
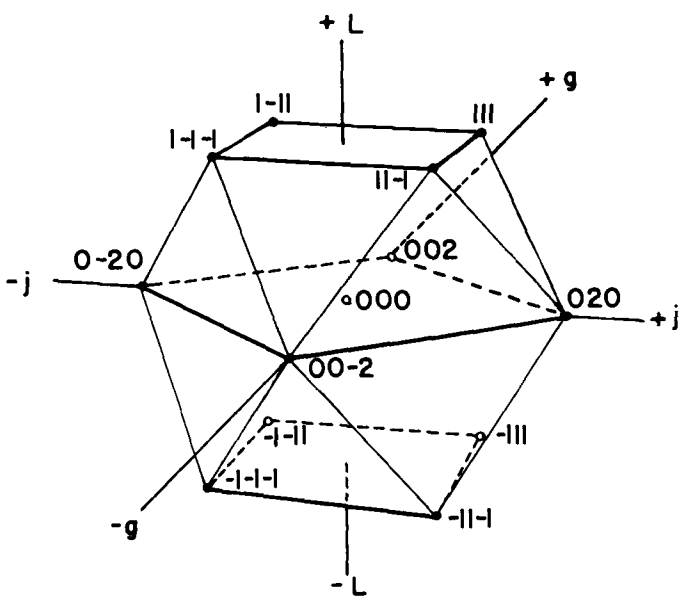

FIG. 16–Cuboctahedron around the center point of the OSA system showing its three axes, ± *L* (lightness), ± *j* (yellowness-blueness), and ± *g* (greenness-redness). There are twelve nearest neighbors around the center point, with the *L,j,g* coordinates shown. The entire OSA space is formed by extending this figure in all directions [*16*].

specified aim points with a mean accuracy of about one CIELAB unit. Many other collections, produced by printing, exist. Of necessity, they all have the characteristic that large groups of samples are produced at the same time; it is not possible to adjust the color of each one individually for closest conformance to the aim point. In many instances average accuracy is much poorer than that for the painted atlases,

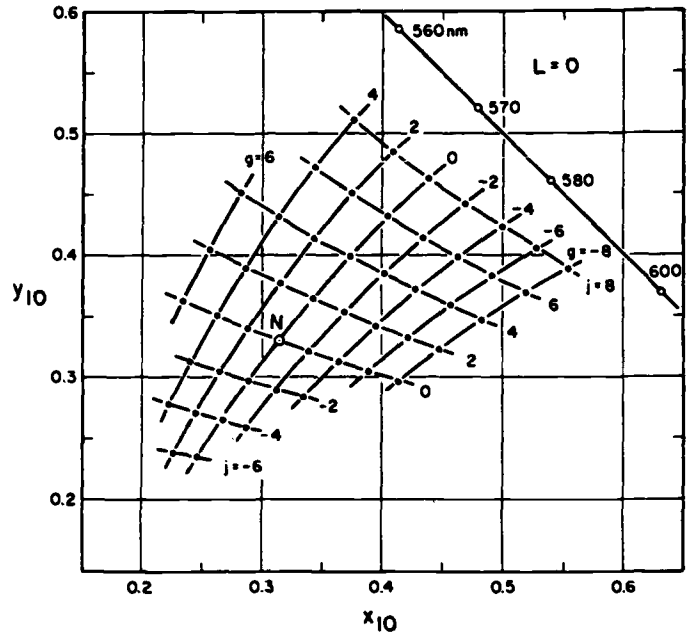

FIG. 17–Section of the CIE 1964 x_{10}, y_{10} diagram showing the locations of points on the *L* = 0 plane of the OSA system (ASTM E 1360, from Ref *3*).

and it is especially difficult to reproduce the samples accurately in subsequent printings or editions. Their cost is, however, relatively low.

Single-Number Color Scales

Occasions arise in which the colors of samples vary along a single direction in color space. In such a case the color can be described adequately by a single scale value. Three cases are of interest: whiteness, yellowness, and series ranging from colorless to highly colored as the concentration of a colored component increases.

Whiteness Indices

Whiteness scales start at the point corresponding to an ideal white, which may be the perfect reflecting diffuser (see subsection earlier in this chapter entitled **Calculation of Tristimulus Values**) or some other industry standard, often assigned a whiteness of 100. From this number are subtracted amounts corresponding to departures toward lower lightness and the addition of chromaticness. For example, in ASTM Test Method for Indexes of Whiteness and Yellowness of Near-White, Opaque Materials (E 313), the recommended equation for whiteness index *WI* can be expressed in terms of CIE 1931 tristimulus values for Illuminant C as

$$WI = Y - 4(0.847Z - Y)$$

The first term is the luminance, *Y*, which approximates perceived lightness, and the second term is a measure of departure from white toward yellow. The CIE has defined a whiteness index [*12*] as

$$W = Y + 800(x_n - x) + 1700(y_n - y)$$

where x and y are the 1931 chromaticity coordinates of the sample with lightness Y, and x_n and y_n are the values for the

illuminant point. CIE 1964 values can also be used. This equation allows for departures from white in any hue direction, weighted by the factors shown. In each case the value for the perfect white is 100.

Yellowness Indices

Indices of departure from achromatic toward yellow are formulated similarly to the second term in the ASTM E 313 WI equation given above. The indices start at zero and increase as yellowness increases. In ASTM E 313, the yellowness index YI is given by

$$YI = 100(1 - 0.847Z/Y)$$

A similar equation, given in ASTM Test Method for Yellowness Index of Plastics (D 1925), includes the effect of change in tristimulus value X as well as Y and Z

$$YI = 100[(1.28X - 1.06Z)/Y]$$

This equation is equally applicable to paint films.

Scales for Liquids

When only a limited range of color is involved, for example, in the testing of the color of oil, clear varnish, lacquer, or solvents used in the paint industry, simple methods are used consisting of comparison of the specimen with standard colored solutions or glasses ranging from colorless to highly colored. A standardized series of these colors is used to provide a specialized color scale. The color is often a measure of concentration of ingredient. One difficulty in the use of these special color scales is that the color of the specimen may not match that of the standard; this can make rating on a single-number scale difficult. Nevertheless, their simplicity, low cost, and adaptability to special situations has resulted in wide use of single-number scales for certain applications. Among such scales useful to the paint industry are those described in ASTM Test Method for Saybolt Color of Petroleum Products (Saybolt Chromometer Method) (D 156), ASTM Test Methods for Soluble Nitrocellulose Base Solutions (D 365), ASTM Test Method for Color of Clear Liquids (Platinum-Cobalt Scale) (D 1209), ASTM Test Method for ASTM Color of Petroleum Products (ASTM Color Scale) (D 1500), ASTM Test Method for Color of Transparent Liquids (Gardner Color Scale) (D 1544), ASTM Test Method for Color of Solid Aromatic Hydrocarbons and Related Materials in the Molten State (Platinum Cobalt Scale) (D 1686), and ASTM Test Method for Measurement of Color of Low-Colored Clear Liquids Using the Hunterlab Color Difference Meter (E 450). These and other single-number color scales were intercompared [*28*].

INDUSTRIAL COLOR MEASUREMENT

Instruments Using the Eye as Detector

The eye is the ultimate arbiter in color evaluation because, of course, it passes the final judgment on the acceptability of a color. The first color-measuring instruments used the eye as detector, and this practice is still followed when use of a simple color comparator suffices, as in many of the test methods for single-number color scales described in the preceding paragraph. But there are many factors, such as fatigue, poor color memory, and subjectivity, as well as the perceptual phenomena described earlier under **Perception**, that make the eye at least suspect for close color evaluation work. Therefore the use of the eye as detector has been almost entirely replaced by the use of two types of photoelectric instruments developed since the 1940s for color measurement.

Spectrophotometers

Spectrophotometers provide detailed information on the color properties of specimens, in the form of spectral reflectances (or transmittances), required for the calculation of CIE tristimulus values and derived color coordinates, as described earlier under **Colorimetry and the CIE System** and in ASTM E 308. Spectrophotometers are described here and their abridgments in the form of tristimulus (filter) colorimeters in the next section.

When radiation strikes a sample, it may be reflected, absorbed, or transmitted. Each of these can be measured by most spectrophotometers. All spectrophotometers consist of a light source, a monochromator, arrangements for illuminating and viewing the sample, a photodetector, and an output device. In modern instruments, the latter consists of a computer that processes the signals from the detector and provides for the calculation of tristimulus values and a wide variety of other color-related quantities. Each of these components is described briefly.

Light Source

In most cases the exact nature of the light source in a spectrophotometer is of little importance as long as it has adequate power and stability at all wavelengths in the visible spectrum. Incandescent lamps or xenon flash tubes are widely used. When fluorescent samples are measured (see earlier under **Fluorescence**), the source must illuminate the sample directly and may be filtered to simulate a standard source, such as CIE daylight D65. Most color measuring spectrophotometers are designed with these features. ASTM E 991 provides more information on the measurement of fluorescent samples.

Geometry of Illumination and View

In most spectrophotometers, the geometry of sample illumination and viewing follows CIE recommendations [*12*]. Two standard geometries are widely used. In hemispherical geometry, light from the source usually illuminates the white interior of a hollow, approximately spherical cavity called an integrating sphere, and the diffused light from the sphere illuminates the sample from all angles in the hemisphere bounded by its surface. The sample is viewed at an angle near the normal or perpendicular to its surface. If the sample is glossy, the specular or mirror reflection from its surface will result in a portion of the wall of the integrating sphere also being viewed. The user is given the option of making this part of the sphere white, thus including the specular component, or black, excluding it.

In bidirectional geometry, illuminating and viewing are at angles along the normal to the sample surface (designated 0°) and 45° from the normal, or the reverse. The use of

bidirectional geometry with the specimen illuminated by white light is required when fluorescent samples are measured. Hemispherical and bidirectional geometries are described in ASTM Guide for Selection of Geometric Conditions for Measurement of Reflection and Transmission Properties of Materials (E 179) and in ASTM E 1164 as well as by the CIE [*12*].

In typical 45/0 or 0/45 geometry, several illuminating or viewing beams, distributed around the azimuth at 45° to the normal, may be used. When a specimen exhibits directionality, that is, its reflectance changes when it is rotated in its own plane, the use of an instrument with multiple beams provides data that average over the directionality, giving a single number characteristic of the average properties of the specimen. If it is desired to measure the directionality, an instrument with one illuminating (or viewing) beam, or two 180° apart in azimuth, should be used and measurements made at several different specimen orientations.

For the measurement of specimens exhibiting goniochromatism, in which the reflectance changes when the illuminating or viewing angles are changed, the use of special instruments capable of measuring at different combinations of these angles is required. Several such multiangle instruments, known as goniospectrophotometers, are commercially available. To date, no firm recommendations have been made on the number of combinations or the optimum angles required to characterize such goniochromatic specimens. Such specimens of interest in the paint industry include the so-called metallic and pearlescent coatings for the automotive industry.

Monochromator, Detector, and Output

The light reflected or transmitted by the specimen is directed to the monochromator, in which a narrow (typically 10 to 20 nm) band of wavelengths is selected from the full spectrum of the incident light. The monochromators in modern instruments usually use holographic diffraction gratings or interference filters to isolate the narrow wavelength range. Spectral light is received by the detector, usually a silicon photodiode. Detection may be accomplished by an array of diodes, each positioned permanently to receive light of a given wavelength, thus eliminating the need for a spectrum scanning device. The electrical signal from the detector is usually amplified, digitized, and entered in an interfaced computer. In addition to ASTM E 1164, the following test methods cover the operation of modern spectrophotometers: ASTM E 1331, E 1348, and E 1349.

Spectroradiometers

Instruments closely related to spectrophotometers but made to measure light incident from external sources are known as spectroradiometers. They could be used in the paint industry when, for example, the specimen must be sensed remotely after illumination external to the instrument. Methods for making such measurements are described in ASTM Practice for Obtaining Spectroradiometric Data from Radiant Sources for Colorimetry (E 1341) and ASTM Practice for Obtaining Colorimetric Data from a Visual Display Unit Using Colorimeters (E 1455).

Obtaining Tristimulus Values from Spectral Data

The first step in utilizing spectral data is the calculation of CIE tristimulus values, as described earlier under **Calculation of Tristimulus Values**. This step is performed automatically as part of the measurement sequence in all modern spectrophotometers designed for color measurement. It is usual that the spectral bandpass of the monochromator and the measurement interval are selected to be the same. For highest accuracy, the correct set of tristimulus weighting factors, corresponding to the instrument bandpass, selected from among those added to ASTM E 308 in 1994, must be used in calculating tristimulus values. In addition, the user must select the standard illuminant and the standard observer used, and (when hemispherical measuring geometry is utilized) select the inclusion or exclusion of the specular component in reflectance measurement.

Spectrocolorimeters

Some spectrophotometers are designed so that the measured spectral reflectances or transmittances cannot be accessed for examination; only the resulting tristimulus values and other color coordinates can be printed out. Such instruments are designated spectrocolorimeters.

Tristimulus (Filter) Colorimeters

Among the earliest photoelectric color-measuring instruments were those in which the source-filter-photodetector combinations duplicate the tristimulus functions of the Standard Observer and a CIE Standard Illuminant, usually Illuminant C [*29*]. How well their filters are designed and matched to the spectral characteristics of the source and of the detector determines how accurately the instrument performs. Today a high degree of accuracy is attained in the resulting tristimulus values.

Because of their ease of operation, good precision, and relatively low cost, tristimulus (filter) colorimeters have found wide application for industrial control. They are used primarily as color-difference meters to evaluate the difference in color between a production specimen and a standard of similar spectral character. This last limitation is important for most colorimeters. Because of their design, most colorimeters provide colorimetric data for only one combination of illuminant and observer and therefore cannot detect metamerism. When specimens are metameric, a colorimeter can give incorrect data on the differences among them. Filter colorimeters should not be used to evaluate pairs of specimens that may be metameric. This limitation should be clearly understood.

The use of colorimeters is described in ASTM E 1347. This standard replaces ASTM Test Method for Directional Reflectance Factor, 45-deg 0-deg, of Opaque Specimens by Broad-Band Filter Reflectometry (E 97) (discontinued in 1992).

Selection and Calibration of Instruments

The potential user of color-measuring instrumentation must consider with care the selection of the proper instrument(s), depending on his samples and measurement needs. ASTM E 179 and ASTM Practice for Identification of Instrumental Methods of Color or Color-Difference Measurement

of Materials (E 805) address this topic. They should be consulted, if possible, before the purchase of a new instrument.

The user of any color-measuring instrument must give regular attention to its calibration. Appropriate calibration standards, available from instrument manufacturers and, in some cases, national standardizing laboratories, should be obtained, maintained in good condition, and used at frequent intervals in an established routine [*30*]. A collaborative reference program [*31*] is available by means of which a user's instrument performance can be compared to that obtained for the same samples by the color community as a whole and by national standardizing laboratories.

With proper calibration and maintenance, modern color-measuring instruments are capable of a repeatability and reproducibility far greater than the repeatability with which the samples themselves can normally be prepared for industrial measurement. Thus, special care must be taken to establish a highly reproducible method of paint sample preparation and to establish by careful measurement and periodic verification the uncertainties associated with this step in the measurement process. ASTM standards that deal with these matters are E 1164, E 1331, ASTM Practice for Reducing the Effect of Variability of Color Measurement by Use of Multiple Measurements (E 1345), E 1348, and E 1349. See also ASTM Practice for Selection of Coating Specimens and Their Preparation for Appearance Measurements (D 3964) and Standard Guide for the Preparation, Maintenance, and Distribution of Physical Product Standards for Color and Geometric Appearance of Coatings (D 5531).

