations in temperature, relative humidity, and circulation of air and light will have an effect on the drying time of a coating. The typical standard environment used for determining the drying time of air dry coatings is a temperature of 73.4° ± 3.6°F (23° ± 2°C) and a relative humidity of 50 ± 5% under diffuse daylight (about 25 fc).

Relative humidity should be strictly controlled for moisture-cure and two-package urethane coatings since their cure is greatly affected by the existing relative humidity. The effect of variation in temperature was discussed by Algeo and Jones [*1*], who observed a difference of 4 h for a particular paint dried at 73 and 77°F (22.7 and 25°C), both at 50% relative humidity.

All testing should be conducted in a well-ventilated room free from direct drafts and dust. Airflow is important in determining drying time. For films that dry by oxidation, the rate of drying is a function of the concentration of oxygen at the interface. Since oxygen can reach the surface only by diffusion, the rate of drying is a function of the thickness of the stationary air layer. For films that dry by solvent evaporation, the continuous removal of solvent-laden air hastens drying.

TEST METHODS

ASTM D 1640: Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature

Method D 1640 is the most commonly used method to determine the various stages and rates of film formation in the drying of organic coatings normally used under conditions of ambient room temperature. The method describes eight stages of the drying process:

1. *Set-To-Touch Time*

   The test film is lightly touched with the tip of a clean finger, and the fingertip is immediately placed against a piece of clean, clear glass to determine when the film does not adhere to the finger or transfer to the glass.

2. *Dust-Free Time*

   This test is generally performed by either of two methods that determine when dust or cotton fibers lightly dropped

Copyright© 1995 by ASTM International

TABLE 1—Recommended film thickness of materials to be tested.

Material	Dry Film Thickness, mils
Oil paints	1.8 ± 0.2
Enamels	1.0 ± 0.1
Drying oils	1.0 ± 0.1
Water-based paints	1.0 ± 0.1
Varnishes	0.85 ± 0.1
Lacquers, resins solutions	0.5 ± 0.1

on the test film can be removed by blowing over the test film.

a. *Cotton Fiber Test Method*

Individual absorbent cotton fibers are dropped from a height of 1 in. (25 mm). The film is considered to be dust free when the cotton fibers can be lightly blown off the test film.

3. *Tack-Free Time*

The test film is considered to be tack free when no stickiness is observed under moderate pressure. This can be measured by either of two methods:

a. *Paper Test Method*

A special paper (K-4 Power Cable Paper) [*3*] is placed on the test film under a weight of 2 psi (13.8 kPa). After 5 s, the weight is removed and the test film inverted. If the paper drops off within 10 s, the film is considered tack-free.

A variation of the above method is used to test the tack-free time of insulating varnishes. The varnish is considered tack free when the paper is placed on the test film under a weight of 1 lb (450 g) for 1 min and tested as above.

b. *Tack Tester*

This is a mechanical device which consists of a strip of metal 1 in. (25 mm) wide, 3 in. (75 mm) long, and 0.016 to 0.018 in. (0.41 to 0.46 mm) in thickness. It is bent to form a base 1 in. (25 mm) square and a vertical length 1 by 2 in. (25 by 50 mm) angled at 135°. The bottom of the base of the tester is covered with aluminum foil [*4*] (Fig. 1). A 300-g weight is placed on the center of the base and allowed to set for 5 s. The test film is tack free when the tester tips over immediately after the weight is removed. Occasionally, tack-free time may be longer than dry-hard or dry-through time due to the inclusion of external plasticizers in the coating.

4. *Dry-To-Touch Time*

The test film is considered dry-to-touch when no mark is left when the film is touched by a finger. The following variations are used:

a. *Drying Oils*—The film is considered dry-to-touch when it does not rub up appreciably when a finger is rubbed lightly across the surface.

b. Lacquers (and Sealers)—The film is considered dry-to-touch when no pronounced marks are left by a finger touching the film. Sealers are generally tested on wood or other porous substrates.

5. *Dry-Hard Time*

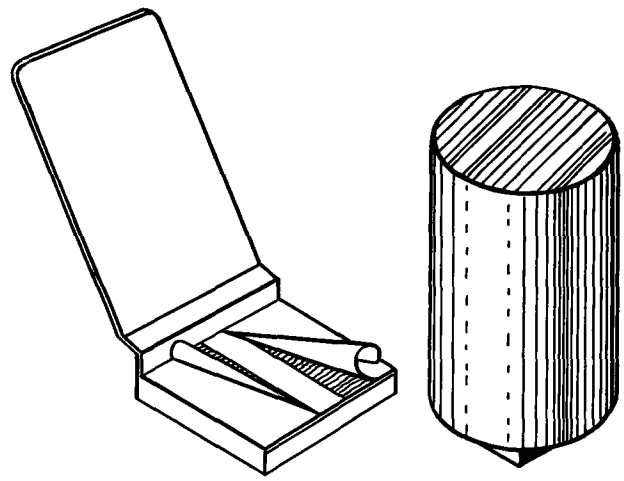

FIG. 1–Zapon Tack Tester. The base of the tester is padded and wrapped with aluminum foil. The weight, at right, is set on the base for a definite interval. After the weight is removed, the time required for the tester to tip over is the measure of tack.

The test film is considered dry-hard after maximum downward thumb pressure (without twisting) applied to the test film leaves no mark when the contacted area is lightly polished with a soft cloth.

6. *Dry-Through (Dry-To-Handle) Time*

The test panel is placed in a horizontal position at such a height than when a thumb is placed on the film, the arm of the operator is in a vertical line from the wrist to the shoulder. The operator bears down on the film with the thumb, exerting moderate pressure and at the same time twisting the thumb through an angle of 90°. The test film is considered dry through when the film is not distorted by bearing down with moderate thumb pressure and twisting 90°.

7. *Dry-To-Recoat Time*

The test film meets this requirement when a second coat can be applied without causing any film irregularities, e.g., lifting, wrinkling.

8. *Print-Free Time*

The test film meets this requirement when imprinting fabric under a pressure of ½ or 1 lb/in.^{2} (3.5 or 7.0 kPa) shows the coating to be print free. This procedure is similar to ASTM D 2091: Test Method for Print Resistance of Lacquers.

An indication of the accuracy of these methods is the precision statement developed in ASTM D 1640 in which duplicate determinations within a laboratory should agree within ±10% [*5*].

Federal Test Method Standard 141C, Method 4061.2: Drying Time

This method is similar to ASTM D 1640. It includes essentially the above stages of drying with the exception of dry-to-

touch. However, it includes a test for free-from-after-tack. This test is applicable to coatings where tackiness persists beyond, or reappears at, the through-dry stage. It is similar to the Paper Test Method, discussed earlier in this chapter, except that a 2.8-kg (6.2-lb) weight is used.

ISO Standard 9117: Paints and Varnishes—Determination of Through-Dry State and Through-Dry Time—Method of Test

This standard describes a method for determining under standard conditions whether a single coat or a multi-coat system of paint or related material has, after a specified drying period, reached the through-dry state, i.e., a pass/fail test. The test procedure may also be used to determine the time taken to achieve that state.

1. *Through-Dry State*

   This state defines the condition of a film in which it is dry throughout its thickness as opposed to that condition in which the surface of the film is dry but the bulk of the coating is still mobile. A single coating or a multi-coat system of paint or varnish is considered to be through-dry when a specified gauze attached to a plunger is placed on the test film under specified pressure (1500 g) for 10 s, after which time the plunger head is turned through an angle of 90° over a period of 2 s and removed (Fig. 2). If no damage or markings are noted on the test panel, the film is said to have achieved "through-dry state."

2. *Through-Dry Time*

   This is the period of time between application of a coating to a prepared test panel and the time to achieve the "through-dry state" as outlined above.

British Standard B.S. 3900: Methods of Test for Paints

Parts C-1 thru C-4 of British Standard B.S. 3900 describe drying tests for determining the wet edge time, surface drying, hard-drying, and freedom from residual tack tests. Part C-8 describes a test for determining print-free state or time.

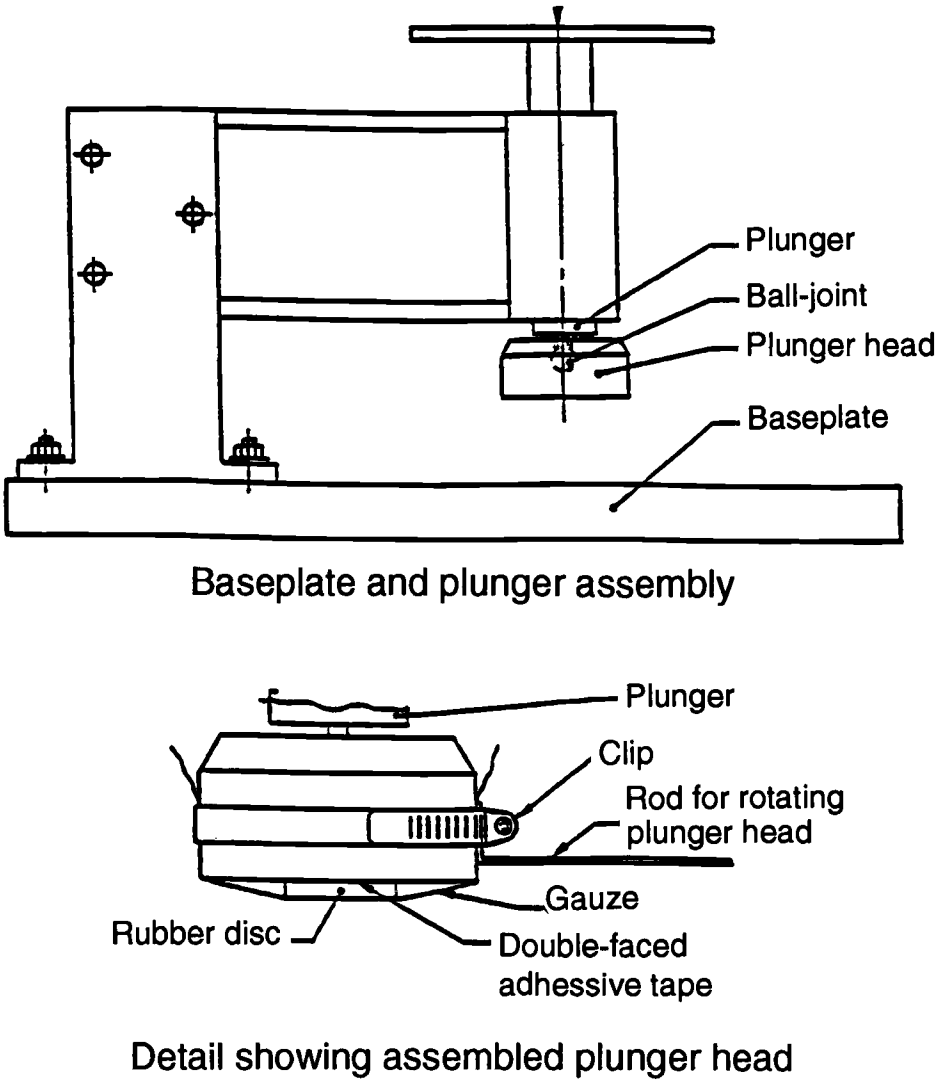

FIG. 2–Through-Dry Tester.

1. *Wet Edge Time (BS3900, C1)*

   This procedure is used for determining whether the edge of a film of paint remains "alive" after a specified period of drying. Following a touch-up coat over the film after the specified drying period, the area is evaluated for lack of film continuity, absence of leveling, or variation in color or sheen.