The following two subsections apply mainly to spectrophotometers.

Precision

The modern age of computer-interfaced color measuring spectrophotometers began in the mid-1970s. By then it had been clearly demonstrated that such instruments could surpass the eye in the precision of color measurement. Repeatability of instrumental color measurement is about 0.1 CIELAB unit of color difference [*32*] (see later in this chapter under **Color Difference Calculations**). The average reproducibility within a group of similar instruments is about 0.2 CIELAB units [*33*]. Note that 0.5 CIELAB unit is approximately the smallest difference that can be detected visually. Repeatability and reproducibility values are published in the Precision and Bias section of ASTM E 1164.

Bias

This quantity, the difference between a measured result for a standard sample and the result when it is measured in a reference laboratory, is difficult to quantify in the color field where there are no "absolute" values. It is usual to accept the results obtained in a national standardizing laboratory as the reference. On this basis, when instruments are selected to minimize differences in measuring geometry and are properly calibrated and used, the average bias for a group of standard samples can be as low as 0.5 CIELAB unit [*34*]. In addition, the differences between the two sets of measurements can be utilized effectively to model and correct the systematic spectrophotometric errors leading to the bias [*35*].

Commercial Instruments

Instrument design changes have been so frequent in recent years that published information in a manual such as this would almost certainly become obsolete by the time the manuscript is printed. For this reason, detailed information on suppliers and their instrumentation is not included. Such information, including types of instruments manufactured and their design features and performance characteristics, can best be found by first consulting buyers' guides [*36,37*] that are revised annually. Another useful source of information is the lists of exhibitors at paint shows, such as the descriptions published annually in the *Journal of Coatings Technology*. In contacting suppliers of instrumentation, the user might request that they send literature, measure samples sent them, or have a representative visit the user to demonstrate the instrument. Another procedure is to negotiate a rental-purchase contract. While some suppliers are reluctant to negotiate such contracts, the procedure provides users the opportunity to evaluate the instrument with their own operators at their own facilities. Most major manufacturers currently in the field supply both spectrophotometers and colorimeters meeting the descriptions given earlier under **Spectrophotometers** and **Tristimulus (Filter) Colorimeters**.

Several recent trends provide insight into possible future developments in color-measuring equipment and its uses. These trends can be classified in three groups: (1) miniaturization, (2) multi-angle evaluation, and (3) location and type of use.

1. *Miniaturization.* Many manufacturers now supply portable spectrophotometers and colorimeters that provide small size and light weight. Many are battery operated for full portability; others may use fiber-optics probes to separate the measuring head from the remainder of the instrument. In many, the precision is good, but limitations related to measurement geometry may increase bias. If very small illuminated and viewed areas are used, there may be an advantage in that smaller portions of samples can be measured, but averaging of multiple measurements (see ASTM E 1345) may be required to obtain representative values for nonuniform samples.
2. *Multi-Angle Evaluation.* Several manufacturers now supply instruments with multi-angle geometry for the measurement of goniochromatic samples, such as those containing metal flake or pearlescent pigments. For research in this field, a goniospectrophotometer is required. For quality control, however, use of one angle of illumination with several angles of view may suffice. As noted earlier under **Spectrophotometers**, the selection of illuminating and viewing angles has not yet been standardized.
3. *Location and Type of Use.* In earlier times, production samples were taken to a quality-control laboratory for evaluation. This procedure is still desirable in some instances to permit control of such variables as ambient light, temperature and humidity, and atmospheric contamination, but today time is being saved by making measurements on the production floor. For continuous processes, on-line instrumentation is finding greater use. In addition, color measurement and computer-aided color matching (see later in

this chapter under **Instrumental and Computer-Aided Color Matching**) are today finding extensive use at point-of-purchase locations such as retail paint stores.

COLOR DIFFERENCE EVALUATION FOR COLOR CONTROL

The control of the color of industrial paint products may be aided by use of the results of color measurement, as described in the last section. The instruments provide color coordinates of sample and standard from which accurate measures of color difference may be derived. These data can also be used to establish color tolerances. Of course, color differences may also be judged visually, and several ASTM standards address this topic: ASTM Practice for Visual Estimation of Color Differences (D 1729), ASTM Test Method for Evaluation of Visual Color Difference With a Gray Scale (D 2616), and ASTM Guide to the Selection, Evaluation, and Training of Observers (E 1499). This guide also describes materials and methods for the testing and evaluation of the observer's color vision.

Color-Difference Calculations

In the 1931 and 1964 CIE systems, equal distances in different parts of color space do not represent equally perceived color differences. Although many proposals for more uniform color spaces have been made, an ideally uniform space has not been and may not ever be devised. However, modern color-measuring instruments compute sets of color coordinates that correlate better with perceived color differences than do CIE tristimulus values.

Among the many modifications of CIE tristimulus values that have been proposed for more uniform color spaces, those proposed by Hunter [*29*], MacAdam [*38–40*], and the CIE [*12*] are preferred for use in the paint industry and are given in ASTM Test Method for Calculation of Color Differences from Instrumentally Measured Color Coordinates (D 2244). The most widely used of these is the CIE 1976 $L^*a^*b^*$ (CIELAB) space discussed earlier in the subsection entitled **Uniform Color Spaces**. Omitting subscripts *ab* throughout for convenience, the total CIELAB color difference, ΔE^*, is given by

$$\Delta E^* = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$$

where, for example, $\Delta L^* = L^*_{\text{TRIAL}} - L^*_{\text{STANDARD}}$. It is convenient to express ΔE^* in terms of differences in the Munsell-type coordinates hue, chroma, and lightness, but the hue angle h defined earlier in the subsection entitled **Uniform Color Spaces** does not have the same dimensions and scaling as chroma C^* and lightness L^*. Instead of using h, it is necessary to define CIELAB hue difference ΔH^* to combine with ΔC^* and ΔL^*

$$\Delta H^* = [(\Delta E^*)^2 - (\Delta C^*)^2 - (\Delta L^*)^2]^{1/2}$$

Then

$$\Delta E^* = [(\Delta H^*)^2 + (\Delta C^*)^2 + (\Delta L^*)^2]^{1/2}$$

Alternative equations for determining ΔH^* and its sign have been described [*41*]. The unit of CIELAB color difference is two to three times the just perceptible color difference.

In the use of color differences, it is important to examine the components of the color difference, such as ΔL^*, Δa^*, and Δb^*, or ΔL^*, ΔC^*, and ΔH^*, as well as ΔE^* itself. The magnitudes and signs of these components can provide valuable information on remedial action needed to bring a production batch on shade.

The interpretation of measured color differences becomes more complex when the specimens are goniochromatic and measurements are made at several combinations of illuminating and viewing angles. The quantitative meaning of color differences as the angles change has not yet been thoroughly studied.

Since the adoption of the CIELAB equations and their inclusion in ASTM D 2244, a number of new color-difference equations have been developed. One of these, known as the CMC (l:*c*) equation [*42,43*], is a modification of CIELAB that has improved uniformity of visual perception of its color differences. It will be included in an "ASTM Guide to the Selection and Use of Color-Difference Equations" (under development).

Color Tolerances

A valuable means of recording the experience gained in the production of a given color is through the use of color tolerances, expressed as numerical limits to ΔE^* and its components or as color-tolerance charts. Because no color space is entirely uniform and industrial color tolerances are often based on acceptability considerations between buyer and seller, not perceptibility, color differences should be used only as a guide until enough experience has been accumulated for each color to allow specification of a tolerance limit.

Tolerance Charts

Color-tolerance charts are usually enlarged sections of a nearly visually equally spaced diagram, such as the CIELAB a^*, b^* diagram. A color-tolerance chart is set up with the coordinates of the standard at the center, and the differences Δa^* and Δb^* of production batches are entered as they are made (Fig. 18*a*). The process is described in ASTM Practice for Establishing Color and Gloss Tolerance (D 3134). As experience is gained, it should be possible to draw a tolerance-limit curve enclosing most, if not all, of the acceptable batches and excluding most, if not all, of the unacceptable batches. Because no known diagram is perfectly visually uniform, the tolerance limit figure may not be a circle or an ellipse and may not be centered on the location of the standard.

Lightness differences between the standard and batch must also be taken into account. This can be done by use of a separate tolerance for ΔL^*, but better practice is to use a second chart (Fig. 18*b*), in which ΔL^* is plotted against either Δa^* or Δb^*, depending on the data. The batch readings should fall within the tolerance figure on both charts.

It must be emphasized that the final criterion for acceptance of a color is always its visual appearance, to which instrumental measurements, color differences, and tolerance

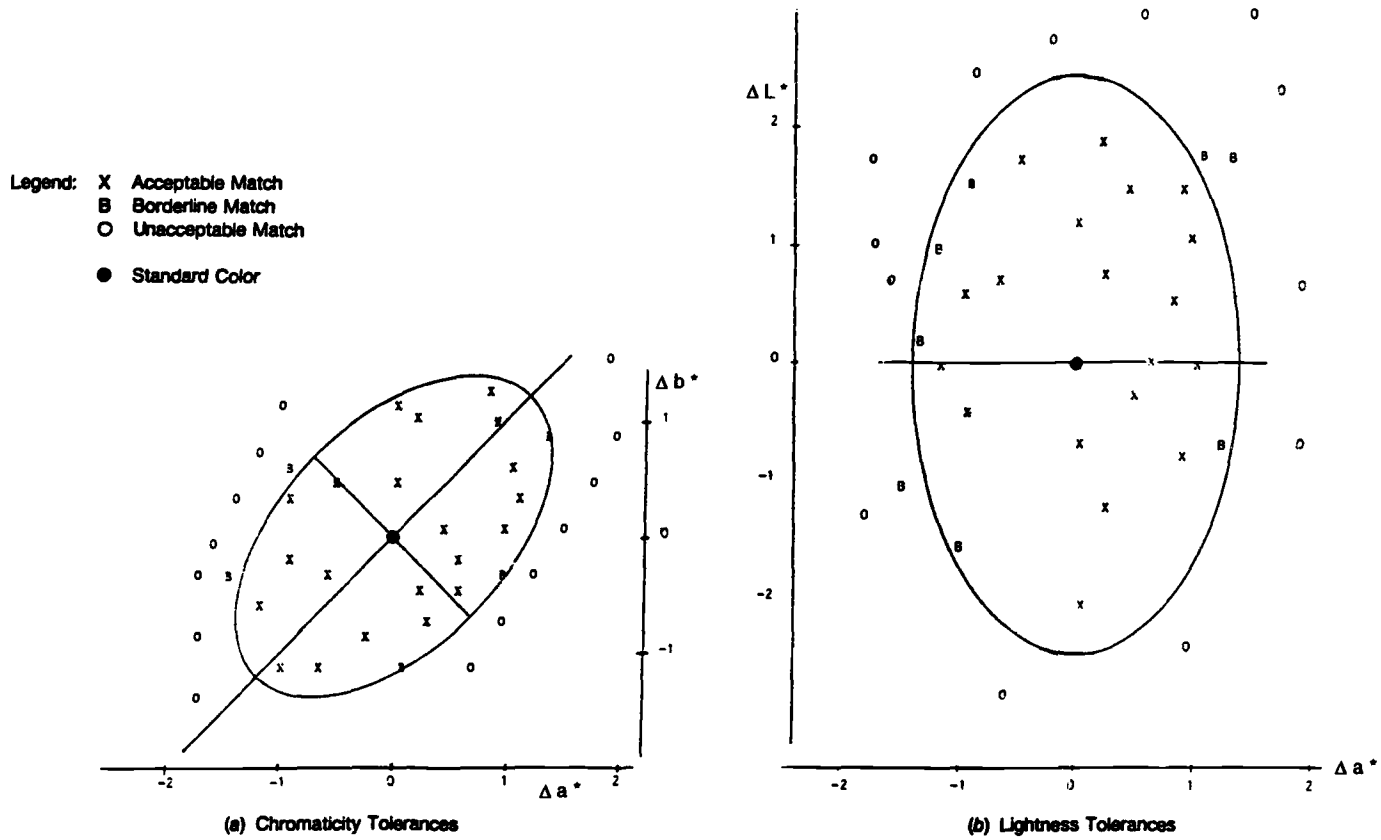

FIG. 18–Color tolerance charts plotted in the CIELAB system: (*a*) chromaticity tolerance figure on a Δa^*, Δb^* diagram; (*b*) lightness tolerance figure on a ΔL^*, Δa^* diagram. In this case, a plot of ΔL^* versus Δb^* would have served as well. (Based on ASTM D 3134.)

charts provide only clues. Instrument malfunctions, miscalibrations, miscalculations, and operator errors can be revealed only by use of confirming visual observations.

Indices of Metamerism

Another important use of color-difference equations is to quantify indices of metamerism as an aid in reducing this defect between standard and batch. The CIE [*12,44*] has recommended that indices of metamerism be calculated as the color differences between two samples that match under a standard illuminant or to a standard observer when measured for a test illuminant or a test observer. For illuminant metamerism, the standard illuminant is usually daylight, and the second can be selected by the user. For observer metamerism, the standard observer is either the CIE 1931 or 1964 observer, and a corresponding second "standard deviate" observer is provided [*44*] based on the range of normal color vision found in the human population.

COLOR MIXING

Additive Mixing of Lights

When a white card is illuminated, its apparent color is the color of the incident light; a red light, for example, makes it appear red. Three colored lights (red, green, and blue), if carefully chosen, would, when placed to overlap on the same area of the card, produce white again (Fig. 19). In this area, the reflected lights from the three sources add together. These three lights are called the additive primaries. By adjusting the intensities of each of the three lights, a wide range of colors can be produced.

The procedure just described can provide an analytical tool for color measurement. If an adjacent spot on the white card is illuminated by light of an unknown color, it could be matched visually, in principle, with the three-light combination by adjusting their intensities. This is the basis for color matching by addition of lights. The additive principle is used to produce the colors in television [*45*].

The analytical device described above is also a simple version of the visual colorimeter used to generate the tristimulus values of the spectrum colors that form the basis for the CIE Standard Observers (see earlier in this chapter under **CIE Standard Observers**). At each wavelength, the total light reflected is the sum of the power reflected from each of the three primary lights. Since tristimulus values are obtained by adding such sums across the spectrum, they too are produced by additive mixing. It is not necessary to know the spectral nature of the additive primaries to predict the resulting colors.

Subtractive Mixing in Transparent Films

Now consider the light falling on a white card after passing through a film that contains three transparent colorants, yel-

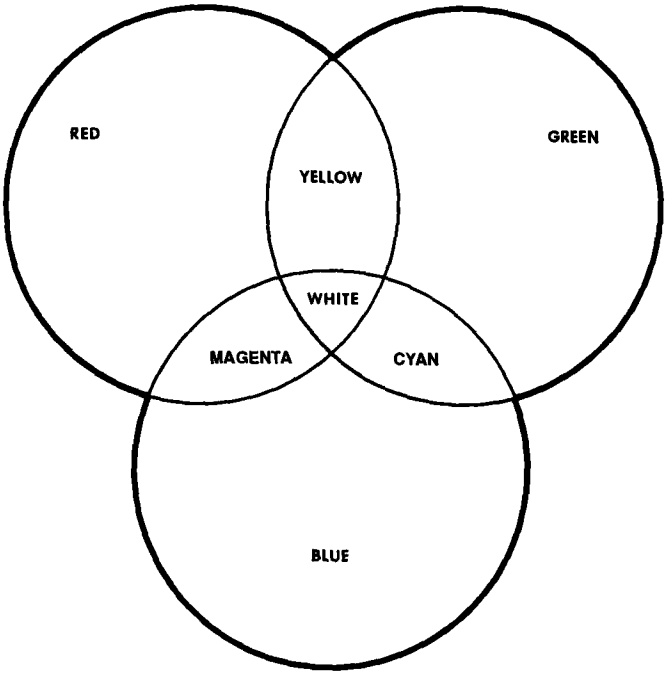

FIG. 19–Representation of the additive mixing of colored lights showing the additive primaries red, green, and blue forming the mixture colors yellow, cyan, and magenta where the primaries overlap in pairs and white where all three overlap.

low, cyan (blue-green), and magenta (red-purple). This might be the situation with a free-standing transparent plastic film, for example. If the three colorants were ideally chosen, all the light would be absorbed when all three were present, and the result would be black (Fig. 20). These three colorants are called the subtractive primaries. If varying quantities of them were combined in subtractive mixing, a wide variety of colors could be produced. However, these mixture colors cannot be predicted from the colors of the primaries alone, as in the additive mixing described above. One must also know their spectral character and compute, wavelength by wavelength, how much light is removed by each primary through absorption, using the well-known Beer's law relationship. From what is not absorbed, tristimulus values can be calculated in the usual way.

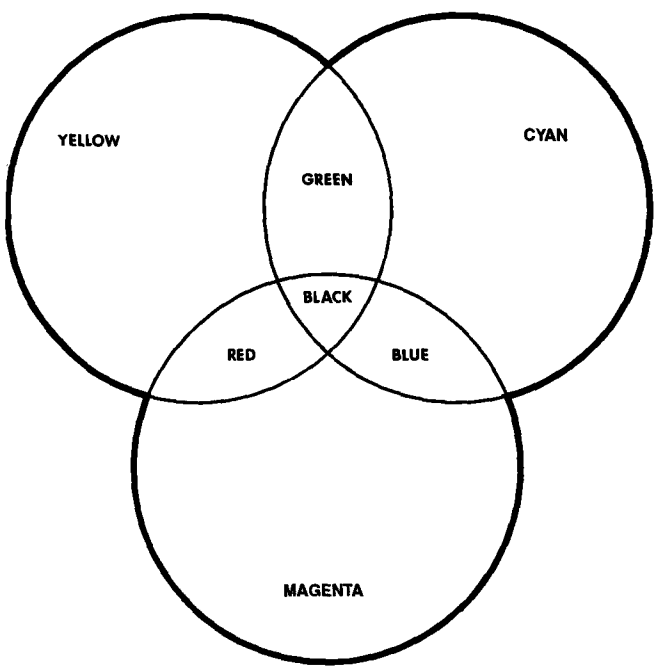

FIG. 20–Representation of the subtractive color mixing of transparent colorants showing the subtractive primaries yellow, cyan, and magenta forming the mixture colors green, blue, and red where the primaries are mixed in pairs and black where all three are mixed together.

Pigment Mixing

Most paint films contain, in addition to three colored pigments (one of which may be black), a white pigment used as an opacifier. The mixing of colors produced in this way is more complex than simple subtractive mixing in transparent films because of the scattering of light caused by the white pigment (and by opaque colored pigments as well). Again, it is necessary to know the spectral character of all the colorants present. The Beer's law calculation of the transparent case is replaced by the Kubelka-Munk relation: For opaque films, as is usually the case in the paint industry, this is a simple equation relating the reflectance $R(\lambda)$ of the film at each wavelength to the ratio of two constants describing what happens to the light in the film

$$K(\lambda)/S(\lambda) = [1 - R(\lambda)]^2/2R(\lambda)$$

where $K(\lambda)$ is the Kubelka-Munk absorption coefficient, and $S(\lambda)$ is the Kubelka-Munk scattering coefficient. Here $R(\lambda)$ must be expressed as a fraction, not the usual percentage. The quantities $K(\lambda)$ and $S(\lambda)$ refer to the mixture of pigments in the paint film. These are calculated by adding the separate contributions of each pigment, using its $K(\lambda)$ and $S(\lambda)$ weighted by its concentration C in the mixture

$$\frac{K(\lambda)_{\text{MIXTURE}}}{S(\lambda)_{\text{MIXTURE}}} = \frac{C_1K_1(\lambda) + C_2K_2(\lambda) + \cdots}{C_1S_1(\lambda) + C_2S_2(\lambda) + \cdots}$$

where there are as many terms as there are pigments used. These equations form the basis for computer color matching described in the next section.

COLOR MATCHING

One of the major objectives of industrial coloring is to match the color a customer wants. Whether this is done visually or with the aid of instruments and computers is often a matter of work load and economics. Therefore we address both visual and instrumental matching. In either case, a major objective of color matching in paint systems is the formulation of a nonmetameric match to a given paint sample. The difference in spectral character of the samples of a metameric pair is the property determining their metamerism, and achieving a nonmetameric match places several requirements on the formulation.

First, the same pigments must be used. This requires identification of the pigments in the sample to be matched. Second, the pigments must be used in the same resin system since the spectral properties of pigments can depend upon

the choice of binder. Finally, the same degree of dispersion must be achieved since the absorption and scattering properties of pigments that determine their spectral character change with degree of dispersion. This usually means that the same method of dispersion must be used.

Visual Color Matching

The selection of visual color matchers should be made with great care, and reference should be made to ASTM E 1499 for details of how to make the selection, test the color vision of the candidates, and train them in making visual judgments.

Beyond this there is no substitute for the experience of the visual color matcher. He or she must learn the skill by practice. This should include becoming familiar with one of the better color order systems and atlases and learning how to use it, coupled with knowledge of the behavior of the paint system and pigments available, to predict the colors that result from mixing them under carefully controlled conditions. Careful record keeping to document the results is essential. Visual methods of recognizing and controlling metamerism have been described [*46,47*]. These require no more than knowledge of the behavior in mixtures of the pigments used and a good color matching booth (see earlier in this chapter under **Color Matching Booths**).

Instrumental and Computer-Aided Color Matching

The importance of eliminating metamerism dictates that, for a color matching aid, the instrument of choice is clearly the spectrophotometer. Display of the spectral curves of samples, and the computer-aided color-matching operations that lead to spectral curve shapes minimizing metamerism, cannot be achieved by the use of other types of instruments. The spectrophotometer can also be used in a simple but powerful method of organic pigment identification [*48*] based on extraction of the pigments into solution followed by spectrophotometry. This can be an important aid to selecting the same pigmentation for the match as was used in the standard.

Many modern color-measuring spectrophotometers can be obtained with computer software for color matching. Most of these systems work very well, but it must be emphasized that the investment in building up the database that is essential for their use, and in taking all the steps necessary to bring the coloring process under precise control, is not a small one; only when large numbers of colors must be matched on a daily basis can the cost of setting up and maintaining such a system be justified.

The details of how computer color matching works are beyond the scope of this chapter. In summary, most systems call for measurement of the sample to put its spectral data into the computer. These data are matched at each of (usually) 16 wavelengths across the spectrum by Kubelka-Munk-type calculations (see earlier under **Pigment Mixing**), using stored values of $K(\lambda)$ and $S(\lambda)$ for the useful pigments in the product line. The results are the pigment concentrations in the formulation. Several formulations arising from mixing different pigments are usually produced. Additional calculations of metamerism indices and pigment costs allow the selection of the most suitable results.

Computer color matching has been discussed in a book [*49*], and some textbooks [*1,2,5,50,51*] provide useful summaries. The underlying Kubelka-Munk theory, applied to paint systems, has been the subject of several articles [*52–55*] directed to paint colorists. More complex theory appears to be needed only in special cases, such as matching automotive paints containing metal flake or pearlescent pigments. The development of such theories is still in its early stages.

Gloss

by Harry K. Hammond III[1] *and Gabriele Kigle-Boeckler*[2]

THE APPEARANCE OF AN OBJECT or material can be described by its color and gloss characteristics. Like color, gloss can be subdivided into several aspects depending on viewing conditions. In 1937, Richard Hunter identified five aspects of gloss [*1*] and the functions of reflectance by which they could be evaluated. Latest studies by K. Lex [*2*] expanded Hunter's gloss terms and divided them into two groups. One group is based on visual observation with the eye focused on the surface of the material (Fig. 1). For the other group, the eye is focused on the image of the object reflected by the material (Fig. 2). However, experience has shown that no single objective measurement of gloss will provide perfect correlation with the integrated subjective appraisal of glossiness that the eye so quickly renders. For this reason, the gloss evaluation requirement of an object or material should first be examined and the most useful gloss measurement aspects then selected.

ASPECTS OF GLOSS AND THEIR DEFINITION

The simple term "gloss" is defined in an ASTM standard, Terminology of Appearance (E 284) [*3*] as "angular selectivity of reflectance, involving surface-reflected light, responsible for the degree to which reflected highlights or images of objects may be seen as superimposed on a surface." To indicate specific types of "angular selectivity," such as those involving specular gloss, sheen, or haze and to illustrate the difference between an evaluation where the focus is on the surface and one where the focus is on the reflected image, the complexity of the phenomenon "gloss" is illustrated in Fig. 3.

By focusing on the reflected image of an object, an observer obtains information on how distinctly the object is reflected by the surface. A reflected light source may appear brilliant or diffuse depending on the specular gloss of the surface. The outline of a reflected object may appear distinct or blurred depending on image clarity. A halo surrounding the image of the reflected object is an indication of haze. Focusing on the surface of an object provides information on the size, depth, and shape of surface structures contributing to such things as waviness or directionality of brush marks.

Specular Gloss

Specular gloss is defined in ASTM E 284 [*3*] as the "ratio of flux reflected in specular direction to incident flux for a specified angle of incidence and source and receptor angular apertures" (Fig. 4). This aspect of gloss has been measured most frequently because it is the one for which an instrument is most easily constructed. In practice the divergence angles of source and receptor are precisely specified in ASTM Test Method for Specular Gloss (D 523) [*4*] as are the directional angles of incidence and reflection. Tolerances are specified for all angles. For simplicity, glossmeter geometries are identified by reference to the incidence angles, most frequently 20, 60, and 85°. However, the associated source and receptor aperture angles and their tolerances play a vital role in determining the reproducibility of instrument readings.

Sheen

Sheen is defined in ASTM E 284 [*3*] as "the specular gloss at a large angle of incidence for an otherwise matte specimen." The usual angle for sheen measurement is 85° from the perpendicular to the specimen. This is about the maximum angle that can be used without encountering difficulty in positioning the optics to illuminate and view the specimen at near-grazing angles.

Haze

Haze in coating films is often designated "reflection haze" because in plastics there is encountered a near-forward scattering in transmission that is designated transmission haze. ASTM E 284 [*3*] defines haze in reflection as "percent of reflected light scattered by a specimen having a glossy surface so that its direction deviates more than a specified angle from the direction of specular reflection."

Image Clarity

This aspect of gloss has often been referred to as "distinctness of image." It is essentially independent of haze or change in specular gloss. ASTM E 284 [*3*] defines distinctness-of-image gloss as "the aspect of gloss characterized by the sharpness of images of objects produced by reflection at a surface." During visual observation, the sharpness of the light-dark edge of a reflected object can be observed. Image

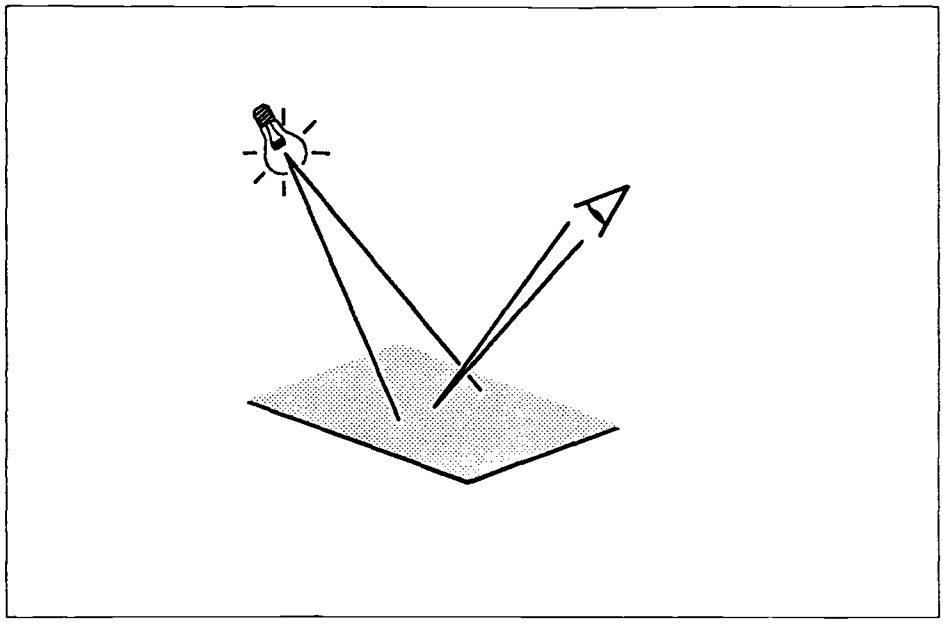

FIG. 1–Observer focuses on the image of reflected object.

clarity is a critical parameter of glossy surfaces having only small amounts of waviness.

Waviness

One obvious type of waviness is designated "orange peel." ASTM E 284 [3] defines orange peel as "the appearance of irregularity of a surface resembling the skin of an orange." A surface may be described as exhibiting orange peel when it has many small indentations that are perceived as a pattern of both highlighted and non-highlighted areas. This pattern is interpreted by an observer as a three-dimensional structure of hills and valleys.

Directionality

ASTM E 284 [3] defines directionality, perceived, as "the degree to which the appearance of a surface changes as the

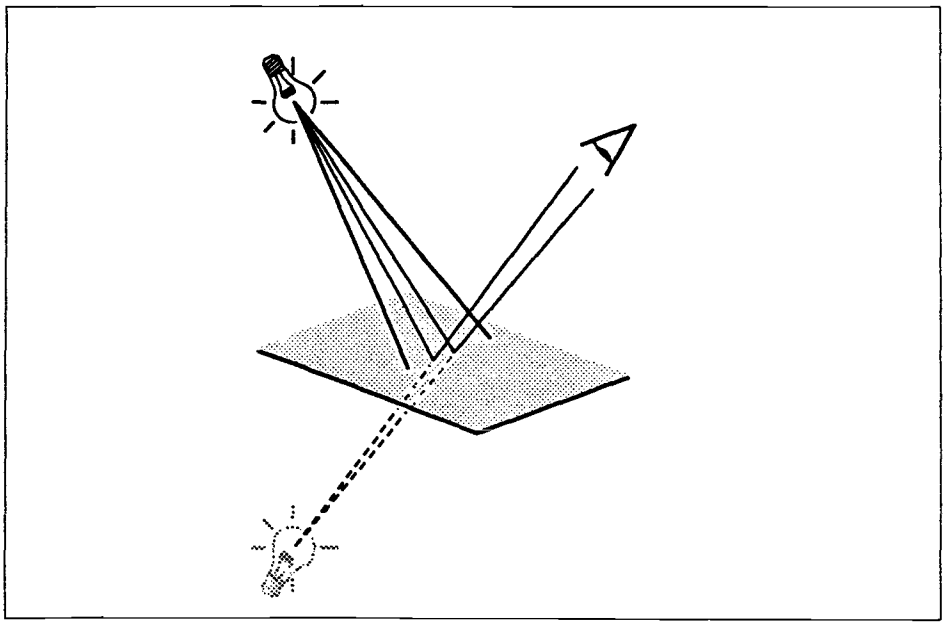

FIG. 2–Observer focuses on the illuminated surface of object.