2. *Surface Drying (BS3900, C2)*

   This procedure is used to determine the time after which a coating is applied and when approximately 0.5 g of the ballotini (small transparent solid glass spheres) can be poured onto the surface of the film from a height of between 50 and 150 mm and lightly brushed away without damaging the surface.

3. *Hard-Drying Time (BS3900, C3)*

   A rubber-faced plunger is covered with cotton twill, rough side outwards, and then loaded to a toal weight of 1.8 kg (4 lb). The rotating plunger drops into the panel and makes a three-quarter turn while in contact. The paint film is dry-hard when no damage is observed (Fig. 3).

4. *Freedom from Residual Tack (BS3900, C4)*

   After a specified drying period, a paper-backed gold leaf is placed on the test panel and covered with a microscope slide and an 800-g weight. After 10 s, the weight and slide are removed and the panel is held vertically and lightly tapped to detach the gold leaf. The surface of the paint film is examined for adhesion of gold leaf.

5. *Print-Free (BS3900, C8)*

   The state of a coating or varnish when gauze of a specified grade, under specified force and after a specified time, does not leave an imprint on the surface of a coating.

DIN 53 150: Determination of Drying Time of Paints

Drying time is determined in this method by the adherence or nonadherence of sand or paper to the film under various loadings. Stage 1 is determined with sand (0.16 to 0.315 mm) or glass beads (ballotini). The sand is allowed to remain on the film for 10 s. The remaining stages are determined using disks of typewriter paper (22 mm in diameter and weighing about 60 g/m^2) and various loads ranging from 5 to 5000 g/cm^2. Interposed between the load and the test disk is a soft rubber cushion. The load remains on the disks for 60 s. The criteria for the seven stages are as follows:

1. Sand easily removed with a soft brush.
2. Disk under load of 5 g/cm^2 does not adhere.
3. Disk under load of 50 g/cm^2 does not adhere.
4. Disk under load of 500 g/cm^2 does not adhere, but film is temporarily marred.
5. Disk under load of 500 g/cm^2 does not adhere, but film is not marred.
6. Disk under load of 5000 g/cm^2 does not adhere, but film is temporarily marred.
7. Disk under load of 5000 g/cm^2 does not adhere, but film is not marred.

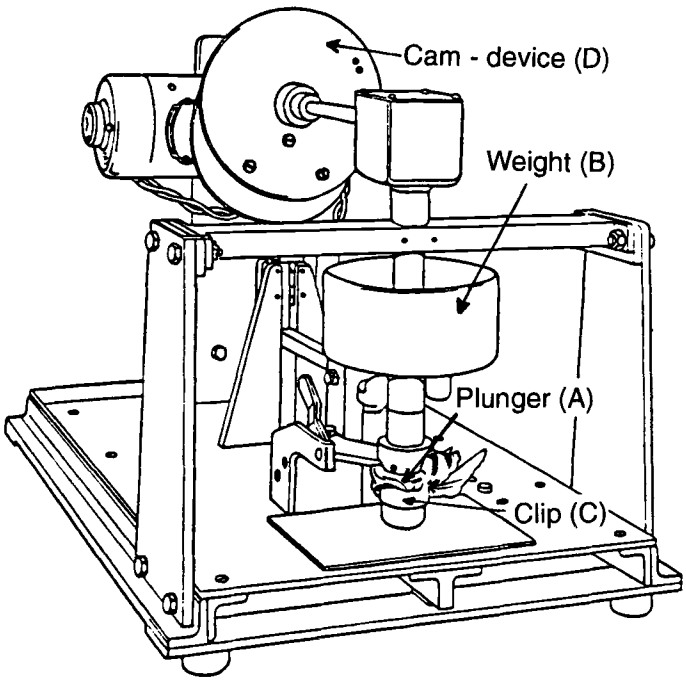

FIG. 3–Hard-drying time apparatus: Assembly.

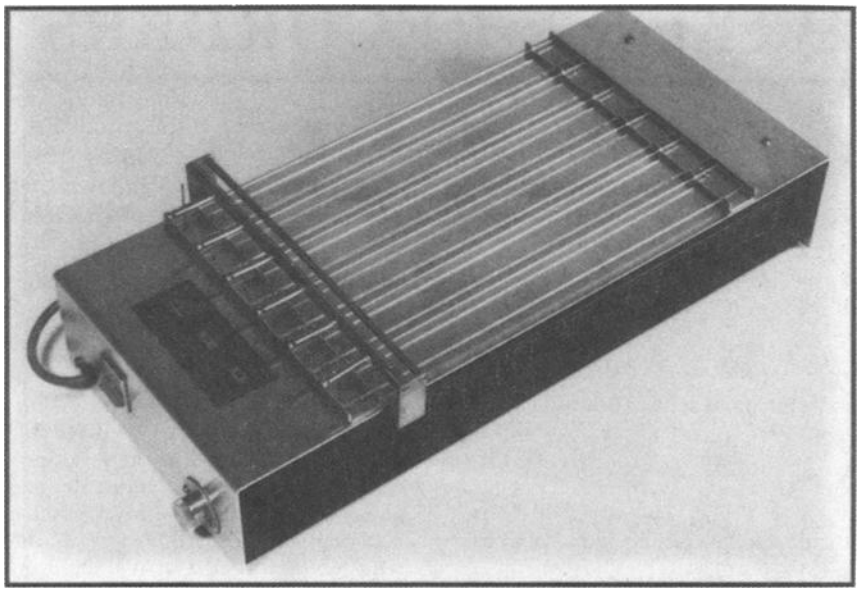

FIG. 5–Straight line recorder. (Courtesy of Byk-Gardner.)

MECHANICAL DEVICES

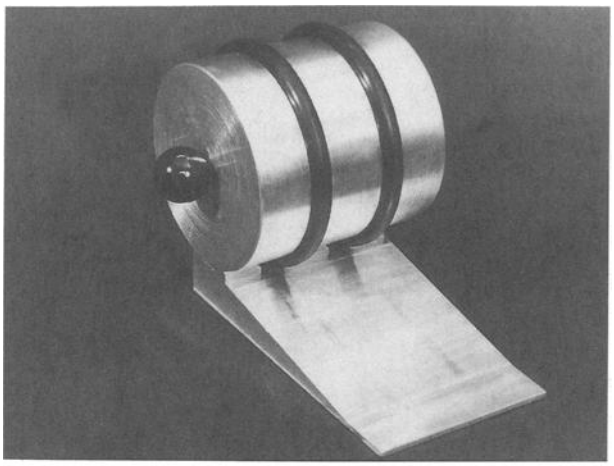
In an attempt to improve the accuracy and reproducibility of the drying time test procedure, various mechanical devices have been developed. The following sections outline these devices and the procedures used in determining drying characteristics.

Circular Drying-Time Recorder

The device consists of a synchronous motor in a metal case resting on a rubber-tipped tripod and rotating a vertical shaft. A pivotal arm assembly is attached to the shaft, operating a vertical stylus with a Teflon sphere that does not stick to the drying film [6]. Under a 12-g load, the stylus scribes an arc in the drying film. Motor speeds are available to cover drying times of 1, 6, 12 and 24 h (Fig. 4).

A transparent template with time increments can be placed over the dried coating at the end of the test. The appropriate time circle can then be used to determine the dry time. During the early stages of drying, the coating tends to flow back into the wake of the stylus. When the tendency of the flow has ceased, the film may be considered set. As the drying process continues, a skin will form. Visually, this part of the film formation is seen when the stylus begins to tear the surface of the film. The film may be considered surface dry or dust free when the skin is no longer ruptured by the stylus. It is considered through dry when the stylus rides above the film.

Circular drying time devices have been developed for use when determining the drying time of bake finishes that cure



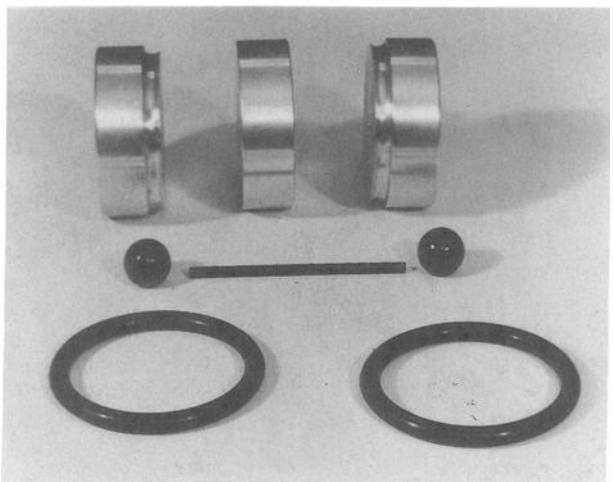


FIG. 6–No pick-up time traffic paint roller. (Courtesy of Byk-Gardner.)

at elevated temperatures [up to 500°F (260°C)]. The compactness of the instrument allows the user to place it in an oven at a specified temperature.

Straight Line Drying Time Recorder

This device consists of multiple needles being drawn over multiple (up to six) parallel coated glass strips [7]. Its speed can be varied to cover drying periods of 6, 12 and 24 h (Fig. 5). It defines the following stages in the drying process:

1. The first stage is a pear-shaped depression corresponding to the time it takes for the solvent to evaporate.
2. The second stage is the cutting of a continuous track corresponding to a sol-gel transition.
3. The third stage is an interrupted track corresponding to the surface dry time.
4. In the fourth stage, the needle no longer penetrates the film, indicating the final drying time.

Five-gram brass weights may be added to apply greater pressure on the needles and thus record through drying. The instrument has also been found useful in evaluating gel time of many two-component surface coatings.

I.C.I. Drying Time Recorder

This instrument consists of a metal box platform which will accommodate flat panels, usually made of glass. A gantry moves between and parallel to the long dimension of the flat panels [8]. This gantry will carry up to three detachable devices for each panel. These include a flock dispenser, a sand hopper, a bandage roller, and a ball-pointed needle. These can be used in any combination to test up to six coatings, three on each panel.

The different stages in drying which can be measured, depending on the device used, are dust free, surface dry, and dry through.

NO PICK-UP TIME TRAFFIC PAINT ROLLER

This device is described in ASTM Standard D 711: Test Method for No-Pick-Up Time of Traffic Paint.

The apparatus consists of a steel cylinder weighing 11 lb, 14 oz (5385 g) with two O-rings [6]. It is rolled along a drying film of traffic paint which has been applied on a glass plate. The paint is dry when no paint adheres to the O-rings (Fig. 6).

Part 10: Optical Properties

40

Color and Light

by Fred W. Billmeyer, Jr.[1] *and Harry K. Hammond, III*[2]

BECAUSE COLOR IS A SIGNIFICANT FACTOR in the appearance of an object, it is an important characteristic of any paint. Appearance, of which color is a part, is one quality of a product that every customer can judge for himself. No matter how good the physical properties of a paint, if its color does not meet the expectation of the customer, the finished product will be rated as unsatisfactory.

Color, often thought to be a property of the paint itself, depends on three objective aspects: (1) the spectral composition of the light in which the paint is viewed, (2) the spectral reflectance of the paint, and (3) the spectral response of the eye of the observer. The subjective interpretation of the response to these aspects by the brain is also an essential part of color. Describing the color of a paint or other material requires consideration of all of these and not merely the spectral character of the material. The three objective aspects of color are considered in sections entitled **LIGHT SOURCE, REFLECTION AND TRANSMISSION**, and **THE EYE**. The sciences involved include chemistry, physics, physiology, and psychology. These are broad subjects, and only enough discussion is included to provide a background for understanding the development of test methods. Readers desiring to pursue these subjects in detail should consult an appropriate text [*1–6*].