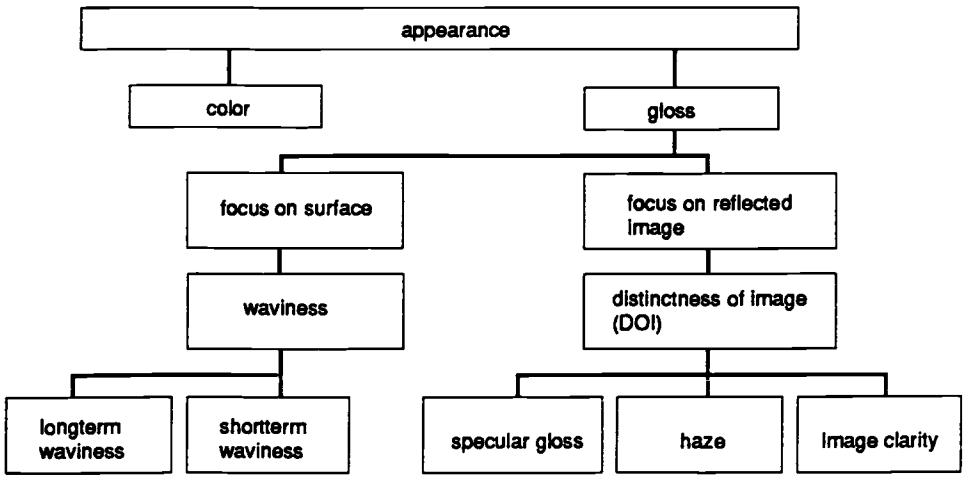

FIG. 3–Flow chart depicting relationships of various appearance characteristics.

surface is rotated in its own plane, under fixed conditions of illumination and viewing." A surface exhibits directionality when specular gloss measurements are a function of the direction for which measurements are made. When paint is applied by brushing in one direction, the brush marks can cause the surface to have a directional characteristic. Metallic materials frequently exhibit directionality when the surface is polished in one direction.

VISUAL GLOSS EVALUATION

Early investigations of gloss were carried out by observing differences in the characteristics of images reflected in the surfaces of specimens. In 1932, the Detroit Paint and Varnish Production Club [5] reported on investigations carried out with their distinctness-of-image gloss comparator. In 1936, Hunter [6] reported an investigation where reflected images of a target pattern were observed.

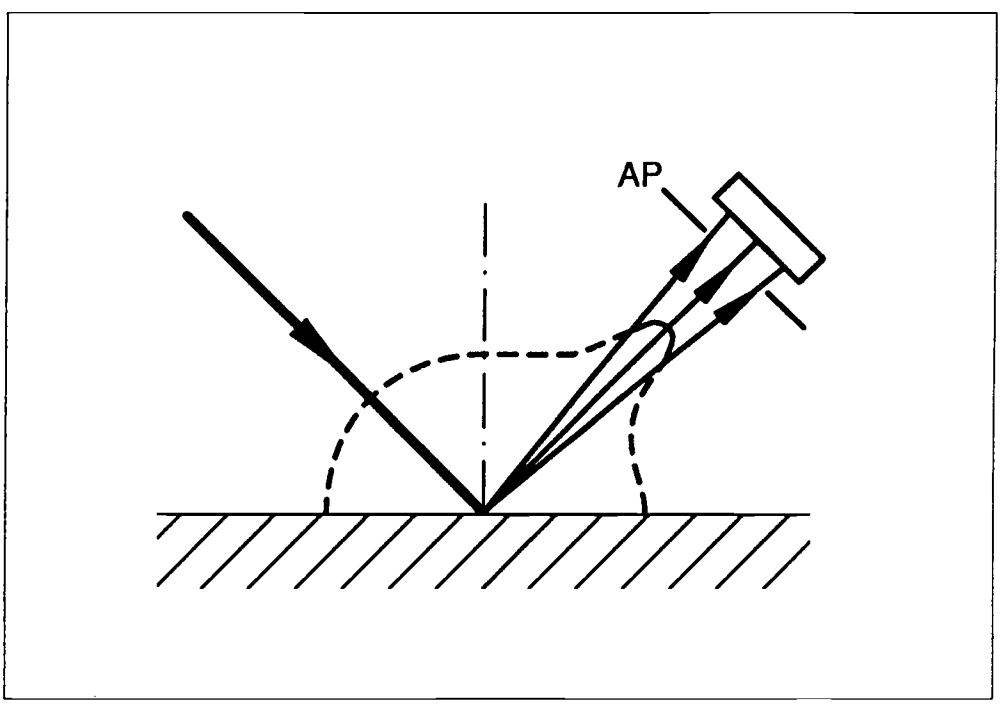

FIG. 4–Reflected light flux distribution from a semigloss surface is depicted by a broken curve. Three lines are shown proceeding from the specimen surface. The center one depicts the specular direction, the image of a ray reflected from a mirror-like surface. The two other rays represent the range of angles passing through the aperture (AP) to the detector (shown as a rectangle).

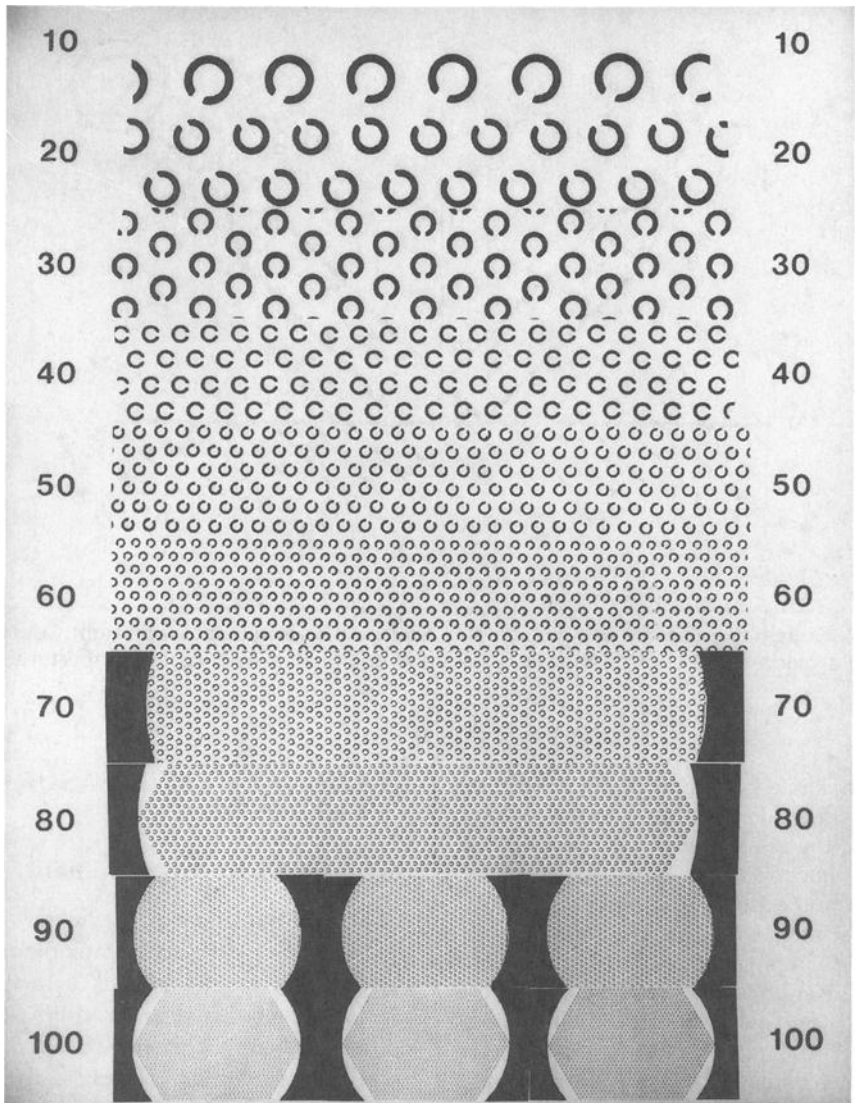

FIG. 5–"Landolt Rings." Broken rings of bvarious sizes are used to provide a scale for visual evaluation of the distinctness of surface-reflected images.[3]

Only in comparatively recent times has there been a major effort to investigate visual scaling of gloss and to endeavor to develop correlation between visual and instrumental measurements. O'Donnell did a doctoral thesis on visual gloss scaling at Rensselear Polytechnic Institute, Troy, New York. Results were first presented, in part, at an ASTM Symposium in 1984 [*7*] and more fully in a journal article in 1987 [*8*].

Development of a Documentary Standard

In 1990, ASTM Committee D-1 on Paint and Related Coatings and Materials published ASTM Method for Visual Evaluation of Gloss Differences Between Surfaces of Similar Appearance (D 4449) [*9*] for making visual evaluations of gloss between surfaces of similar appearance. It uses two types of light sources. One source consists of a tubular fluorescent desk lamp modified by placing a matte-black reflecting material behind the tubes and a coarse wire-mesh screen in front. The directions of illumination and view can be adjusted to be 20, 60, or 85° as desired for comparing specimens having high gloss, intermediate gloss, or sheen. The other light source is a clear-bulb incandescent lamp. Light from the selected source illuminates the specimens at the chosen angle. The sharpness of reflected images permits a subjective comparison of the relative gloss of similar surfaces.

Use of Landolt Rings

Landolt rings have been used by ophthamologists to evaluate visual acuity for nearly a hundred years [*10*]. The test

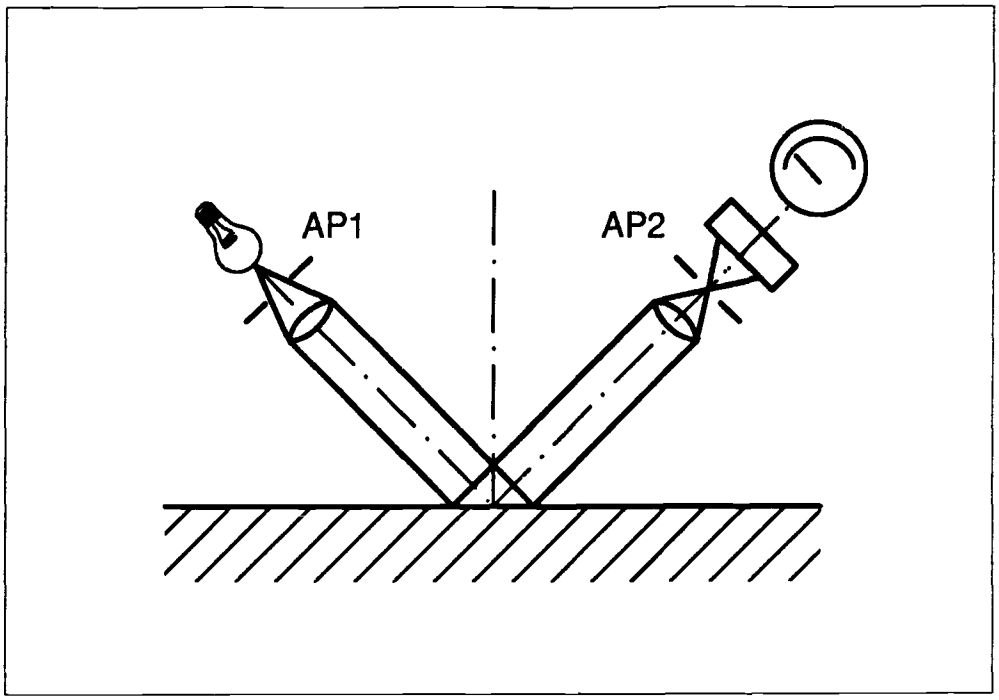

FIG. 6—Schematic diagram of a gloss meter. Source is on left, detector on right. Lenses are used to provide beam control. Source aperture is designated AP1, receptor aperture AP2.

consists of locating the gaps in a graduated series of sizes of incomplete rings whose radial thickness and gap are equal to one fifth the diameter of the ring. For gloss evaluation of trans-illuminated rings, reflections are viewed on mylar. Rings have different sizes and different gap orientations. An image-gloss scale is associated with the different sizes of rings. An image-gloss scale ranging from 10 to 100 in steps of ten was established for eleven sizes of rings from the largest to the smallest. The development of the scale is not documented, but it ostensibility took place in the General Motors Automotive Division about January 1977. Visual observers select the smallest size of ring for which they can call the gap orientation correctly. The numerical size of the rings is used as an inverse index of distinctness-of-image gloss (Fig. 5). ASTM has not published a method for visually evaluating distinctness-of-image gloss by using Landolt rings, but equipment for this purpose is available.[3]

Visual Evaluation of Orange Peel

The automotive industry established a physical standard for orange peel consisting of ten high-gloss panels with various degrees of orange peel structure.[4] The panels are visually ranked from 1 to 10 with Panel Number 1 depicting very pronounced orange peel and Panel Number 10 illustrating no orange peel. The visual observer can use these panels as a supportive tool to evaluate degree of orange peel.

[3]Apparatus for evaluating distinctness of image using Landolt rings, available from Paul N. Gardner Co., Pompano Beach, FL.

[4]Set of orange-peel panels can be obtained from Advanced Coatings Technology, 273 Industrial Dr., Hillsdale, MI 49242.

INSTRUMENTAL MEASUREMENT TECHNIQUES

Specular Gloss Measurement

The design of many gloss meters is based on the precise measurement of the specular component of reflected light. A light source, usually a small filament incandescent lamp, is placed at the focal point of a collimating lens. The axis of the collimated beam is set to the desired angle of illumination. A receptor lens with an aperture in the focal plane followed by an illumination detector completes the basic optical design (Fig. 6 and Fig. 7). The size of the receptor aperture and the size of the source image in that aperture are the elements that complete the optics and that determine the high, low, and intermediate gloss scale readings. The specular angle largely determines the magnitude of the reflected light. However, the tolerances assigned to the source and receptor apertures are what determine the accuracy and reproducibility of measurements made with instruments having the same angles of illumination and view.