TERMINOLOGY

To understand this chapter and to make the best use of it, the reader should be familiar with the terminology of appearance. The precise definition of terms is becoming increasingly important in today's world community. The paint terminology standard, ASTM Definitions of Terms Relating to Paint, Varnish, Lacquer, and Related Products (D 16), is the primary source of terms and definitions relating to paint, but it contains very few appearance terms. The reader should refer to ASTM Terminology of Appearance (E 284) for terms and definitions relating to color and other appearance attributes. All significant terms used in this section are defined in ASTM E 284.

An important international source of appearance terms is the *International Lighting Vocabulary* [*7*], published jointly by the International Commission on Illumination (CIE) and the International Electrotechnical Commission (IEC). However, this is structured from the viewpoint of illuminating engineering. It is less readily available and a much more costly document than ASTM E 284.

LIGHT SOURCES

Light is electromagnetic radiation weighted by the response of the normal human eye. It occupies a small portion of the electromagnetic spectrum between ultraviolet and infrared radiation. Its wavelength range is approximately 380 to 780 nm (Fig. 1).

Natural and Artificial Daylight

Despite modern dependence on interior illumination, daylight is still an important light source since most objects are at some time viewed in it. The spectral composition of daylight, however, is quite variable, depending upon the hour of day, the season of year, and the amount of cloud cover. One way of dealing with this variability is to use standard light sources and their spectral power distributions when making visual or instrumental color measurements and calculations (see later in this chapter under **CIE Standard Sources and Illuminants**).

Incandescent Sources

Other light sources must replace daylight when appropriate. For use in homes, incandescent lamplight is generally preferred because it imparts a soft, mellow effect similar to that of candlelight.

Fluorescent Sources

In stores and offices, fluorescent lamps can provide high levels of illumination with low power consumption and heat generation. The most commonly used fluorescent lamp, known as cool white, has a spectral distribution consisting of a relatively smooth curve throughout the visible spectrum. This arises from the fluorescent emission from a phosphor coated on the inside of the lamp tube. The fluorescence is excited by ultraviolet radiation from mercury vapor inside the tube. This lamp is, however, deficient in power in the red end of the visible spectrum. Modifications of it, known as deluxe and super-deluxe versions, have been designed to overcome this deficiency. Fluorescent lamps have also been

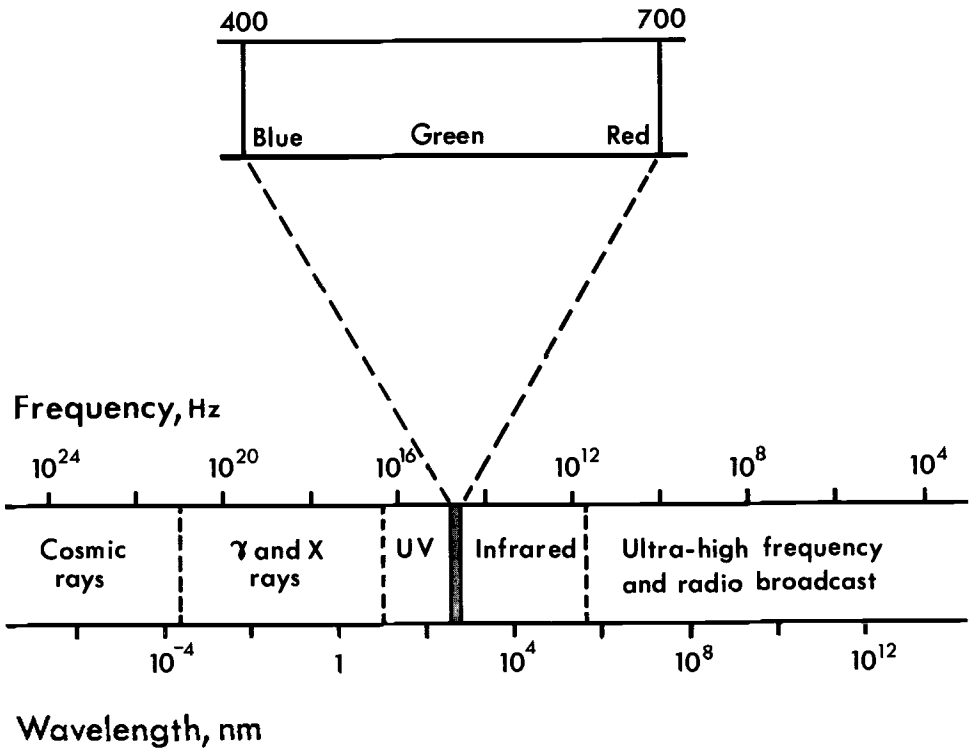

FIG. 1–Electromagnetic spectrum showing the relatively small portion that the visible spectrum occupies.

designed with phosphors emitting only in three rather narrow regions of the spectrum. When these three bands are selected to peak near 450, 530, and 610 nm, light is provided that is especially pleasing to the eye and energy efficient.

The color-balance and color-rendering properties among the various types of commercial fluorescent lamps can be vastly different one from another.

Other Sources

Other light sources have been developed for special purposes. They include arc lamps (sodium, mercury, neon, xenon), metal halide lamps, and high-intensity discharge (HID) lamps. None of these lamps has been adopted as standard for use in color measurement.

Color-Matching Booths

Because of the variation in spectral composition of different natural and artificial sources, it is essential that visual color matching be done under standardized illumination, such as that provided by a color-matching booth. This device allows the colorist to compare the colors of specimens under controlled and standardized illumination. Carefully manufactured and maintained light booths permit a colorist to make a visual match with confidence that the illumination duplicates that used at another time or place. However, the spectral power distribution of daylight illumination in color-matching booths is not the same as that of natural daylight.

REFLECTION AND TRANSMISSION

Opaque, Transparent, and Translucent Films

When light strikes an object, some of it may be reflected, some may be absorbed, and if the object is not opaque, some may be transmitted. The reflected light may be concentrated in a glossy, mirror-like reflection, scattered uniformly in all directions, or distributed between these two extremes, which are known as specular reflection and diffuse reflection, respectively. A highly polished metal can reflect as much as 99% of the incident light in the specular direction. A white powder, such as barium sulfate, scatters light uniformly in all directions, and it, too, can reflect as much as 99% of the incident light. Specular reflection is related to the visual perception of gloss; diffuse reflection is related to the visual perception of lightness and, when it is wavelength dependent, to that of color.

Transmission can also be diffuse or regular, depending on whether or not light is scattered in passing through a material. Specimens that both transmit and reflect light are called translucent.

A spectrophotometer is used to provide information on the spectrally selective character of a material. Figure 2 shows typical spectral reflectance curves of some paints. A trained colorist can obtain valuable information from such curves, but spectral data alone are unsatisfactory as a means for color identification.

Among the ASTM standards on reflectance and transmittance measurement [*8*], the most useful include ASTM Practice for Obtaining Spectrophotometric Data for Object-Color Evaluation (E 1164), ASTM Test Method for Reflectance Factor and Color by Spectrophotometry Using Hemispherical

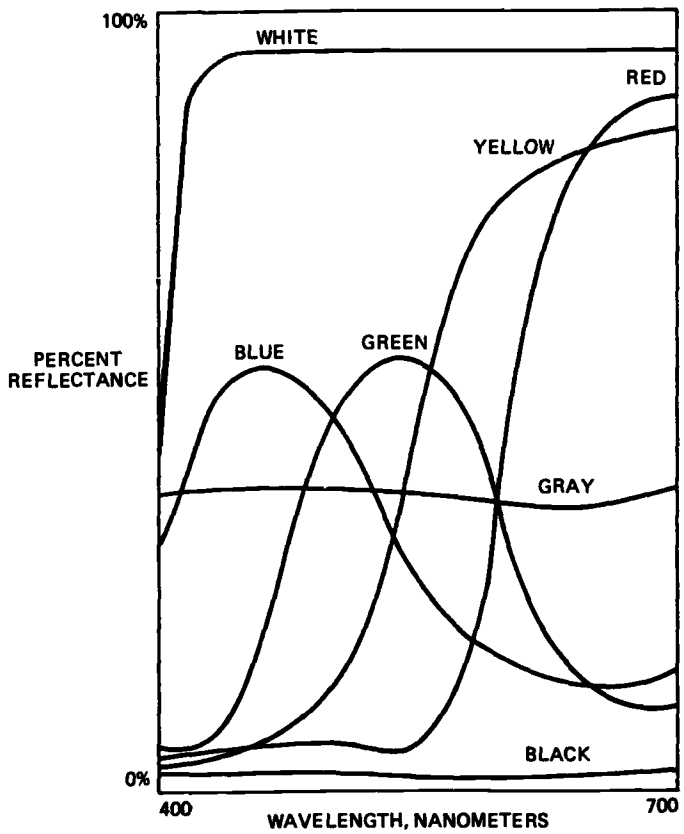

FIG. 2–Spectrophotometric curves typical of those measured on paint films. Note the sharp drop in the curve for rutile titanium dioxide (white) as the violet end of the spectrum is approached. The drop continues in the ultraviolet, where this pigment absorbs light strongly. (Based on Ref. 2.)

Geometry (E 1331), ASTM Test Method for Color and Color-Difference Measurement by Tristimulus (Filter) Colorimetry (E 1347), ASTM Test Method for Transmittance and Color by Spectrophotometry Using Hemispherical Geometry (E 1348), and ASTM Test Method for Reflectance Factor and Color by Spectrophotometry Using Bidirectional Geometry (E 1349).[3]

Ultraviolet and Infrared Spectral Regions

Ultraviolet and infrared radiation can have important effects on paint. Ultraviolet radiation, with wavelengths shorter than 380 nm, is the principal stimulus of fluorescence of certain pigments, is an aid to identification and analytical determination of certain ingredients of paint, and may promote decomposition of pigments or binders. Colorless pigments absorbing in the ultraviolet region can impart protection against such decomposition. Rutile titanium dioxide absorbs in the ultraviolet, as its spectral curve shows (see Fig. 2).

[3]As noted in ASTM E 284, in the Discussion under *reflectance*, "The term *reflectance* is often used in a general sense or as an abbreviation for *reflectance factor*. . . ." This simplifying convention is used in this chapter, as it is in many textbooks. The reader should refer to ASTM E 284 for the definitions of *reflectance, transmittance,* and *radiance,* and the corresponding factors. Note that commercial instruments measure *reflectance factor,* not *reflectance.*

Infrared radiation, with wavelengths longer than 780 nm, is associated with heat transfer. It is widely used for the identification and analysis of chemical compounds. The near-infrared region, with wavelengths from 780 to about 10 000 nm, is important for camouflage detection. Most paint pigments do not absorb radiation in this region, but some inorganic pigments reflect visible light and absorb radiation in the near-infrared.

Fluorescence

Some materials have the property of fluorescing when irradiated by ultraviolet or short-wavelength visible radiation. They emit radiation at longer wavelengths in the visible range or even in the near-infrared. The effect of fluorescence is to increase the apparent reflectance since the eye responds to the sum of the fluoresced and the reflected energy. This sum may even exceed the amount of light reflected by an ideal white material at the wavelengths of maximum fluorescent emission. Many fluorescent pigments have relatively poor lightfastness in outdoor applications.

Most modern colorimeters and spectrophotometers are designed to evaluate properly the colors of fluorescent materials, although many do not have light sources adequately simulating the ultraviolet content of natural daylight. In such a case the instrument will not produce the same amount of fluorescence as would daylight.

Two ASTM standards apply to the measurement of fluorescence. ASTM Test Method for Identifying Fluorescence in Object-Color Specimens by Spectrophotometry (E 1247) provides two instrumental methods to supplement simple visual examination of the specimen under ultraviolet light to detect the presence of fluorescence. ASTM Practice for Color Measurement of Fluorescent Materials (E 991) specifies the instrument geometry required for the measurement and shows how to assess the performance of daylight-simulating instrument light sources.

Retroreflection

Retroreflection is defined in ASTM E 284 as "reflection in which the reflected rays are preferentially returned in directions close to the opposite of the direction of the incident rays. . . ." It is important in paints and coatings used for signs viewed at night, pavement and pedestrian markings, and other safety devices. The measurement of retroreflection requires special instrumentation and special test methods for the determination of daytime and nighttime colors of retroreflecting materials. Among the ASTM standards dealing with this subject are: ASTM Practice for Describing Retroreflection (E 808), ASTM Practice for Measuring Photometric Characteristics of Retroreflectors (E 809), ASTM Practice for Measuring Colorimetric Characteristics of Retroreflectors under Nighttime Conditions (E 811), ASTM Test Method for Coefficient of Retroreflection of Retroreflective Sheeting (E 810), ASTM Test Method for Retroreflectance of Horizontal Coatings (D 4061), ASTM Guide to Properties of High Visibility Materials Used to Improve Individual Safety (F 923), and ASTM Specification for Nightime Photometric Performance of Retroreflective Pedestrian Markings for Visibility Enhancement (E 1501).

THE EYE

The Visual System

The human eye functions in a manner similar to a camera. It has a lens to focus images of objects and an iris to control the amount of light that enters (Fig. 3). A complex light-sensitive layer, called the retina, plays a role analogous to that of the film in a camera. Neither the structure of the retina nor its function are fully understood. It contains two different types of light receptors that send information along neural pathways to the visual cortex of the brain. They are called rods and cones because of their shapes. The rods are responsible for black-and-white vision at low light levels; they are not considered further in this section. At usual daylight levels, the rods are overwhelmed and do not contribute to vision. The cones are responsible for color vision. There are three types of cones, each with a different spectral sensitivity. The exact spectral response of each type of cone is not known, although it is assumed that each cone response function is related to the absorption curve of its pigment. The absorption curves are broad and overlapping (Fig. 4). They peak in the short, middle, and long wavelength regions of the visible spectrum; thus the designations blue, green, and red (sensitive) cones are sometimes used.

Detailed models of color vision have been proposed [*10,11*], but they are presently based on incomplete information. What happens to the neural signals from the retina on the way to and in the brain is not well understood, but for most work related to color and appearance, it does not need to be.

Perception

Perception is defined as the translation of retinal images by the observer into meaningful information about the environment. The perception of objects and their colors thus represents the overall response of the visual system, including both the eye and the brain. Vision is called a psychophysical phenomenon—physical in the way light reaches the eye, psychological in how the brain interprets the neural signals. The psychological factor determines, for example, whether a given color combination is interpreted as pleasing or displeasing. The mechanism of seeing is physical; the interpretation of what is seen is psychological.

Objective color measurement is, however, confined to physical aspects. For example, the perceived color of a specimen may be changed by changing the color of the area surrounding it. This phenomenon, called simultaneous contrast, cannot yet be evaluated instrumentally.

Another example of a perceptual phenomenon is chromatic adaptation, defined as the changes in the visual system's sensitivities due to changes in the spectral quality of the illuminating and viewing conditions. These changes tend to compensate, for example, for the effect of the change in illumination from distinctly bluish daylight to distinctly yellowish incandescent lamplight. The colors of familiar objects tend to appear the same (they tend to exhibit color constancy) when the observer goes between environments illuminated by the two kinds of light. Yet the actual colors have all been shifted because of the change in spectral composition of the incident light.

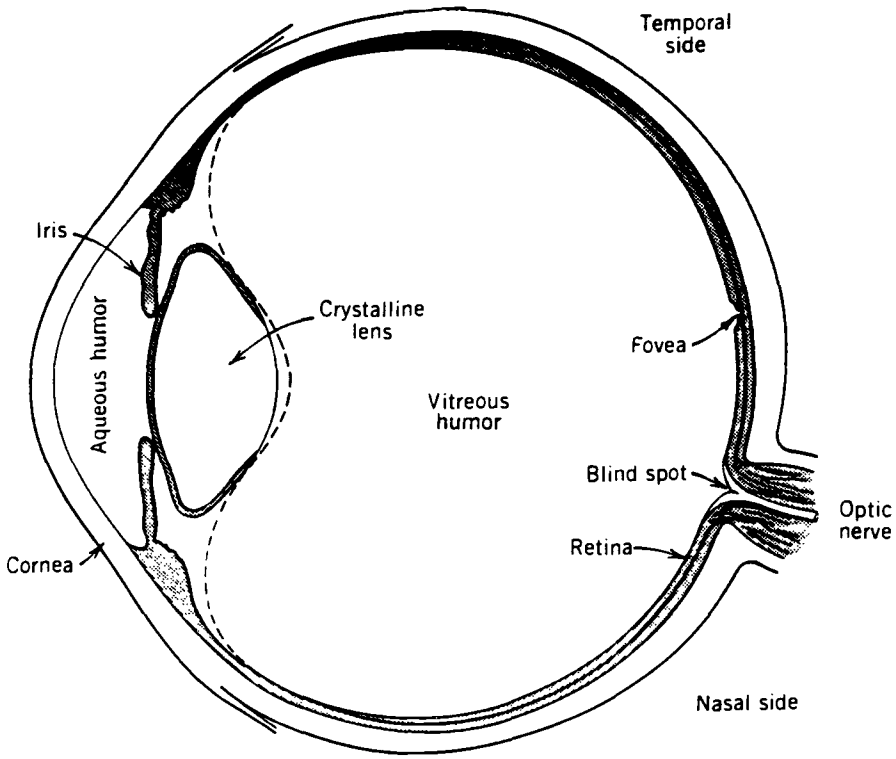

FIG. 3–Cross-sectional diagram of the eye showing features of most interest for color vision [*9*].

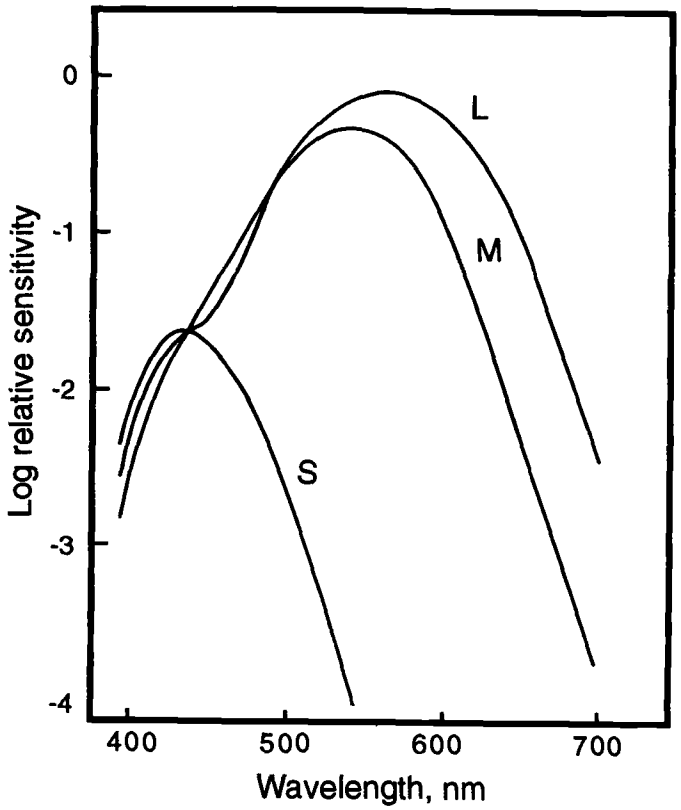

FIG. 4–Spectral curves showing the relative sensitivities of the three types of cones in the eye, peaking in the short (S), medium (M), and long (L) wavelength regions (based on Ref *10*.)

The Variables of Perceived Color

The fact that the eye perceives color because it has three types of cones with differing spectral sensitivities implies, and experience confirms, that perceived color should have three variables. Several sets of these variables are of interest because of their wide use.

Object Colors: Cylindrical Systems

Of great interest to the paint colorist are the variables applying to the perception of object colors. Hue is always one of the variables; the Munsell system (see later in this chapter under **Munsell System**) is an example. Hue is defined as the attribute of color described by common names such as red, yellow, green, blue, etc. The hues are commonly arranged in a circle in the order of their appearance in the spectrum, with the circle closed by the purples, mixtures of the red and blue at the ends of the visible spectrum (Fig. 5).

A second important variable of object colors is lightness, the attribute by which an object is judged to reflect more or less light. It is often represented graphically by a line through the center of the hue circle and perpendicular to its plane (also shown in Fig. 5). The upper and lower ends of this line, often called the neutral or achromatic axis, are white and black, respectively.

The third variable in this set has several different names, referring to variations among what we can perceive: Chroma, saturation, and colorfulness are examples. The common factor among these names is a sense of the amount, in contrast to the kind, of hue in the color. In this section we use chroma as the name for this third variable and show it also in Fig. 5. This quantity is exemplified by the distance between the point representing the color and the neutral axis.

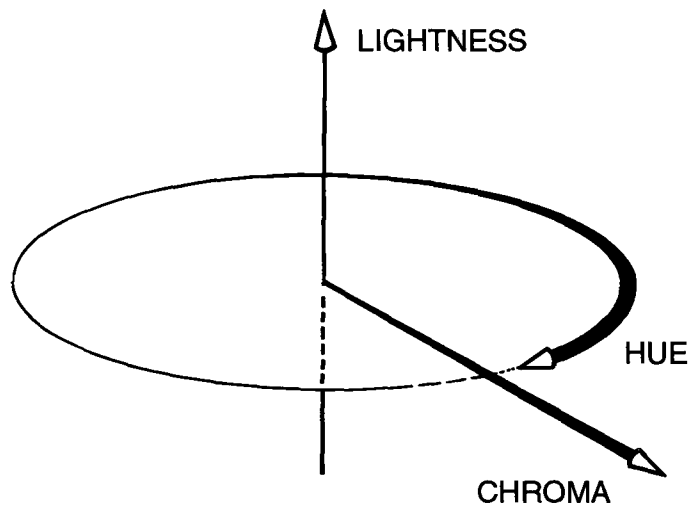

FIG. 5–Arrangement of the hue, lightness, and chroma axes in the usual cylindrical representation of color space.

Colored Lights

When we deal with colored lights instead of objects, two changes need to be made in the above system: Lightness is replaced by brightness and chroma by saturation. Brightness in this sense is defined as the attribute by which an area appears to emit more or less light.

Object Colors: Opponent Systems

A widely used alternative to the hue-lightness-chroma system described above is an opponent-color system that mimics the behavior of the neural signals transmitted from the retina to the brain. The lightness axis, often labeled L, is retained, but the hue circle is replaced by two opponent-type axes at right angles and perpendicular to the lightness axis (Fig. 6). Commonly they are a redness-greenness and a yellowness-blueness axis labeled a and b, respectively, as in the figure. Scales of this type are displayed in many color-measuring systems; examples are given later in this chapter under **COLOR ORDER SYSTEMS**.

Color Constancy and Metamerism

Color Constancy

As previously noted under **Perception**, color constancy is the general tendency of colors to remain constant in appearance when the color of the illumination is changed. Note that this term refers to what happens to the color of a single specimen when the illumination is changed.