Periodic calibration or verification of instrument performance requires the use of calibrated gloss standards. For permanence they should be made of glass or ceramic material. ASTM D 523 recommends the use of a primary standard of polished black glass of known refractive index for which the Fresnel (specular) reflectance [*11*] has been computed for the angle of incidence of the geometry for which the instrument is designed. Since about 1990, national standardizing laboratories have preferred a primary reference stan-

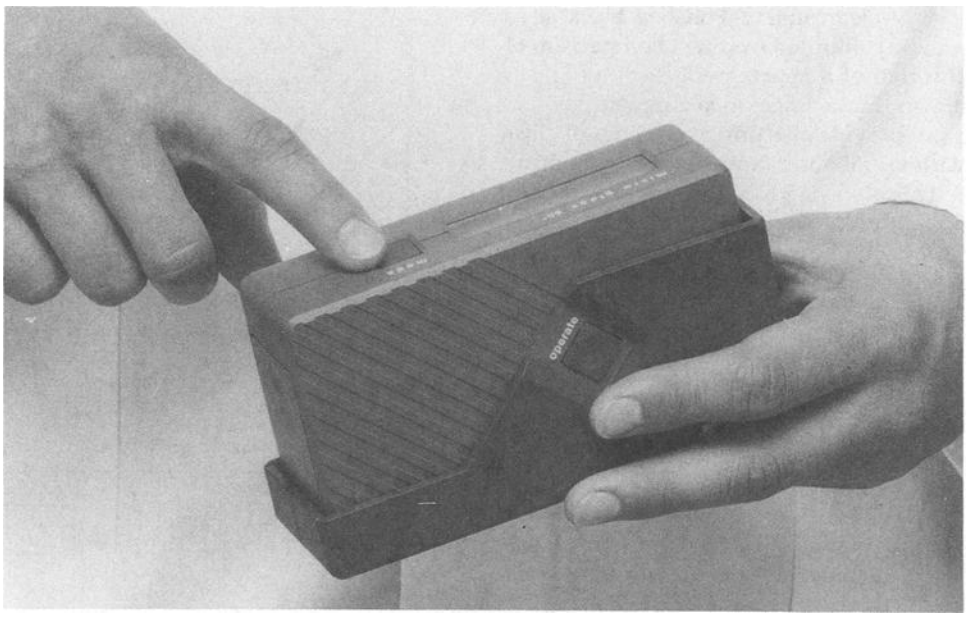

FIG. 7–Photograph of a modern miniature glossmeter. Note size of the hand holding the instrument.[5]

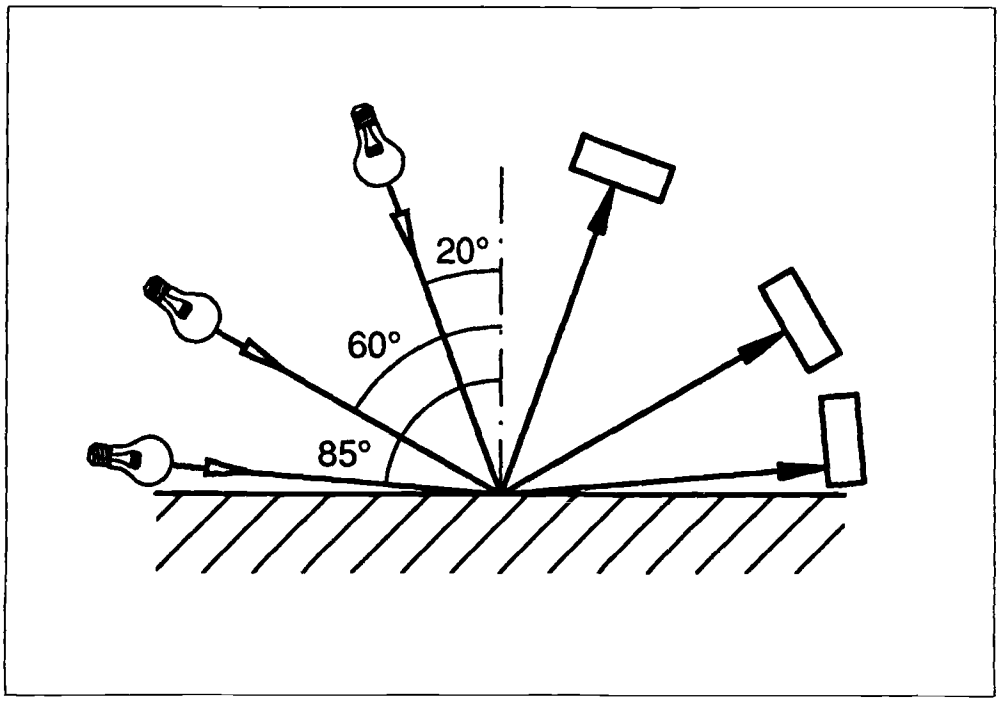

FIG. 8–Diagram depicting the positions of source and receptor for the three geometries of ASTM D 523.

[5]Apparatus designated "micro-TRI-gloss," available from BYK-Gardner USA, Silver Spring, MD.

dard made of a wedge of clear quartz. Polished black glass working standards can be calibrated by direct comparison of their reflectances with that of a quartz wedge.

Experience has shown that a single measurement geometry, such as 60°, may not provide instrument readings of gloss that correlate well with visual observations when comparing different gloss levels. This is why ASTM D 523 [*4*] provides for measurement at three different angles of incidence, namely 20, 60, and 85° (Fig. 8). Each of the three geometries uses the same source aperture, but a different receptor aperture. The choice of geometry depends on whether one is: (1) making a general evaluation of gloss, (2) comparing high-gloss finishes or (3) evaluating low-gloss specimens for sheen. ASTM D 523 [*4*] states that the 60° geometry is used for intercomparing most specimens and for determining when the 20 or 85° geometry may be more applicable. The 20° geometry is advantageous for comparing specimens having 60° gloss values higher than 70. The 85° geometry is used for comparing specimens for sheen or near-grazing shininess. It is most frequently applied when specimens have 60° gloss values lower than 10.

The ASTM documentary gloss standard originally published in 1939 contained only the 60° geometry [*12*]. The desirability of using an auxiliary geometry of 85° for sheen evaluation was recognized shortly afterward. However, the use of another geometry with smaller angles of incidence and view, such as 20°, and a smaller receptor aperture to provide improved differentiation of high-gloss finishes was not published until 1947 [*13*]. The three geometries, 20, 60, and 85°, were originally published as separate ASTM standards. In 1953, ASTM D 523 was revised to incorporate all three geometries, and it still does.

Meanwhile the Paint Committee of the International Organization for Standardization, ISO TC-35, was investigating gloss measurements with various commercial instruments prior to drafting an international standard. A paper documenting what the committee had been doing was published in 1976 by the Chairman of the Gloss Task Group, Dr. Ulrich Zorll [*14*]. In 1978, the ISO Paint Committee published ISO 2813, essentially an international version of ASTM D 523 [*15*]. In keeping with the usual ISO procedure, the standard was made available in English, French, and German.

Instrument manufacturers report that measurement precision, reproducibility, and data-handling capabilities of gloss meters have been improved markedly in recent years. New instruments have been designed that are smaller, more portable, and more convenient to use. Data storage and analysis are frequently included as well as the capability of electronically transferring data to a personal computer [*16,17*].

Goniophotometry

Gonio means angle, and photometer means light; so a goniophotometer is an instrument for measuring the angular distribution of reflected or transmitted light. This type of instrument is used regularly in the research laboratory to investigate the distribution of light flux (Fig. 9). A goniophotometer with appropriate apertures can also be used to provide gloss data for a wide variety of angles and apertures. When goniophotometric measurements are desired,

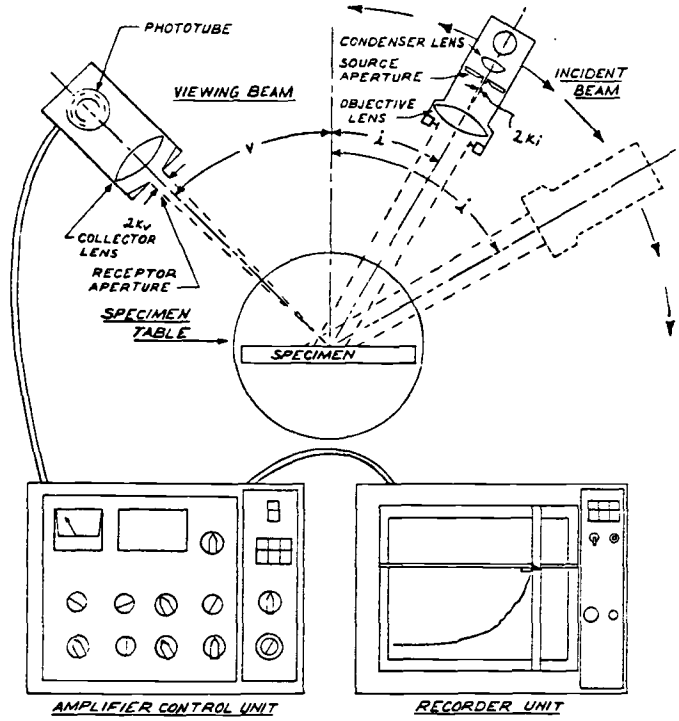

FIG. 9–Schematic diagram of a goniophotometer.

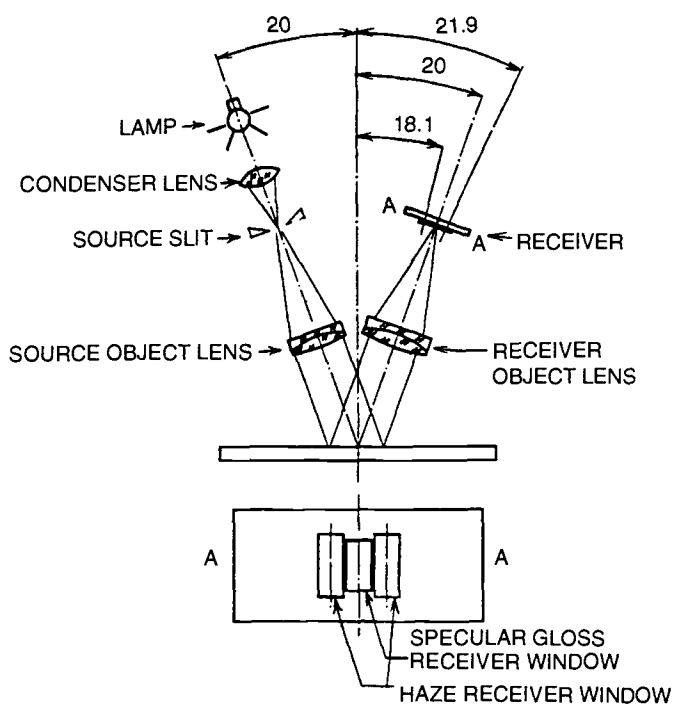

FIG. 10–Schematic diagram of an instrument for reflection haze measurement.

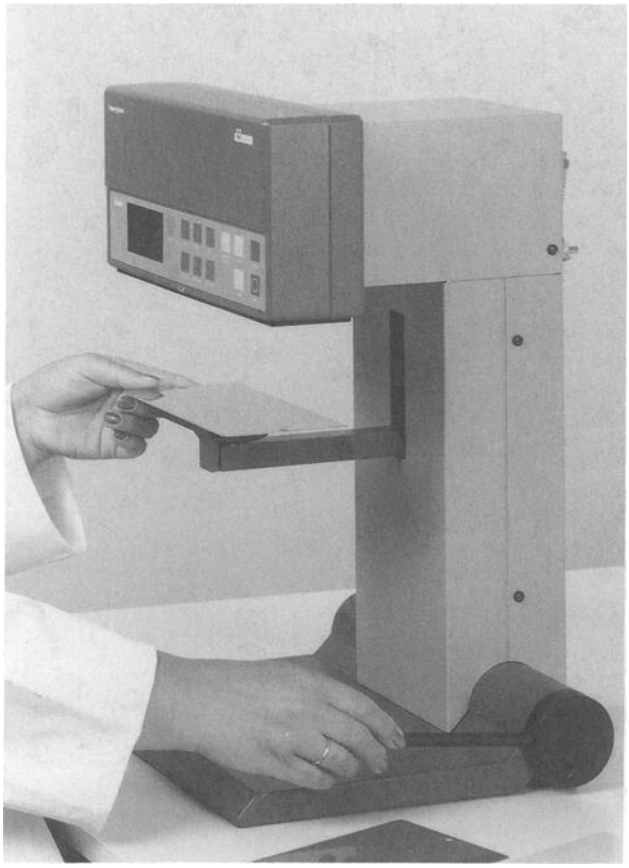

FIG. 11–Photograph of a haze-and-gloss-measuring instrument.[6]

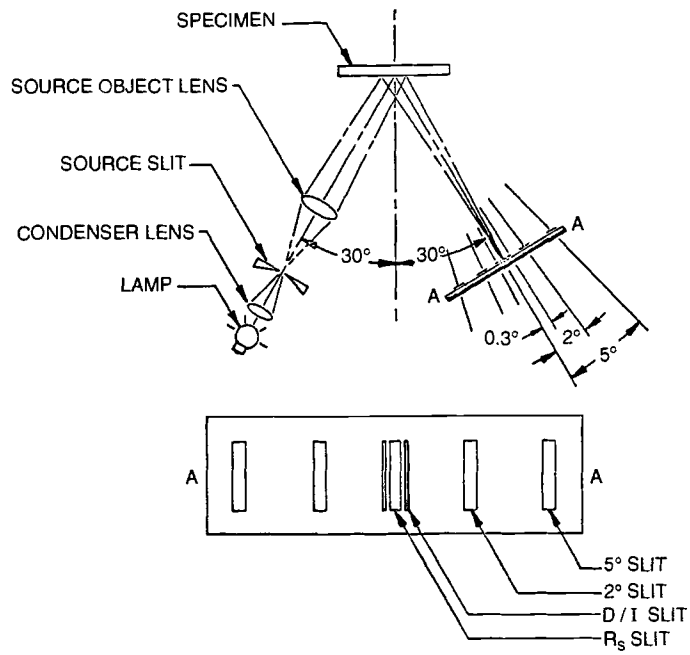

FIG. 12–Schematic diagram of an instrument for image clarity measurement.[7]

reference should be made to ASTM Practice for Goniophotometry of Objects and Materials (E 167) [*18*]. Analysis of goniophotometric curves was treated by Nimeroff [*19*].

Measurement of Reflection Haze

Haze is a gloss parameter that causes a high-gloss surface to appear milky and lighter, thereby losing contrast. When visually evaluating the reflected image of a hazy object, one observes halos around distinct reflection outlines caused by scattered light. Haze can result from various material or process parameters such as degree of dispersion, flocculation, incompatibility of raw materials (pigment-additive-resin) or from poor application procedures. Microscopic irregularities cause small amounts of reflected light to be scattered adjacent to the direction of specular reflection or to modify the refractive index of the material just beneath the surface.

Haze is most often associated with high-gloss surfaces when small amounts of reflected light are scattered in a region 1 to 4° from the direction of specular reflection. Therefore, it is useful to place apertures several degrees wide on each side of the specular receptor aperture (Fig. 10). ASTM Test Methods for Measurement of Gloss of High Gloss Surfaces by Goniophotometry (E 430) [*20*] describes two methods for evaluating reflection haze, one at 20°, another at 30°. An instrument using a 30° angle has been commercially available for more than 15 years.[7] Since about 1992, a 20° laboratory gloss meter has been equipped with auxiliary apertures for haze evaluation, thus permitting measurement of 20° specular gloss and haze with the same instrument (Fig. 11).

Measurement of Image Clarity

A variety of different technologies is commercially available to measure image clarity [*21-24*]. The two most often used principles are: (1) measurement of the contrast in dependence of the wavelength of the transferred sinus wave (fourier-transformation) resulting in a modulation transfer function or (2) evaluation of the steepness of the reflection indicatrix. ASTM E 430 [*20*] describes the design of a commercially available instrument based on the evaluation of the reflection indicatrix (Fig. 12). The instrument illuminates the specimen at a 30° angle and measures the light reflected at 0.3° from the specular angle with an aperture of 0.3° width.

An attempt was made to correlate the surface waviness of coatings with image clarity measurements [*23,25*]. However, different surface profiles provided nearly the same image clarity readings [*21*].