Metamerism

Of greater concern to the colorist, because it is of industrial importance and largely under his control, is what happens to the relationship of two colors when the illumination is changed. Suppose, for example, that two colors, matching in

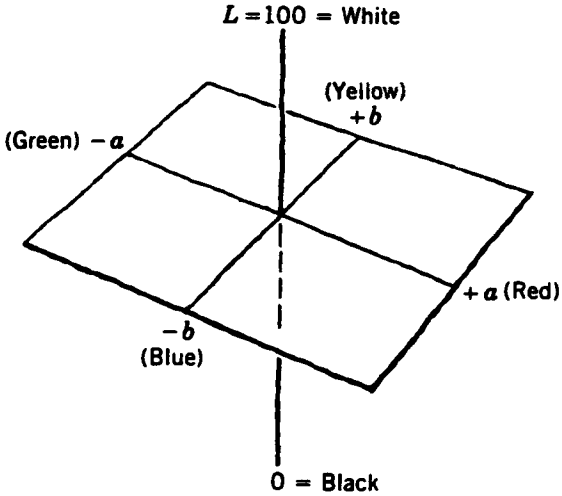

FIG. 6–Arrangement of the lightness, redness-greenness, and yellowness-blueness axes in the usual opponent-color representation of color space [*1*].

daylight, are formulated by using different sets of pigments. The two colors may not match under another type of illumination, such as incandescent lamplight, since the two specimens may exhibit different types and degrees of color constancy. This phenomenon is known as illuminant metamerism, and the colors are said to be metameric. Illuminant metamerism is defined as the property of two specimens having different spectral characteristics (resulting in the example from the use of different pigments; see Fig. 7) and having the same color when viewed under a given source, but different colors when viewed under a different source. Observer metamerism also exists in which two colors match to some observers but not to others.

Only when colors have identical spectral curves can they be expected to match under all types of light and to all observers; this is why the same pigment formulation should be used when remaking the color. Whenever pigments used for the match have different spectral characteristics from those used in the sample, the resultant color match should be tested for the absence of metamerism by several observers and under several different types of illumination, for example, daylight, incandescent lamp light, and fluorescent lamp light, preferably using a color-matching booth. If the match is not satisfactory, spectrophotometric analysis of the two formulations should be carried out to determine their spectral differences, and the new formulation should be adjusted to minimize these differences. ASTM Practice for Visual Evaluation of Metamerism (D 4086) specifies procedures for identifying the presence of metamerism and evaluating it semiquantitatively. Means of minimizing metamerism in both visual and instrumentally aided color matching are described later in this chapter in the section entitled **COLOR MATCHING**.

COLORIMETRY AND THE CIE SYSTEM

Colorimetry is defined as the science of color measurement. Its modern development began in 1931, when, in the interest of standardization and to focus attention on the properties of material objects such as paint films, international standards and recommendations were established by the International Commission on Illumination (Commission Internationale de l'Éclairage, CIE). These recommendations [*12*] define standard lights and observers and a methodology for combining their properties with those of the objects to describe color and related appearance parameters.

CIE Standard Sources and Illuminants

Here it is necessary to note two conventions of CIE terminology [7] reflected in ASTM E 284. A source is defined as a real emitter of light, whereas an illuminant is defined as a

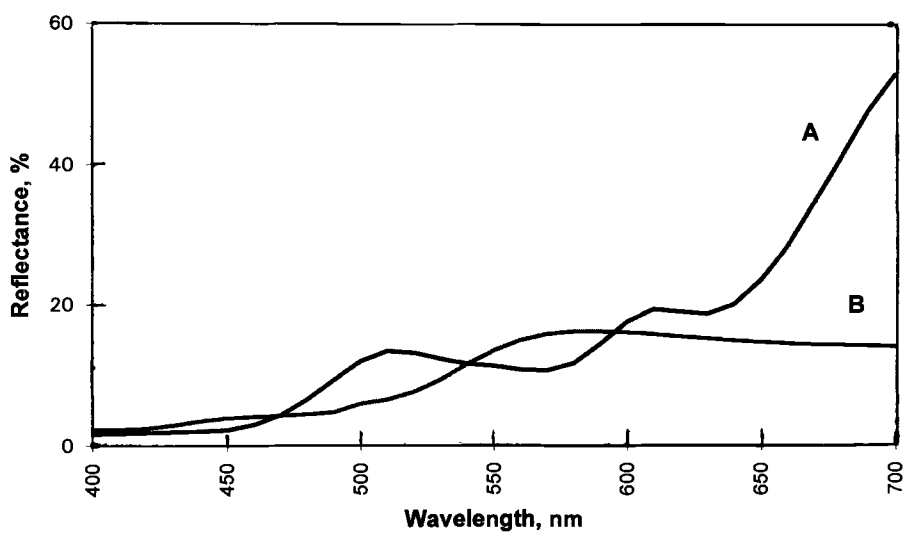

FIG. 7–Spectrophotometric curves of two highly metameric paint films. To most observers, the films match visually and are a dull green color in daylight, but Sample A shifts color to a strong reddish brown in incandescent lamp light while Sample B exhibits color constancy for this change of illumination.

table or figure giving the spectral power distribution of the corresponding source.

Incandescent Source and Illuminant

In 1931, the CIE defined a tungsten-filament incandescent lamp of 2856 K color temperature (see later in this section under **Other Features of the CIE System**) as Source A. Later, when measurement of spectral power distributions became easier, the fundamental definition was changed to the lamp's spectral power distribution, known as Illuminant A. The spectral power distribution of Illuminant A is given in Ref *12*, in a CIE/ISO standard [*13*], and in abbreviated form in ASTM Practice for Computing the Colors of Objects by Using the CIE System (E 308).

Daylight Source and Illuminants

The CIE also recommended in 1931 standard Source C, consisting of liquid filters used in combination with Source A, representing north-sky daylight. Later, the fundamental definition was changed to that of Illuminant C [*12*].

Source and Illuminant C do not duplicate the ultraviolet content of natural daylight and thus do not provide correct daylight color rendition of fluorescent materials. For this reason, the CIE adopted in 1968 a series of standard illuminants duplicating the spectral power distributions of various phases of natural daylight, called the D series. They are designated by their correlated color temperatures (see later in this section under **Other Features of the CIE System**). The most important of these daylight illuminants [*12,13*] is D65, with a correlated color temperature of 6500 K. The spectral power distributions of Illuminant C and several of the D series are tabulated in ASTM E 308. Unfortunately, very few real sources, whether for visual or instrumental use, simulated any of the D illuminants satisfactorily. The CIE has recommended procedures for assessing the quality of daylight simulators [*14*]. The relative spectral power distributions of CIE Standard Illuminants A, C, and D65 are shown in Fig. 8.

Fluorescent Illuminants

In 1986, the CIE defined [*12*], but did not recommend as standard illuminants, a series of twelve spectral power distributions representative of various types of fluorescent lamps, including cool white, lamps simulating daylight well, and three-band lamps. These data should be used when calculations involving fluorescent lamps are required.

CIE Standard Observers

1931 CIE Standard Observer

In order to evaluate colors consistently, a standard observer was defined by the CIE in 1931 [*12,15*] by evaluating the spectral responses of a small group of well-trained individuals. The spectral responses of the CIE 1931 Standard Observer were determined by means of experiments, like those described later in this chapter under **Additive Mixing of Lights**, in which the observer determined the amounts of three primary colors (red, green, and blue) required to match the colors of all wavelengths of the visible spectrum. These sets of three values are called tristimulus values. For convenience, the data were transformed mathematically to correspond to the use of imaginary primary lights designated X, Y, and Z. The Standard Observer is defined by the amounts, $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$, of these primaries required to match the spectrum colors; these are plotted in Fig. 9. The symbol (λ) indicates that the quantity depends on the wavelength, λ. The quantities $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ are known as the color-matching functions of the 1931 CIE Standard Observer.

The transformation from real primaries to X, Y, and Z was made so that the color-matching function $\bar{y}(\lambda)$ is equal to the spectral luminous efficiency function $V(\lambda)$, that is, the effectiveness of radiation to stimulate the perception of light. This choice means that the tristimulus value Y of a given color, called its luminance, contains all the information about the lightness of the color.

1964 Supplementary Standard Observer

The data for the CIE 1931 Standard Observer were obtained with a visual colorimeter in which the field of view subtended an angle of only 2° at the eye of the observer. This was selected to correspond to the size of the fovea, that part of the retina containing only cones used in color vision. Later, the CIE studied color vision in a 10° field, with the central 2° portion disregarded. This corresponds to sample sizes more like those used in commerce, but for which the spectral sensitivity of the eye is somewhat different from that for the 2° field. With the newer data, the CIE established the 1964 Supplementary Standard Observer [*12,15*]; see also ASTM E 308. Where confusion might result, quantities referring to the 1964 Supplementary Standard Observer are given the subscript 10; for example, its color-matching functions are $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, and $\bar{z}_{10}(\lambda)$.

Calculation of Tristimulus Values

The tristimulus values X, Y, and Z of a color can in principle be obtained by direct matching, as were the tristimulus values of the spectrum colors defining the standard observers. But this is impractical, and one of two other methods is always used. One of these involves the design and use of tristimulus (filter) colorimeters and is discussed later in this chapter under **Tristimus (Filter) Colorimeters**. The other requires knowledge of the spectral reflectance curve of the specimen, obtained by spectrophotometry, and the following procedure.

At any wavelength, the contribution to a tristimulus value is given by the product of the relative spectral power of the illuminant, $S(\lambda)$, the reflectance of the specimen, $R(\lambda)$, and one of the color-matching functions of the observer, for example, $\bar{x}(\lambda)$. These products are summed over the visible wavelengths, then normalized by multiplication by a normalization factor k; for example,

$$X = k\,\Sigma\, S(\lambda)\, R(\lambda)\, \bar{x}(\lambda)$$

(and similar equations for Y and Z), where Σ is the sign for summation over the visible wavelength region. The quantity k is chosen to make Y for perfect white equal to 100:

$$k = 100/\Sigma\, S(\lambda)\, \bar{y}(\lambda)$$

The CIE had defined "perfect white" as the perfect reflecting diffuser, the ideal reflecting surface that neither absorbs or transmits light, but reflects all of it. Most textbooks,