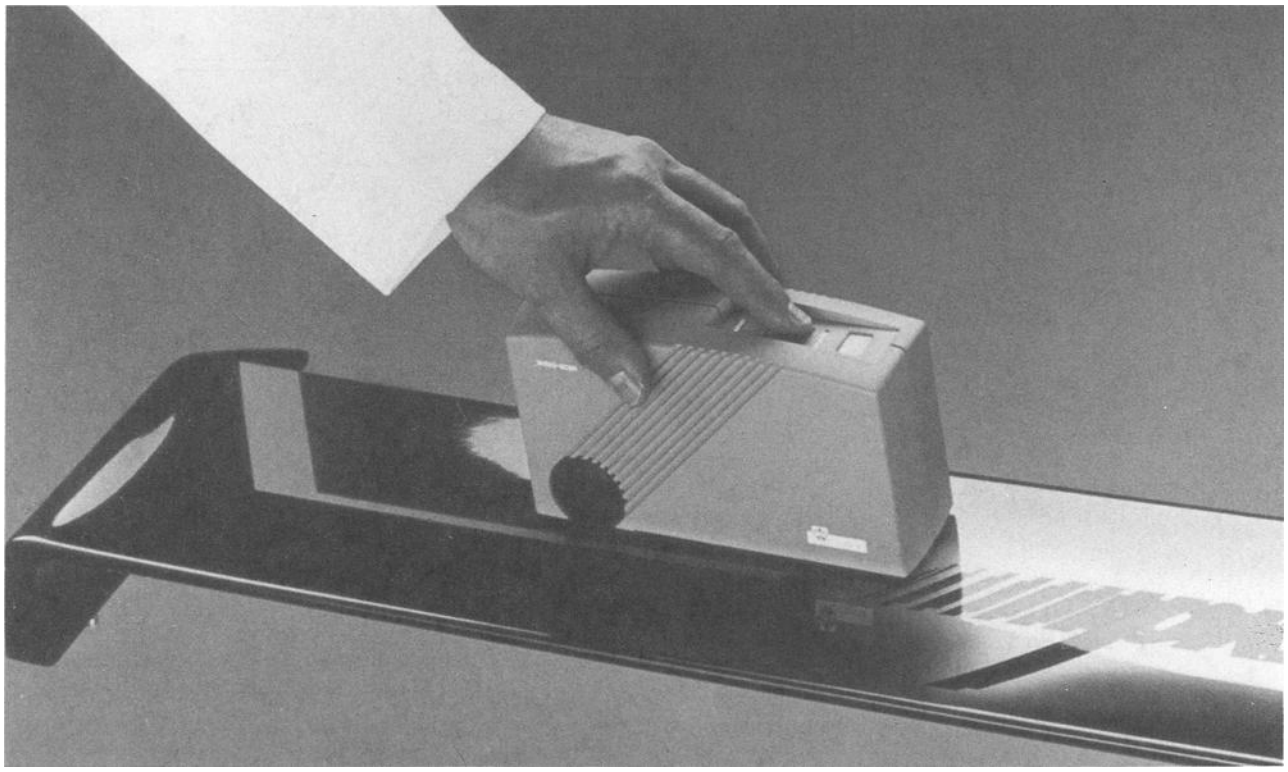

FIG. 13–Photograph of an orange-peel-measuring instrument.[8]

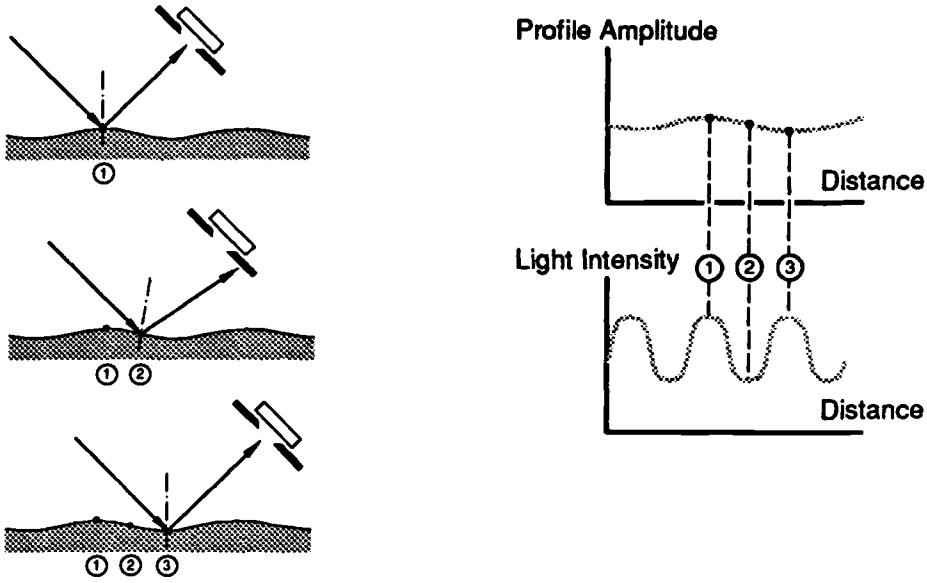

FIG. 14–Schematic diagram of the measurement principle for evaluation of orange peel.

[8]Apparatus designated "wave-scan," available from BYK-Gardner USA, Silver Spring, MD.

Measurement of Waviness (Orange Peel)

The phenomena of waviness is most observable on a glossy surface, a critical appearance phenomena in the automotive industry. Waviness has been evaluated by visual means and by use of a profilometer. The correlation between profilometry measurements and visual perception is satisfactory for surfaces with similar optical properties. The operation of a profilometer, however, is very time consuming and limited to laboratory use. When the eye of an observer is focused on a painted surface, various types of waviness can be identified that involve size, structure, and shape. Variations in process or material parameters can cause differences in surface structure. For example, poor flow or levelling properties of a coating will usually cause a long wave structure often called orange peel. Changes in substrate roughness, on the other hand, will exhibit a shortwave structure of higher frequency. Because waviness is often caused on the production line, it is important to control it there.

After considerable research, an instrument was produced in 1992 that will provide an objective evaluation of waviness [*26*] (Fig. 13).

A diode laser source is used to illuminate the specimen at 60°. The reflected light intensity is evaluated at the specular angle. During the measurement the instrument is moved along the surface for a distance of about 10 cm. The intensity of the reflected light is a maximum when coming from a valley or peak of an orange peel element. The detector receives less light from the slopes (Fig. 14). The human eye cannot resolve the actual heights of the structural elements of a painted surface (2 to 4 μm), but the contrast between light and dark areas provides an impression of depth. The contrast of a surface structure can be expressed by use of the statistical parameter "variance." The final measurement results are divided into a short wave component (structure size between 0.06 and 1 mm) and a long wave component (structure size between 1 and 10 mm) using an electronic filtering procedure. This evaluation reflects the simulation of the visual perception at different distances and permits categorizing structure sizes with their causes.

Hiding Power

by Leonard Schaeffer[1]

1. CONCEPTS, RELATIONSHIPS, TERMINOLOGY

a. Opacity

When light enters a paint film, some or all of it is absorbed or reflected by the film before reaching the substrate, thereby hiding the substrate to a lesser or greater degree. The light that reaches the substrate is partly absorbed by it and partly reflected back in conformance with the substrate's visual pattern. Reflection from the substrate eventually emerges from the film carrying the substrate reflectivity information perceived as visibility or lack thereof and referred to as *hiding*. Opacity may be qualitatively defined as the property of a paint film that enables it to prevent the passage of light and thereby to hide the substrate on which it has been applied. Note that *opacity* is a film property, whereas *hiding power* is a property of the whole paint. *Hiding* is a more general term used frequently to refer to either opacity or hiding power.

b. Light Absorption

If most of the light is absorbed by the film before reaching the substrate, the film is dark in color and hides the substrate well, in which case hiding has been produced by light absorption.

c. Light Scattering

If most of the light entering the film is reflected back and reemerges without having reached the substrate, the film is white or light in color and hides the substrate well. The reflection mechanism of the film involves multiple internal refractions and reflections that scatter the light to produce a net reversal in its direction. Hiding in this case is produced by light scattering.

d. Incomplete Hiding

In all cases, the light-absorbing and light-scattering properties of the film act together to produce its opacity. If the film is low in both light-absorption and light-scattering ability, much of the light reaches the substrate. Such a film therefore hides poorly and is characterized as being low in opacity.

e. Standard Test Substrates

An opacity test substrate generally has an ordered pattern of contrasting colors or shades, usually black and white, although black and grey and grey and white are also used. Juxtaposition of contrasting areas permits both visual observation and photometric measurement of film opacity. For photometric measurements only, individual black glass and white glass panels are sometimes employed to take advantage of their excellent planarity. Clear plastic can also be used as an opacity test substrate by placing it over black-and-white backgrounds. Standard black-and-white opacity test substrates are defined in paint technology as having CIE-Y reflectances of 0.01 (1%) maximum and 0.80 (80%), respectively.[2] White test areas are seldom exactly 80%, but equations are available for correction of photometric values to that standard (see Eqs 1 and 2).

f. Contrast Ratio

The extent to which a paint film obscures or hides the contrasting features of the test substrate on which it is uniformly applied is the measure of its opacity. This is expressed photometrically as the ratio of the luminous (CIE-Y) reflectance over the darker to that over the lighter area of the substrate, which is referred to as the contrast ratio (CR). The Y-reflectance is employed because this CIE parameter is designed to match the sensitivity of the human eye. The CR and the reflectance are expressed as a percentage or as a decimal fraction, the latter to be assumed unless otherwise indicated. A CR value of unity indicates that too little light has reached the substrate for the substrate reflectance characteristics to have a measurable effect on the emergent light flux; thus, there is complete absence of contrast, or complete hiding. Lesser CR values define intermediate levels of contrast, or incomplete hiding. The contrast ratio of a given paint film varies with substrate reflectances and therefore has significance only with respect to a known substrate and primarily to a standard black-and-white substrate as defined in 1.e. In practice, the white area of a commercially available black-and-white substrate normally deviates somewhat from the ideal reflectance of 80%, whereas the black area is normally 1% or less, which has no measurable effect on test results and is therefore treated mathematically as having zero reflec-

tance. Conventional symbols used in this connection are as follows:

W = the reflectance of the white area of the test substrate,
R_w = the reflectance of the paint film over a white area of reflectance W,
R_0 = the reflectance of the paint film over the black area,
C_w = R_0/R_w, the CR of the applied paint film,
$C_{0.80}$ = $R_0/R_{0.80}$, the CR when $W = 0.80$, and
C = $C_{0.80}$, the abbreviation sometimes used in equations.

In careful hiding power measurements, if the white substrate reflectance deviates more than 0.01 from the standard value of 0.80, one of the following correction equations[3] is employed

$$C_{0.80} = f(R_0, R_w, W) = \frac{WR_0(1 - 0.80R_0)}{R_0(W - 0.80) + 0.80R_w(1 - WR_0)} \quad (1)$$

$$C_{0.80} = f(C_w, R_0, W) = \frac{WC_w(1 - 0.80R_0)}{C_w(W - 0.80) + 0.80(1 - WR_0)} \quad (2)$$

g. Visual Observations of Contrast

Although intermediate levels of contrast cannot be directly quantified by visual means, the eye is qualitatively very sensitive to contrast variations. It can identify equalities or nearly complete absence of contrast with considerable precision, which is the basis for the original as well as several current hiding power methods to be described. Indeed, such visual observations are the basic criteria of what constitutes hiding and hiding power, to which all instrumental hiding measurements trace their validity.

h. Film Thickness

This is usually expressed in thousandths of an inch (mils) or in micrometers (μm). A liquid paint usually contains a substantial quantity of volatiles, so that its dry film thickness (DFT) is substantially less than the original wet film thickness (WFT). The WFT of architectural paints applied in the field are typically in the neighborhood of 3 to 4 mils (75 to 100 μm). With other coating types, it might be as low as 1 mil (25 μm) or as high as 60 mils (1500 μm). With volatile-free liquid coatings, the WFT and DFT are the same except for a possible small increase in density during curing. With powder coatings, for which film formation and curing are concurrent, the term WFT is inapplicable and DFT redundant, so that it is appropriate to refer simply to *film thickness.*

i. Spreading Rate

When paint is applied, whether for test purposes or in actual usage, the area covered per unit quantity of paint is called the spreading rate (SR) for that particular application. When the quantity of coating is expressed volumetrically, as is usual with liquid paints, the SR is usually expressed in square feet per gallon (ft^2/gal) or square metres per litre (m^2/L). When the quantity is expressed gravimetrically, the SR is usually expressed in square feet per pound (ft^2/lb) or square metres per kilogram (m^2/kg). SR is inversely related to the film thickness; thus, for a given paint, the lower the SR, the higher the film thickness and film opacity.

j. Spreading Rate and Film Thickness Relationships

Let

H = spreading rate of the coating (equivalent to SR),[4]
T = wet film thickness (equivalent to WFT),[4]
D = coating density (prior to loss of volatiles),
t = dry film thickness (exclusive of air)[5] (equivalent to DFT),
d = dry film density (displacement density),[5]
N = nonvolatile fraction by weight (equivalent to NVW), and
N_v = nonvolatile fraction by volume (equivalent to NVV).

(1) U.S. Units

$$H\,(\text{ft}^2/\text{gal}) \times T\,(\text{mil}) = 1604.2 \quad (3)$$

$$H\,(\text{ft}^2/\text{gal}) \times t\,(\text{mil}) = 1604.2\,ND \div d \quad (4)$$

$$H\,(\text{ft}^2/\text{lb}) \times T\,(\text{mil}) = 1604.2 \div D\,(\text{lb/gal}) \quad (5)$$

$$H\,(\text{ft}^2/\text{lb}) \times t\,(\text{mil}) = 1604.2\,N \div d\,(\text{lb/gal}) \quad (6)$$

(2) Metric Units[6]

$$H\,(\text{m}^2/\text{L}) \times T\,(\mu\text{m}) = 1000 \quad (7)$$

$$H\,(\text{m}^2/\text{L}) \times t\,(\mu\text{m}) = 1000\,ND \div d \quad (8)$$

$$H\,(\text{m}^2/\text{kg}) \times T\,(\mu\text{m}) = 1000 \div D\,(\text{kg/L}) \quad (9)$$

$$H\,(\text{m}^2/\text{kg}) \times t\,(\mu\text{m}) = 1000\,N \div d\,(\text{kg/L}) \quad (10)$$

(3) U.S.—Metric Unit Conversions

$$H\,(\text{ft}^2/\text{gal}) = H\,(\text{m}^2/\text{L}) \times 40.746 \quad (11)$$

$$H\,(\text{ft}^2/\text{lb}) = H\,(\text{m}^2/\text{kg}) \times 4.8882 \quad (12)$$

$$T\,(\text{mil}) = T\,(\mu\text{m}) \div 25.4 \quad (13)$$

$$D\,(\text{lb/gal}) = D\,(\text{kg/L}) \times 8.3454 \quad (14)$$

(4) Dry Versus Wet Film Relationships[7]

$$ND = N_v d \quad (15)$$

$$t = N_v T \quad (16)$$

$$T = td \div ND \quad (17)$$

2. DEFINITION OF HIDING POWER (HP)

Qualitatively, hiding power is the property of a paint that is manifested as opacity in its films. Quantitatively, it is the

[3]Derived from Eq 39 by equating to $W = 0.80$.

[4]Note that WFT and SR, when the latter is expressed by volume, are inverse ways of stating the same information.

[5]Refers to films containing no air or hypothetically compressed to exclude air.

[6]The following metric notations are identities: kg/L = g/mL = g/cm^3 = g/cc.

[7]These are applicable to both common and metric units since the units all cancel.

spreading rate at which the film opacity is just sufficient to give complete hiding over the specified standard black-and-white substrate (see 1.e). The "complete hiding" point is determined visually in some test procedures and photometrically in others.

a. Visual Hiding Power End-Point

In the visual determination of hiding power, the operator increases the film thickness gradually and records the amount of paint applied at the supposedly exact point of complete hiding. In practice, instead of perceiving such a point, a range of uncertainty is reached beyond which, when hiding seems unquestionably complete, it also seems that the true end-point has been exceeded. To resolve this dilemma and to obtain repeatable results, the operator chooses an end-point at which it seems that only a negligible increase in film thickness is required to completely obscure the contrasting features of the substrate. This so-called *complete hiding* end-point is therefore more accurately described as just short of complete hiding.

b. Photometric Hiding Power End-Point

Uncertainty as to the end-point also exists when measuring hiding power photometrically. A curve of film thickness versus contrast ratio approaches CR = 1 asymptotically, so in theory there is no point at which the contrast is completely obscured. Thus in practice the CR end-point for hiding power measurements must be less than unity. A CR value of 0.98 is generally accepted in paint technology as representing the point of photometric *complete hiding* because it is in fact very close to being visually complete, and a higher CR end-point could not be identified with as much precision. The concept of 98% as the contrast ratio for complete hiding was originally based on the Weber-Fechner law, which states that differences of 2% in reflectance (with moderate illumination) are imperceptible to the human eye [*1*]. Actually, this level of contrast, though slight, is definitely visible.