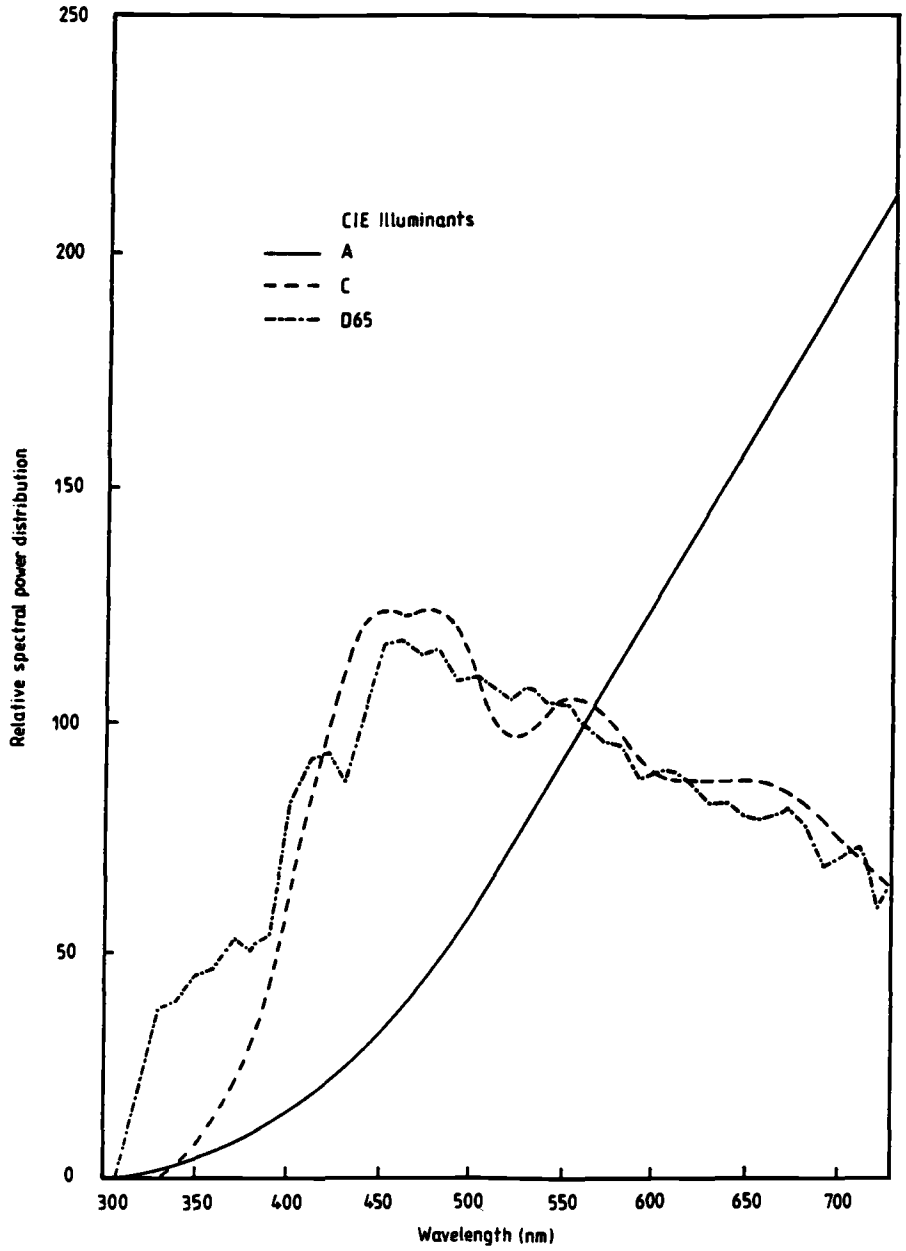

FIG. 8–Relative spectral power distributions of CIE standard Illuminants A (incandescent lamp light), C (north-sky daylight), and D65 (actual daylight) [*6*].

ASTM E 308, and Ref *12* provide examples of the use of these equations. Because the fundamental process is integration, for which summation is an approximation, the process is usually referred to as (tristimulus) integration.

If a large number of sets of reflectance data are to be integrated for the same illuminant and observer, it is convenient to combine quantities such as $S(\lambda)\,\bar{x}(\lambda)$ by multiplying them together and normalizing the products so that $k = 1$. The resulting tristimulus weighting factors can then be stored and used by multiplying them by whatever function $R(\lambda)$ is desired. The CIE has not tabulated or recommended specific sets of tristimulus weighting functions, but a substantial number can be found in ASTM E 308. They may be used for wavelength intervals of 10 or 20 nm. For closer intervals, such as 5 or 1 nm, the tables in E 308, Ref *12*, or Refs *13* and *15* should be used.

Chromaticity Coordinates and Diagram

An important use of the CIE tristimulus values X, Y, and Z is the calculation of coordinates describing the chromaticity of a color, that is, its hue and chroma, ignoring its luminance or lightness. The CIE chromaticity coordinates x, y, and z are computed from the tristimulus values X, Y, and Z by dividing each of these by the sum $X + Y + Z$. Thus $x = X/(X + Y + Z)$, etc. Since $x + y + z = 1$, only two chromaticity coordinates need be given; usually they are x and y. These chromaticity coordinates can be plotted to yield the 1931 CIE x, y chromaticity diagram, shown in Fig. 10, or the 1964 CIE x_{10}, y_{10} diagram for the Supplementary Standard Observer; the two are quite similar.

Features of the chromaticity diagrams include: (1) the locations of the spectrum colors around the horseshoe-shaped

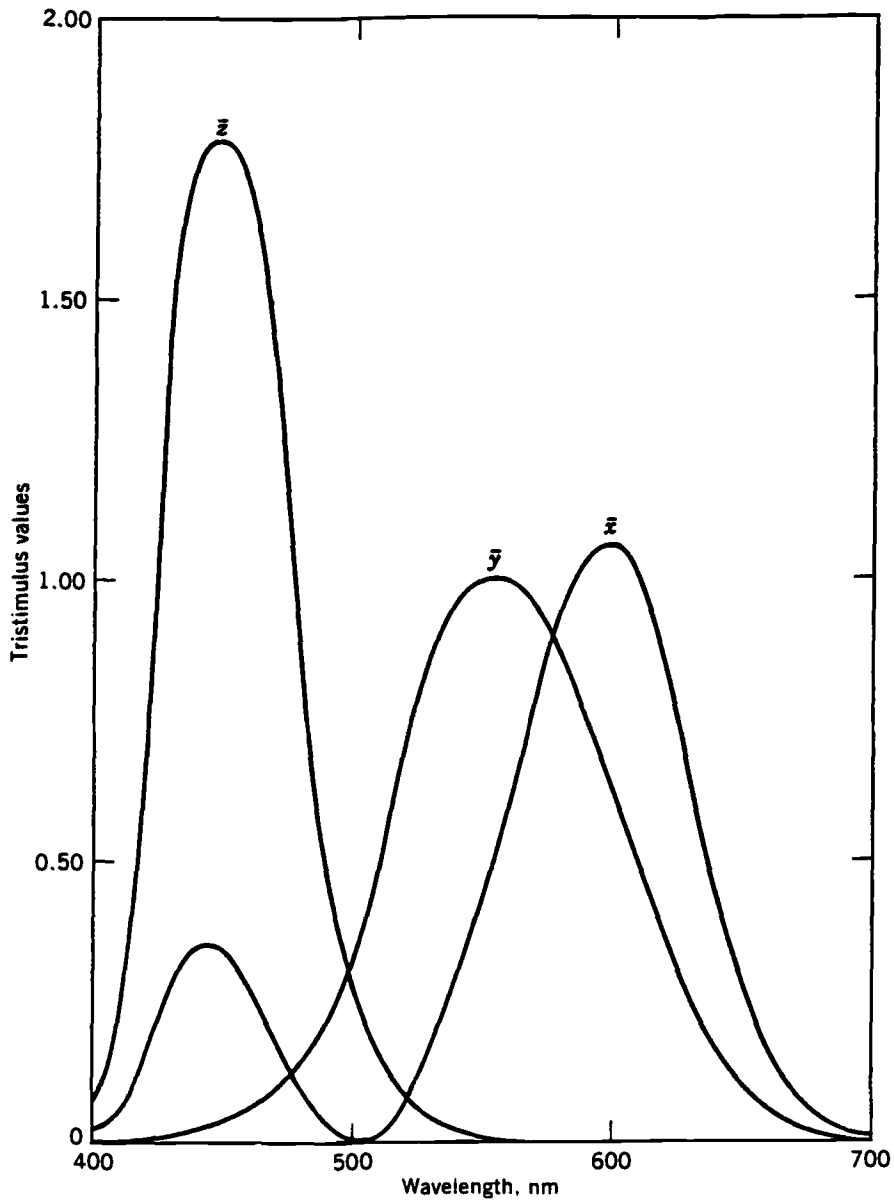

FIG. 9—The color-matching functions of the CIE 1931 standard observer; they are the tristimulus values of the colors of the spectrum [*1*].

spectrum locus, from 400 nm (violet) at the lower left to 700 nm (red) at the right; (2) the straight line along which purples lie joining these two ends of the spectrum locus; and (3) the location of whites (illuminant points) near the middle of the diagram. As an alternative to the three tristimulus values, colors can be specified by the chromaticity coordinates x and y together with the luminance Y (or their equivalents in the 1964 system). These can be arranged in a three-dimensional color space (Fig. 11).

Other Features of the CIE System

Dominant Wavelength, Complementary Wavelength, and Purity

Dominant wavelength is defined as the wavelength along the spectrum locus at the end of a line drawn from the white point (usually Illuminant C) through the sample point to the spectrum locus. For purple colors where the line would end at the purple locus, it is extended back through the white point to the spectrum locus, and the wavelength at that point is designated as the complementary wavelength of the sample. The fractional distance from the white point to the sample point relative to the distance to the spectrum or purple locus is called the (excitation) purity of the sample. Dominant wavelength correlates well with the hue of the sample, but purity does not correlate well with any perceived quantity and is little used today.

Blackbody Locus, Color Temperature, and Correlated Color Temperature

When a metal, such as a lamp filament, is heated, it first radiates heat in the infrared region, then light with a chromaticity at the red corner of the diagram. As it gets hotter, the chromaticity shifts through the oranges and yellows. The line

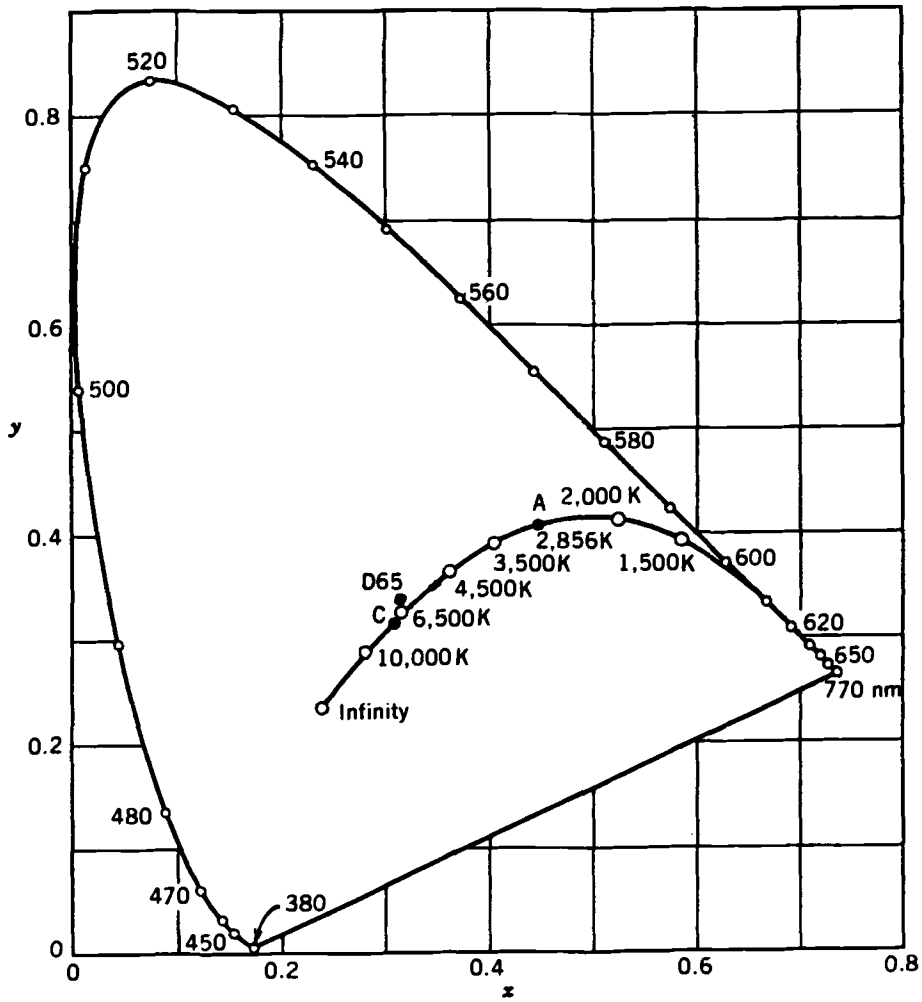

FIG. 10—The CIE 1931 *x,y* chromaticity diagram showing the various features described in the text [*1*].

along which these chromaticities lie for perfect absorbers and emitters of radiation is called the blackbody locus and is shown in Fig. 10. If the metal did not melt, its color would continue along this locus through white to light blue at infinitely high temperature. The temperature of a perfect blackbody can be correlated with its chromaticity and is called the color temperature of the body. It is measured in kelvins, K; the color temperature of Illuminant A is, for example, 2856 K. Many light sources, including the phases of daylight and fluorescent lamps, have chromaticities that are close to, but not on, the blackbody locus. In that case, the color temperature closest to the chromaticity of the source is used and called its correlated color temperature. An example is Standard Illuminant D65, with a correlated color temperature of 6500 K.