3. THE ROLE OF PIGMENTS IN HIDING POWER

a. Binders and Pigments

A typical paint binder, by itself, forms a transparent and virtually colorless film that neither absorbs nor scatters light to any appreciable degree and therefore makes no contribution to the hiding power of the coating of which it is a part. This task resides entirely in the pigment constituent of the paint. Pigments are fine-particle-size, insoluble, and usually crystalline solids that when dispersed in paint vehicles contribute to the various properties of the mixture, among which are the optical properties of color and hiding power. Pigments that absorb light strongly over the entire visible spectrum are black; those that are optically selective, absorbing strongly in parts of the visible spectrum and poorly in other parts, are colored, viz. blue, red, yellow, etc., corresponding to the spectral region of nonabsorption. Those that absorb poorly over the entire visible spectrum are white.

b. White Pigments

When dispersed in a paint binder, some white pigments scatter light strongly and thereby contribute to hiding, while others scatter very poorly and make little if any contribution. On that basis white pigments are classified as *hiding pigments* or as *extenders*. White hiding pigments in a paint formulation are sometimes called "prime pigments" as distinguished from the nonhiding "extender" types. The latter are also referred to as "inerts" in view of their apparent passivity with regard to both light absorption and scattering. The difference in scattering behavior between hiding and extender pigments is a function of their refractive indices.

c. Refractive Index

Most pigments are crystalline in nature. If a single crystal of white pigment were grown sufficiently large, it would be perceived as shiny and transparent like glass, and objects observed through it would look bent and distorted as when observed through a glass prism. This is due to the change in direction, referred to as refraction, that occurs when light passes between media in which it has different velocities, as illustrated in Fig. 1. The relationship between the angles in this figure is expressed by Snell's law of refraction

$$n = \sin i / \sin r \tag{18}$$

in which i and r are the angles of incidence and refraction, respectively, and n is a constant referred to as the refractive index, which is the ratio of the velocity of light in the incident to that in the refraction medium. If the large pigment crystal postulated previously is pulverized and dispersed in a paint film, each small particle will refract incident light in the same way as described for the large one. Light will also be partially reflected at the surface, and both refractions and reflections will occur within the pigment particle itself. This activity, endlessly repeated with a multitude of pigment particles as illustrated in Fig. 2 (Ref *2*, p. 1), results in the scattering of the original incident light with concomitant film opacity and paint hiding power. The greater the difference between the refractive indices of the pigment and the surrounding medium, the greater the amount of light scattering. Refractive

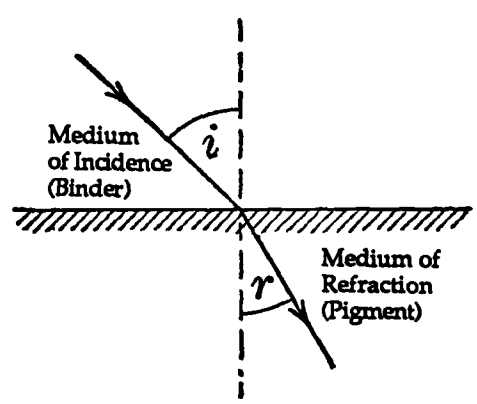

FIG. 1—Bending of a light ray by refraction towards the normal as it enters a medium of lower light velocity (higher refractive index).

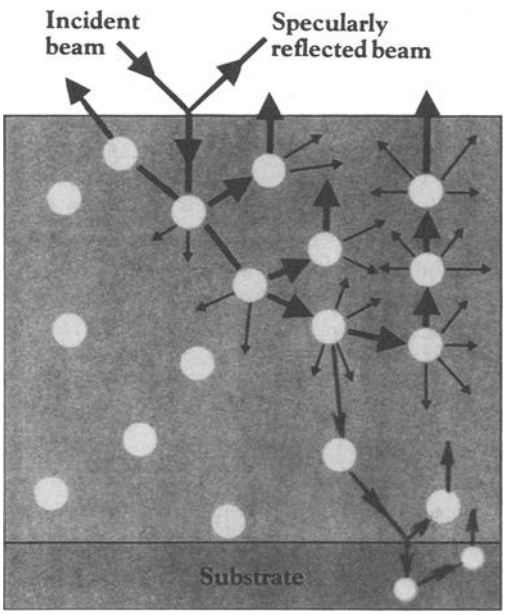

FIG. 2–Light-scattering behavior of a pigmented film.

indices are reported in Tables 1 and 2 with respect to a vacuum as the medium of incidence. Values with respect to air are practically the same. Since white pigments are crystalline in nature, they usually possess different refractive indices along the different crystal axes. Their indices also vary somewhat with the wavelength of the light, generally being higher at the blue (short wave length) end of the spectrum than at the red (long wavelength) end. Tables 1 and 2 give average values [*1*,*3*].

TABLE 1—Refractive index and relative hiding power of some white hiding pigments.

Pigment	Refractive Index	Relative HP, F%[a]
Titanium dioxide (rutile)	2.76	8.8
Titanium dioxide (anatase)	2.55	6.7
Zirconium oxide	2.40	5.3
Zinc sulfide	2.37	5.0
Antimony oxide	2.19	3.5
Zinc oxide	2.02	2.2
White lead carbonate	2.01	2.1
White lead sulfate	1.93	1.6
Lithopone	1.84	1.0

[a]Calculated from Eq 20.

TABLE 2—Refractive index and relative hiding power of some extender pigments.

Pigment	Refractive Index	Relative HP, F%[a]
Barium sulfate	1.64	0.20
Calcium sulfate	1.59	0.08
Calcium carbonate	1.57	0.05
Magnesium silicate	1.57	0.05
Aluminum silicate	1.55	0.03
Silica	1.55	0.03

[a]Calculated from Eq 20.

d. White Hiding Pigments

A rough indication of the relative hiding power of a white pigment can be calculated from its refractive index using the Fresnell equation of reflectivity (Ref *2*, p. 1),

$$F\% = \frac{(n - n_m)^2}{(n + n_m)^2} \times 100 \tag{19}$$

where F is the Fresnell reflectivity, n is the refractive index of the pigment, and n_m is the refractive index of the medium in which it is dispersed. Since the refractive index of a paint binder is in general very close to 1.5, Eq 19 can be rewritten as

$$F\% = \frac{(n - 1.5)^2}{(n + 1.5)^2} \times 100 \tag{20}$$

Tables 1 and 2 illustrate the use of this equation and the general principle that the higher the refractive index of a pigment the greater its hiding power. The relative hiding power values shown therein indicate the magnitude of variation related to index of refraction. Other factors can also affect hiding power substantially, as discussed in Section 9.

e. Extender Pigments

Pigments in this category have low refractive indices in the neighborhood of 1.5. In the form of a powder, with the surrounding medium being air with a refractive index of 1.0, the difference in the two indices produces substantial light scattering, so that extender pigments look white. But dispersed in paint binders, which like themselves typically have a value of about 1.5, they scatter light very poorly and are virtually transparent. This is indicated by the low HP values listed for them in Table 2 as compared with the white hiding pigments in Table 1. Although extender pigments are also referred to as "inerts," the latter term is somewhat of a misnomer. They have an indirect but strong influence on light scattering and hiding power through phenomena referred to as "crowding" and "dry hiding." They also have important effects on other physical properties of paints such as consistency and gloss.

f. Colored Pigments

If a pigment absorbs some wavelengths of light more strongly than others, it reflects back a higher proportion of the weakly absorbed wavelengths and is perceived as having the color of the latter (e.g., red, blue, yellow, etc.). Light absorption of this nature is referred to as "selective." Colored pigments can vary greatly in hiding power depending on their light absorption and light-scattering abilities. With regard to light scattering, as with white pigments this is a function of the refractive index or more specifically the difference in refractive index between the pigment and surrounding medium. Refractive indices of colored pigments vary widely with wavelength, ranging from 1.3 to 2.7. These variations cause such phenomena as bronzing, dichroism, color change with film thickness, and differences in undertone upon dilution with white pigments (Ref *4*, p. 22).

4. EARLY VISUAL HIDING POWER METHODS

a. Brushouts

The earliest methods for determining hiding power employed the practical procedure of brushing the paint uniformly onto combination black-and-white test substrates, increasing the amount of paint in small increments until reaching the point of essentially complete hiding at which the amount of visual contrast was considered negligible. The quantity of paint was determined by weighing the container and brush in grams before and after painting. The corresponding spreading rate (SR) is the hiding power (HP) by definition and was calculated from the equation

$$\text{SR}\,(\text{ft}^2/\text{gal}) = \frac{\text{Test Area}\,(\text{ft}^2) \times \text{Paint Density}\,(\text{lb/gal}) \times 454}{\text{Weight of Paint}\,(\text{g})} \quad (21)$$

For single-pigment paints, the value calculated from Eq 21 can be converted to pigment hiding power using the equation

$$\text{SR}_{\text{pigment}}\,(\text{ft}^2/\text{lb}) = \frac{\text{SR}_{\text{paint}}\,(\text{ft}^2/\text{gal})}{\text{Pigment Concentration}\,(\text{lb/gal})} \quad (22)$$

Variants of these equations provide for the use of metric instead of U.S. units.

b. Early Test Substrates

Originally in the study of hiding power, test surfaces were prepared in individual laboratories by painting black stripes on white-painted panels. In response to the need for standardized test surfaces, studies were made on oil cloth and linoleum having printed checkerboard-type designs [*5*]. The Gardner Contrast Hiding Power Board was a two-square-foot area glass checkerboard with black and white squares painted on the underside of a thin piece of glass (Fig. 3). The first formalized ASTM method used a linoleum checkerboard surface in the brushout test procedure described in 4.a. The Gardner glass board was used in the same way. Since the "complete hiding" end point in those early methods was determined when the paint was freshly applied and still wet, the resultant hiding power value pertained only to the wet hiding power of the paint, not to the dry. This was not a problem in the earliest days of hiding power measurement when typical paints contained relatively little volatile constituent and the opacity of the film therefore did not change markedly while drying. But, with the advent of modern paint formulations containing substantial amounts of volatiles, the composition and with it the opacity of the dry paint film could be substantially different than that of the initially applied film. The need to measure dry hiding power therefore became of paramount importance. As a practical problem in this connection, expensive linoleum and glass test surfaces had to be cleaned for reuse after each test, which made it very difficult to use them for the study of *dry* hiding power. This problem was partly overcome with the introduction of paper test charts circa 1931 that were printed in various designs such as checkerboard, concentric diamond-shaped bands, spirals, crescents, etc., and with various degrees of contrast such as black-white, black-grey, grey-white, and a graded series of stripes from black to white. After printing, a coat of nitrocellulose lacquer or other suitable clear sealer was applied. Many of those chart types became and continue to be commercially available.

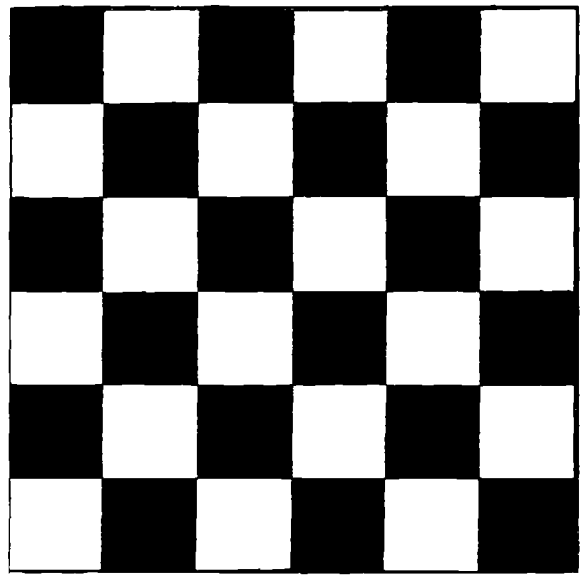

FIG. 3–Gardner contrast hiding power board.

c. Contrast Design and Visual Sensitivity

Kraemer and Schupp [*6*] evaluated contrast surfaces in a variety of designs prepared on glossy photographic paper. These included the customary checkerboard design, a design of narrow 15-mm-wide bands, another with much broader bands, and one with dark half circles on a light background. The results seemed to favor a narrow band design subsequently employed by the Krebs Pigment Co. in preparing the diamond stripe grey and white contrast charts illustrated in Fig. 4. The test area of that chart was 1 ft^2 (0.0929 m^2). The use of a grey-and-white contrast combination was based on the idea that this is more representative than black and white of the degree of contrast encountered by paints in actual use.

d. Relative Dry Hiding Power—Krebs Method

Although the introduction of paper test charts as replacements for linoleum or glass made dry hiding power measurements easier, they were still not easy enough. The problem was that it required the preparation of a considerable number of paint-outs at various spreading rates to obtain one that after drying could be identified with confidence as representing the "complete hiding" end-point. One solution to this problem was to determine comparative or relative dry hiding power. In the Krebs Pigment Co. method, their square-foot grey-and-white diamond stripe chart was used for that purpose in the following manner: A partial hiding ladder of six to eight brushout standards is made by applying a standard paint at spreading rates ranging from 400 to 800 ft^2/gal (10 to 20 m^2/L) and allowing the brushouts to dry. The spreading rates are precontrolled approximately by syringing specified volumes of paint onto each chart and then determined accurately by weight measurements and calculation as described

FIG. 4–Krebs diamond-stripe hiding power chart.

in 4.a. A single test paint panel is likewise prepared at an intermediate spreading rate. After drying, that panel is compared with the standard panels to determine the two that bracket it in contrast. Then by visual interpolation a fairly precise estimate is made of the spreading rate of the standard paint required to match the contrast of the test paint panel. The relative dry hiding power of the test paint is the percent ratio of its spreading rate to that of the standard paint at equal visual contrast, thus

$$\%\,\text{Relative Hiding Power} = \frac{SR_{\text{Test Paint}}}{SR_{\text{Std. Paint}}} \times 100 \qquad (23)$$

e. Pfund Cryptometers

(1) All Black

Introduced in 1919, this was one of the first laboratory instruments made for determining HP [7]. Referring to Fig. 5, A is a plate of black glass whose upper surface is optically flat; B is a transverse groove 10 mm wide and about 2 mm deep. Beginning at the left edge of the groove is a millimetre scale etched in the upper surface of Plate A. C is a plate of clear glass whose lower surface is optically flat. D is a steel shim cemented to C so that a wedge of paint may be formed between the plates. This wedge abruptly becomes "infinitely thick" at B, and so long as hiding is not complete, the line of demarcation is visible. Sliding the wedge to the left eventually

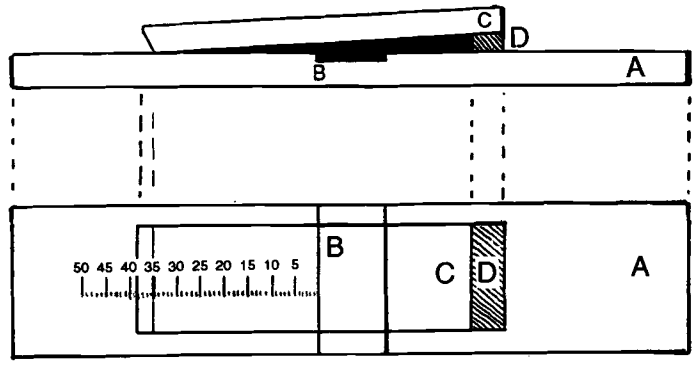

FIG. 5–Diagram of early model of Pfund cryptometer.

causes the line to disappear. The wet film thickness at the point of complete hiding is determined from the scale reading at the toe of the wedge and the thickness of the shim at the heel, from which the HP in ft^2/gal or m^2/L can be calculated using Eq 3 or Eq 7. Dark-colored paints cannot be measured using this instrument because of the lack of contrast with the black glass background. Nelson and Norris of the New Jersey Zinc Co. used this cryptometer to determine HP of colored pigments with results as shown in Table 3. The pastes were prepared by rubbing the colors in No. 0000 lithograph varnish. The rubbing was regulated to represent the maximum development usually obtained in practice. In addition to the regular black glass instrument, they used one specially made with white glass for several measurements.