Uniform Color Spaces

From almost the beginning of the CIE system, it was recognized that distances in the CIE space did not correlate well with visual estimates of the magnitudes of color differences. Many proposals have been made for deriving quantities that are more uniformly visually spaced. In 1976, the CIE recommended two more nearly uniform color spaces that, although not perfect, have been widely used. Here we describe the one that is most widely used in the paint and related industries and mention briefly the second, more useful when colored lights are considered. The equations for these two spaces, known by official acronyms CIELAB and CIELUV, are found in Refs *1* to *6* and *12* and in ASTM E 308.

CIE 1976 L*, a*, b* *(CIELAB) Space*

CIELAB is an opponent-type color space, with a lightness axis L^*, a redness (positive values)-greenness (negative) axis a^*, and a yellowness (positive)-blueness (negative) axis b^*, all mutually perpendicular, as illustrated in Fig. 6. The transformations from Y to L^*, from X and Y to a^*, and from Z and Y to b^* are all nonlinear, using cube-root functions.

The equations for these transformations are:

$$L^* = 116\,(Y/Y_n)^{1/3} - 16$$

$$a^* = 500\,[(X/X_n)^{1/3} - (Y/Y_n)^{1/3}]$$

$$b^* = 200\,[(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}]$$

where X_n, Y_n, and Z_n are the tristimulus values of the illuminant or white point, and there are some restrictions on the

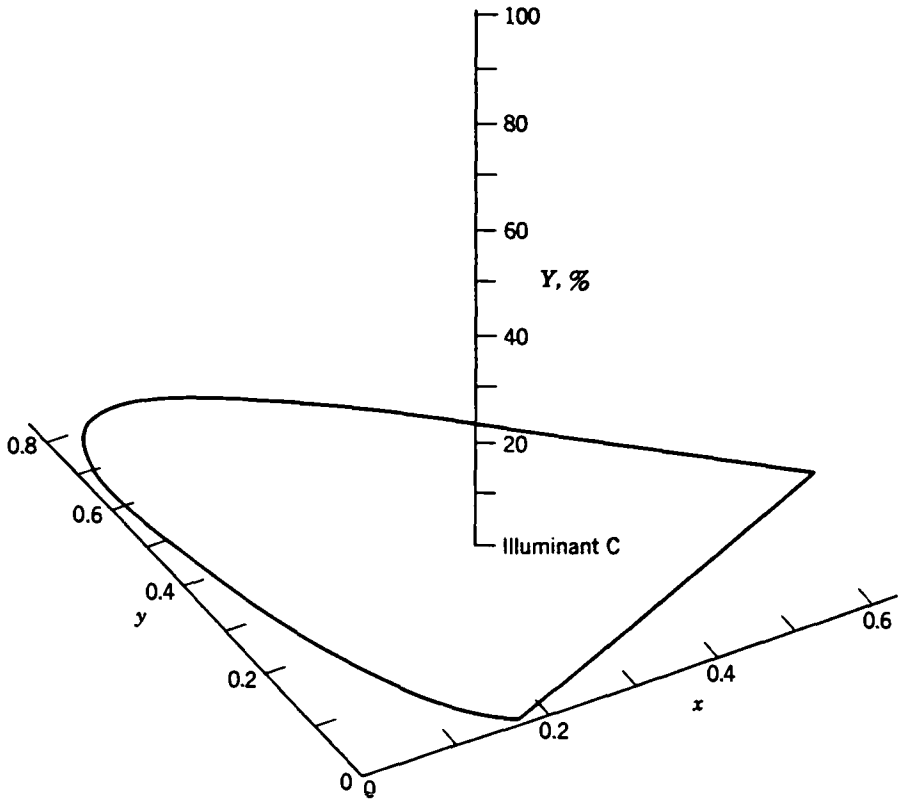

FIG. 11—A three-dimensional representation of CIE color space with the luminance (lightness) axis *Y* rising above the chromaticity diagram [*1*].

use of the equations for very small values of X, Y, or Z described in the references cited above.

Because CIELAB does not have tristimulus values or chromaticity coordinates as defined for the 1931 and 1964 CIE systems in **Chromaticity Coordinates and Diagram**, it does not have a chromaticity diagram.

An alternative set of CIELAB coordinates retains L^* but combines a^* and b^* to give chroma C^* and hue angle h (measured in degrees):

$$C^* = (a^{*2} + b^{*2})^{1/2}; \quad h = \tan^{-1}(b^*/a^*)$$

These correlate well with visual judgments of lightness, chroma, and hue, respectively. Perhaps the widest use of CIELAB is in the calculation of color differences (see later in this chapter under **Color Difference Calculations**).

CIE 1976 L*, u*, v* *(CIELUV) Space*

The CIELUV space has a chromaticity diagram with coordinates u' and v', which are linear transformations of x and y, respectively. The linearity is important for the additive mixing of colored lights (see later in this chapter under **Additive Mixing of Lights**). For the three-dimensional CIELUV space, these are combined with the (nonlinear) L^* transformation to give opponent-type axes u^* and v^*, whose meanings are the same as those of CIELAB a^* and b^*, respectively. An alternative set of hue angle and chroma coordinates, like those in CIELAB, and a color-difference equation, much less widely used than the CIELAB equation, are also part of this system.

COLOR ORDER SYSTEMS

In this section are discussed briefly the major color order systems, consisting of physical exemplifications or atlases illustrating underlying systems. References *16* and *17* provide useful general coverage.

Munsell System

Dating from the early 1900s, the Munsell system is accepted by most users as the standard for equal visual spacing. It is described in ASTM Test Method for Specifying Color by the Munsell System (D 1535). Its color solid is like that of Fig. 5 with the sole exception that lightness is called *value* in the Munsell system. Munsell Hue is designated by position around the hue circle in a notation combining letters designating five major hues (red, yellow, green, blue, purple) and their pairs (R, YR, Y, GY, G, BG, B, PB, P, RP) with numbers from 1 to 10. Munsell Value, to which CIE lightness L^* is a good approximation, runs from zero for black to 10 for white. Munsell Chroma, which expresses the degree of departure of the color from the gray of the same lightness, starts at zero and is open-ended. To describe a color in the Munsell system, the hue, value, and chroma are noted in a prescribed sequence, as for example, 8R 4/10. This designation indicates that the hue is red (toward yellow-red), the value is 4, and the chroma is 10.

The *Munsell Book of Color* is available in two collections of painted color chips. The glossy finish collection contains approximately 1600 removable chips, the matte collection ap-

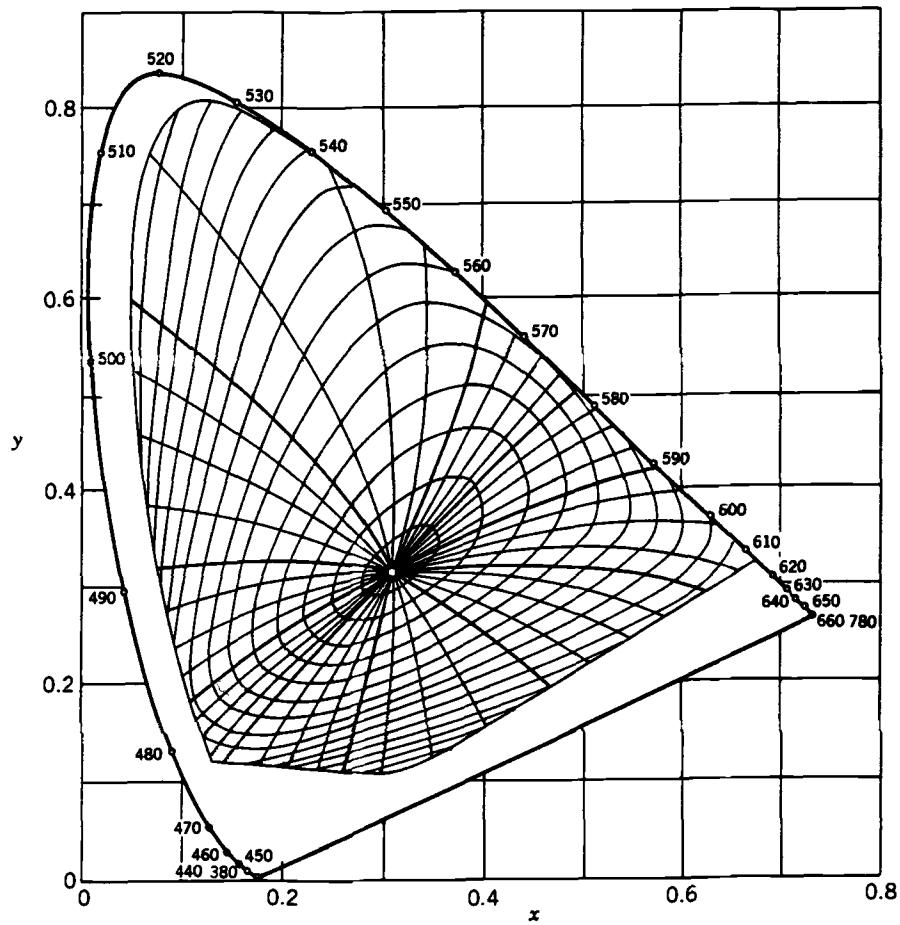

FIG. 12–Lines of constant Munsell Hue and closed curves of constant Munsell Chroma, at Munsell Value 5 plotted on the CIE 1931 chromaticity diagram [*19*].

proximately 1200 permanently mounted chips. The chips are arranged on pages of constant Munsell Hue; in any one row they are perceived as having the same Munsell Value and in any one column as having the same Munsell Chroma when viewed under daylight illumination on a medium-gray background. The colors progress from very light at the top to very dark at the bottom and from neutral at the left to high chroma at the right (or the reverse on facing pages). In 1943, the underlying Munsell system was defined in colorimetric terms [*18*], and since 1968 the chips in the glossy editions of the *Munsell Book of Color* have been produced to match these specifications. Figure 12 shows contours of equal Munsell Hue and Chroma at Value 5 on the 1931 CIE x, y chromaticity diagram.

ISCC-NBS System

In the 1950s the Inter-Society Color Council (ISCC) and the National Bureau of Standards (NBS) developed the ISCC-NBS Method of Designating Colors [*20*] based on the Munsell system but grouping similar colors to produce a smaller number (267) of categories. These are designated by descriptive color names, for example, dark reddish orange for the group containing 8R 4/10.

Universal Color Language

The Munsell system and the ISCC-NBS system are both parts of a Universal Color Language [*20*], a six-level system for describing color to any desired degree of accuracy. Level 1 consists of the use of 13 hue and neutral names. At this level, the color with Munsell notation 8R 4/10 would be described as orange. In Level 2, which has 29 categories, intermediate hue names are added. Here the color would be described as reddish orange. Level 3 is the ISCC-NBS system, and Level 4 is the Munsell system as used in the *Munsell Book of Color*; designations at these levels are given above. Level 5 uses interpolated Munsell notations based on visual comparison of the color with *Munsell Book* chips. With practice it is possible to interpolate accurately to 1/10 value step, 1/4 chroma step, and from 1 hue step at chroma /2 to 1/4 hue step at chroma near /10 and above. Thus, at this level the color might be designated very accurately as 8.25 R 4.1/9.75. The final stage, Level 6, of the Universal Color Language is based on the results of color measurement, expressed as CIE chromaticity coordinates x, y, and Luminance Y. Now the color might be specified with greatest accuracy as $x = 0.527$, $y = 0.343$, $Y = 12.5$.

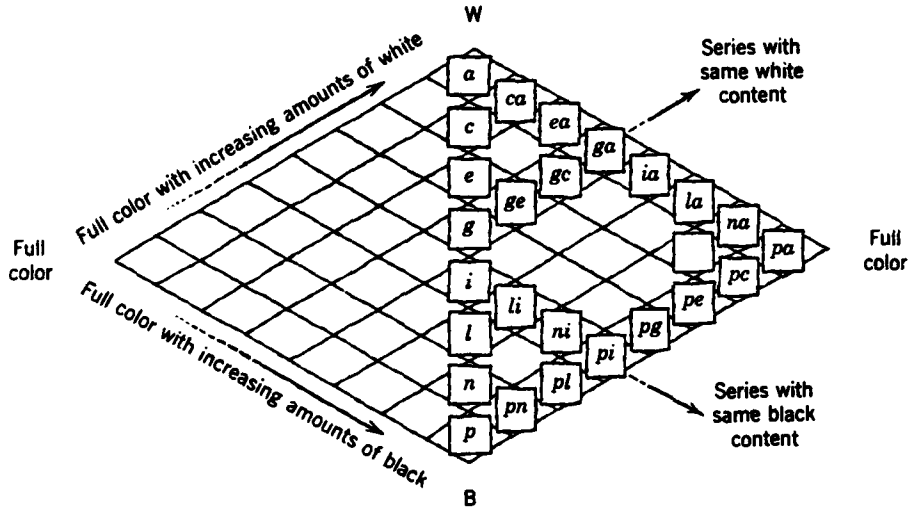

FIG. 13–Two opposing constant-hue pages in the Ostwald system [*1*].

Ostwald System

This system [*21*], which is not illustrated by any set of samples now commercially available, consists of 24 charts of approximately constant hue containing sets of chips having nearly constant chroma but different lightnesses. The chips are arranged (Fig. 13) on each chart in a triangular array, as shown. The most important atlas based on the Ostwald system in the United States was the *Color Harmony Manual*, available in the 1940s and 1950s [*22*].

DIN System

The DIN Color System is the official German Standard Color System [*23*]. Its coordinates are hue (for which dominant wavelength is used), saturation (like chroma except representing difference from black instead of from gray of the same lightness), and relative darkness. Contours of constant DIN hue and saturation, applicable to all lightness levels, are shown on the 1931 CIE x, y diagram in Fig. 14. From time to time, atlases of DIN samples have been available in glossy and matte finish and in transparent films. In the former two, chips are arranged on pages of constant hue, similar to the Munsell arrangement.

Natural Color System

Developed in the late 1960s and 1970s, the Natural Color System (NCS) [*24*] is the national standard color order system in Sweden and several other European countries. It is based on an entirely different principle from that of the other systems discussed, namely the resemblances of colors to six imaginary elementary colors, unique red, yellow, green, and blue, and black and white. The four hues are placed 90° apart on the hue circle. This does not lead to visually equal hue spacing. Two opponent-type axes result, perpendicular to the black-white lightness axis. The third variable of the system is chromaticness.

In terms of resemblances, hue is defined as the resemblance of a color to the two nearest chromatic elementary colors. For example, an orange might be said to have 80% resemblance to red and 20% to yellow; its hue notation would be Y80R. Chromaticness is the resemblance of the color to the (imaginary) color of the same hue having the maximum possible chromatic content. Lightness is not an explicit variable in the system; the third resemblance can be to either white or black. Scales of resemblances to white, black, and the aforementioned maximally chromatic color are chosen so that these three add to 100%, so only one of the resemblances to white or black need be specified. For the notation, resemblance to black has been selected, so that the three variables of the system are blackness, chromaticness, and hue. The complete NCS notation for the orange sample considered above in the Munsell system, for example, is approximately 3070 YBOR.

In the NCS atlas, pages of constant hue notation contain chips arranged on a grid in the form of an equilateral triangle, as shown in Fig. 15. Note that there is a similarity to the Ostwald triangle, the difference being that in the Ostwald system the corner points are real samples; in the NCS, they are imaginary elementary colors. The NCS is subsidized by the Swedish government and aggressively marketed, and thus is available at lower cost than most other atlases.

OSA-UCS System

The Optical Society of American Uniform Color Scales system [*25,26*] was developed by a committee of the OSA between 1947 and 1976. Although the committee concluded that no perfectly equally visually spaced system can exist because color space itself is not Euclidean, it attempted to achieve the best possible compromise and is generally thought to have succeeded. The 558 samples of the OSA atlas are arranged in a rhombohedral lattice in which each sample, except those at the edges, has twelve nearest neighbors. The axes of the color solid are lightness, L (with both positive and negative values around zero at middle gray) and two opponent axes, j (from the French *jaune* for yellow), with positive values toward yellow and negative values toward purple-blue, and g (for greenness), with blue-greens at the positive end and

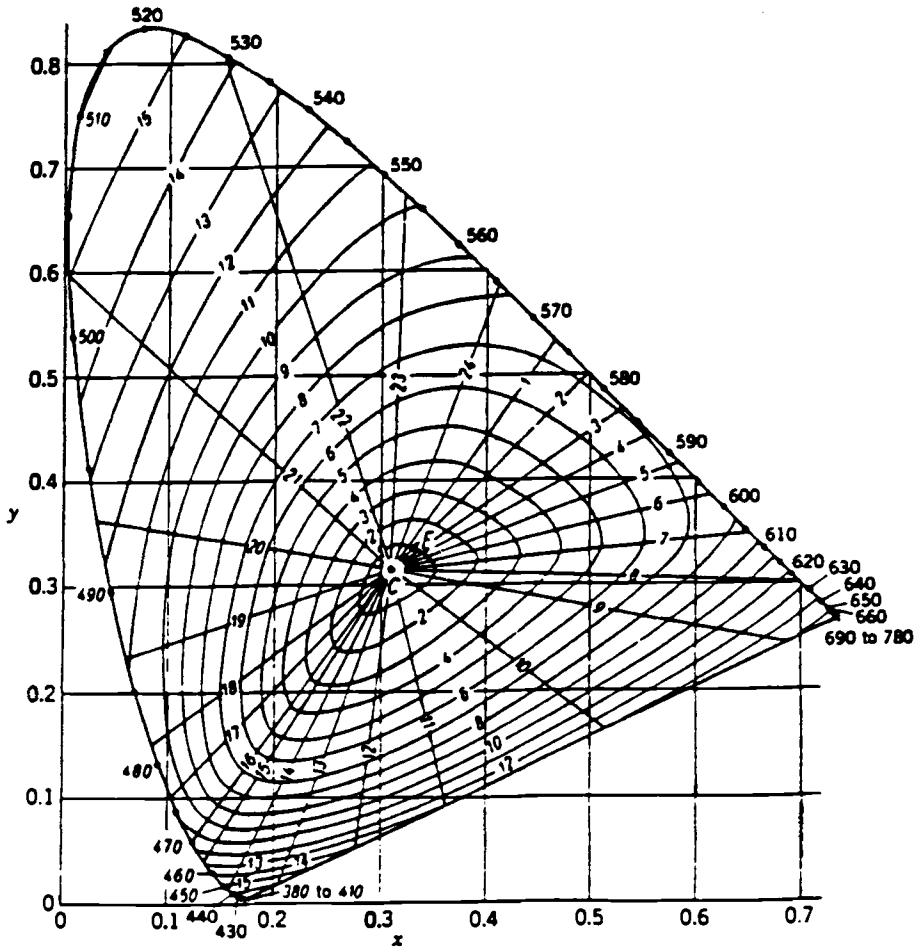

FIG. 14–Lines of constant DIN hue and closed curves of constant DIN saturation on the CIE 1931 chromaticity diagram. The figure applies to all DIN darkness levels [*16*, modified from *23*].

pinks at the negative end. One of the features of the lattice is the existence of many planes of closely related samples, sometimes varying along all three axes, that appear strikingly beautiful.

The OSA-UCS system is described in ASTM Practice for Specifying Color by Using the Optical Society of America Uniform Color Scales System (E 1360). A portion of the OSA-UCS lattice illustrating the arrangement of samples is shown in Fig. 16, and Fig. 17 shows the spacing of samples of the $L = 0$ plane on the 1964 CIE x_{10}, y_{10} diagram.

Colorcurve System

This new color order system was introduced in the United States in 1989. It is based on a color space similar to CIE 1964 tristimulus space [*27*]. Aim points are laid out according to additive mixing (see subsection later in this chapter entitled **Additive Mixing of Lights**) of CIE 1964 tristimulus values X_{10}, Y_{10}, Z_{10} for Illuminant D65, starting from eight specified CIELAB points. The CIELAB lightness axis L^* (designated only as L) is retained, but coordinates along the CIELAB-type opponent axes are replaced by a simple numbering system giving the sample location in terms of the number of lattice steps between it and the neutral axis in the directions of two adjacent major axes directed toward reds, yellows, greens, and blues. A typical Colorcurve notation would be L40 R1Y3, representing at lightness level 40 the lattice point one step away from neutral toward the reds and three steps toward the yellows. This is an orange only slightly different from the sample discussed above. The Colorcurve atlas contains about 2200 painted samples.

Another feature of the Colorcurve system is that spectral reflectances are furnished for the aim points. These can be additively mixed like tristimulus values to obtain the spectral curve corresponding to any Colorcurve notation; this can be the basis for computer colorant formulation (see subsection later in this chapter entitled **Instrumental and Computer-Aided Color Matching**) to provide a match with minimum metamerism to the surrounding Colorcurve samples. ASTM Practice for Specifying and Matching Color Using the Colorcurve System (E 1541) describes the system in more detail, including a tabulation of spectral reflectances, tristimulus values, and CIELAB coordinates for the sample aim points.

Printed Systems

For each of the color order systems described above, atlas samples consist of painted chips individually matched to the

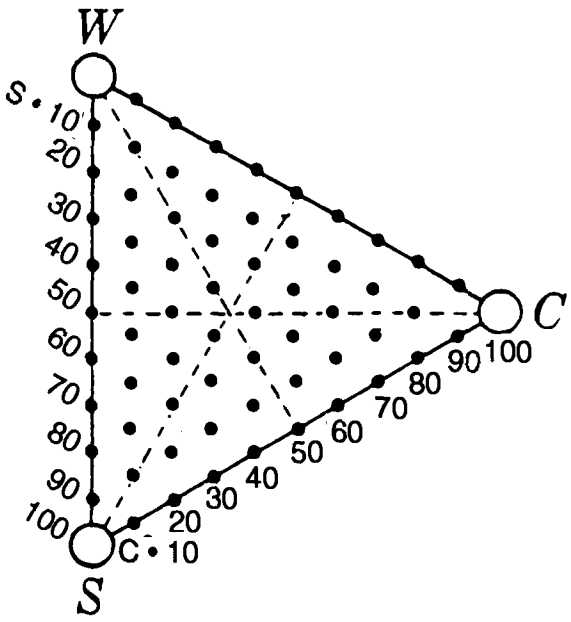

FIG. 15–Arrangement of colors on a constant-hue page in the NCS system. They are located according to their resemblances to ideal white (W), ideal black (B), and the imaginary Color C having 100% chromaticness [*24*].