(2) Black and White

Pfund [8] introduced the black-and-white cryptometer in 1930. It eliminated the well, making cleaning easier, and worked for use with paints of any color because of the black-and-white instead of all-black background. Referring to Fig. 6, the black glass B and the white glass W are fused along line LM. Longitudinal grooves catch the overflow of paint. The wedge is moved to the right to make the line disappear, then to the left to make it reappear. The position of the plate is reversed and the observations repeated. From the mean of all readings, the hiding is calculated as with the all-black cryptometer (4.e.(1)). Comparison of results for white paints shows that the two cryptometer types (all-black and black-and-white) yield the same values within experimental error (Ref 4, p. 22).

(3) Rotary Type

The rotary cryptometer was a short-lived device designed to overcome the jerky movement of the top plate of the regular cryptometer [9]. The wedge of the cryptometers of Figs. 5 and 6 was replaced with a circular glass plate mounted in a metal frame (Fig. 7). The thickness of the film was read on a scale located on the bottom plate. While the movement of the plate was much smoother with this instrument, it was found that bubbles often obscured the end-point.

(4) Assessment of Cryptometers (Ref 4, p. 25)

The cryptometer is a simple instrument requiring only small quantities of paint, and determinations are quickly made. However, reading the end-point is difficult, and the mean of a number of determinations is therefore advisable.

[a]Multiply by 4.9 to obtain HP in ft^2/lb.

Most users can repeat their own results, but agreement among different users is not satisfactory although it is improved by the use of a standard paint [*10*]. Another major disadvantage of cryptometers is that they measure only wet HP. One study [*11*] reported that cryptometers were satisfactory with low-opacity but not high-opacity paints. Consideration of its advantages and disadvantages suggests that the cryptometer is better suited for control work than for specification requirements. The cryptometers shown in Figs. 5 and 6 continue to be commercially available.

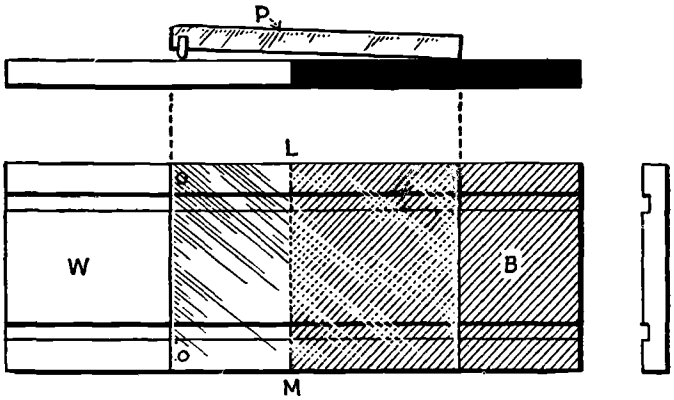

FIG. 6–Pfund black-and-white cryptometer.

f. Hallet Hidimeter

Along with the Pfund cryptometer, the Hallet hidimeter [*12*] was one of the very early devices for evaluating HP. The objective of a regular microscope is replaced by a long tube fitted with a plain ground glass objective; the eyepiece is replaced with a small hole. The principle of the device is the light-diffusing property of ground glass. If a contrast substrate is viewed through a plate of ground glass, the contrast boundaries become more blurred as the distance between plate and substrate increases. If a liquid paint sample is sandwiched between them, it blurs the boundary further, and the distance required to make the boundary disappear decreases. Since that distance is the thickness of the intervening paint film, it is a measure of the hiding power of the paint. This measurement is essentially comparative because it cannot be translated into regular hiding power units.

5. EARLY PHOTOMETRIC HIDING POWER METHODS

a. Pfund Precision Cryptometer

In this device (Fig. 8) a photoelectric cell is used to measure the reflectance of paint contained in a wedge-shaped layer [*13*]. The base plate consists of black-and-white areas B and W, whose boundary is parallel to the length of the plate instead of perpendicular as with the visual cryptometer. The photoelectric device is shifted until a position is found where the reflectance of the paint over the black area is 98% of that over the white area. The film thickness and HP calculations are the same as with the visual cryptometers described in section 4.e.

This cryptometer eliminates the uncertainties of the visual type, as there is no sliding of the top plate over the base plate and no need to estimate visually the appearance and disappearance of an indistinct line. However, it retains the disadvantage of permitting only wet hiding measurements and has therefore been superseded by other photometric devices and methods that permit the measurement of dry hiding power.

b. Hanstock Method

Hanstock [*14*] studied the relationship of light transmission through free paint films to opacity and HP on a black-and-white substrate. For his transmission work, he employed a flicker photometer and found that paint films were perfectly diffusing and that films having the same degree of light transmission had approximately equal opacity. He further showed the correspondence between refractive index, the Fresnel relationship, and HP.

The problem with the transmission concept is that modern paints have so much opacity it is difficult to measure accurately the transmission of films of commercial thickness. Moreover, HP is concerned in practice with paint in intimate contact with opaque surfaces and not as a free film. Consequently, measurement of light transmission through paint films is done today only for very specialized research.

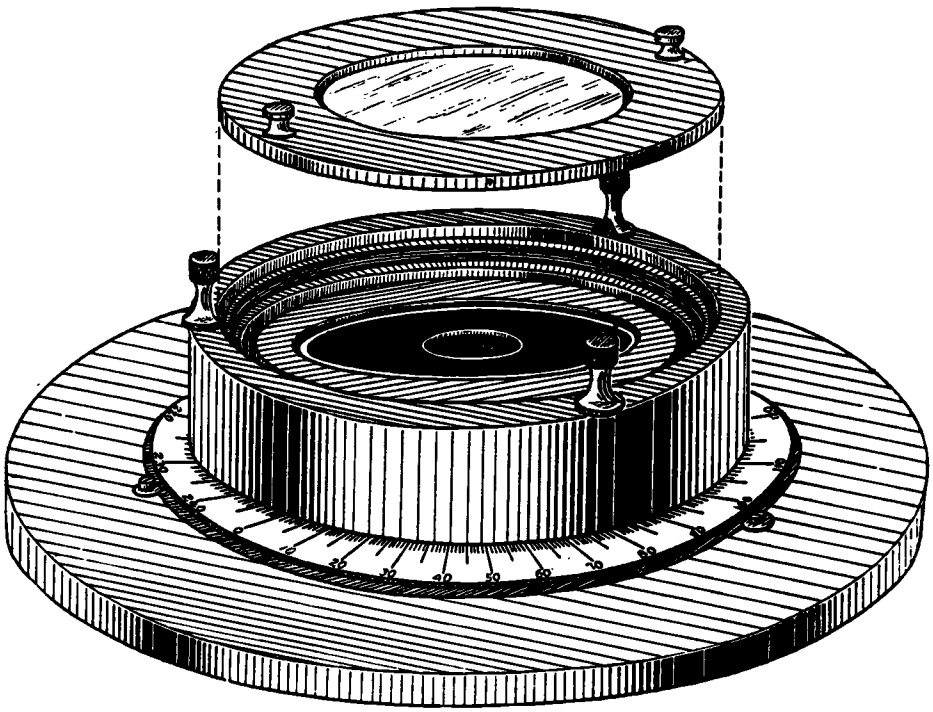

FIG. 7–Rotary cryptometer.

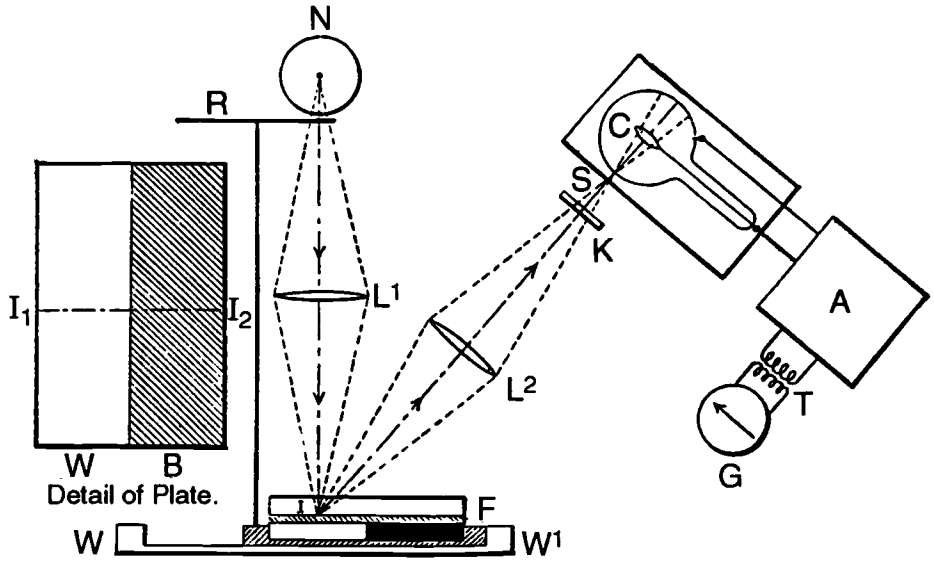

FIG. 8–Pfund precision cryptometer. Uses a photoelectric cell instead of the eye to measure reflectance.

c. Use of the Fell Equation

An empirical relationship between spreading rate (SR) and contrast ratio (CR) was found by Fell and reported by Sawyer [*15*] in the following form

$$\log(\mathrm{CR} \times 10) = m \times \mathrm{SR} + b \qquad (24)$$

where m and b are experimental constants.

Since the graph for this equation is a straight line, it is a simple matter after determining m and b from measurements at two CR levels to find the SR required for any desired CR. This procedure was adapted by Marchese and Zimmerman to determine the hiding power of paints at a contrast ratio of 0.98, and the method was used for many years by the Titanium Pigment Co. (Ref *4*, p. 24). Experience has shown that reasonably satisfactory results can be obtained if the equation is used for interpolation between points close to the desired contrast ratio. But, as pointed out by Switzer [*16*], extrapolation of results can lead to serious errors. He further pointed out that the Fell equation method allows only a single estimate of HP from at least two test applications, thus re-

quiring a considerable effort to obtain an estimate of intralaboratory precision.

d. New York Paint Club (NYPC) Method

This method employed doctor blades to apply films at several thicknesses on black-and-white cardboard hiding power charts. After the films had dried, reflectance, weight, and area measurements were made from which contrast ratios and corresponding wet film thicknesses were calculated. CR values (rather than log 10 CR as in the Fell equation) were plotted against reciprocal film thickness and the HP calculated from the wet film thickness at 0.98 CR. If the white area of the chart deviated appreciably from the standard reflectance of 0.80, the contrast ratio was corrected using Eq 1 or Eq 2. The Club reported that most of the effort in this method was to determine film thicknesses. To minimize that effort they modified the method by casting films on black and white glass plates and determined thicknesses with an Interchemical wet-film thickness gage in accordance with ASTM Test Methods for Measurement of Wet Film Thickness of Organic Coatings (D 1212). Any error in film thickness, of course, carries over to the HP value. According to Mitton, the revised method sacrifices accuracy and precision for speed [*17*]. In addition, graphical averaging makes it burdensome to estimate the precision with which the HP has been determined for the same reason pointed out in 5.c in connection with the Fell equation method.

e. Van Eyken-Anderson Method

The method proposed by Van Eyken and Anderson [*18*] uses CRs and film thicknesses in the same way as the NYPC method described in 5.d, except that films of different thicknesses are applied in a single operation by using a doctor blade having seven clearances. A die is used to prepare uniform area punch-outs of the paper charts to determine spreading rate by the basic weight-area-density-NVW calculation (see Eq 26). The defects of this method are that the small areas used for reflectance and weighing make the achievement of good precision difficult (Ref *4*, p. 31), and there is no provision for correcting CR if the white substrate reflectance differs from 0.80.

f. Federal Test for Dry Opacity

This is Method 4121 of U.S. Federal Test Method Standard No. 141. It is a pass-fail test calling for a minimum dry film contrast ratio at a specified WFT. Black-and-white hiding power charts are used as the test substrate. For routine testing, the paint may be applied either by brush or doctor blade. For referee tests, application is by doctor blade only. The density and the nonvolatile content of the paint are also required. Several drawdowns are made to bracket the specified WFT. The weight of dry paint film is determined for a measured area on each drawdown and the WFT then calculated from the equation

$$\text{WFT (mils)} = \frac{61\,M(\text{g})}{A\,(\text{in.}^2) \times N \times D\,(\text{g/mL})} \tag{25}$$

where

M = the dry film weight,
N = the fractional nonvolatile content of the paint by weight,
A = the film area, and
D = the density of the paint.

The CR of each chart is measured and plotted against the corresponding WFT. From a smooth curve drawn through the points, the CR at the specified WFT is obtained. If this is equal to or greater than the specified CR, then the requirement for dry opacity has been met.

6. GENERAL HIDING POWER METHODOLOGY

a. Film Application

The objective is to determine the spreading rate at a specified level of dry film opacity, which is usually full hiding as perceived visually or corresponding to the contrast ratio: $C = R_0/R_{0.80} = 0.98$. The basic experimental procedure is to apply a uniform film on a suitable test substrate, to observe its opacity either visually or photometrically, and to determine its spreading rate. Since it is not possible to apply a film with precision at a predetermined dry opacity, several such applications need to be made over a range of spreading rates and their results plotted graphically or otherwise interpolated to the desired hiding power end-point. This laborious procedure is exemplified in the visual methods discussed in 4.a and 4.d and in the contrast ratio (CR) methods discussed in 5.e and 5.f. The Fell equation and NYPC methods (5.c and 5.d) attempt to reduce the workload to only two spreading rate determinations by plotting SR against CR or log CR and finding the hiding power end-point graphically on the basis of perceived empirical straight-line relationships. Kubelka-Munk theory (see Section 8) shows how the end-point can be calculated with just one spreading rate determination.

b. Spreading Rate (or Film Thickness) Determination

In both visual and photometric hiding power methods, the procedures for observing film opacity are well-defined and can be performed with dispatch. The experimental task most demanding on the operator's time and ingenuity is to determine the spreading rate or film thickness of the applied coating with good precision. Although gages are available to measure wet and dry film thickness directly and quickly, the most accurate procedure, by far, is to determine the weight of applied paint film on a measured test area and then to calculate the spreading rate or film thickness as described in 4.a and 5.f. The equations in both of those methods contain mixed metric and common units. When the units are all metric, the equations are simpler. Letting M = dry film weight and A = the film area and using the symbolism in 1.j:

$$H\,(\text{m}^2/\text{L}) = \frac{A\,(\text{cm}^2)\cdot N\cdot D\,(\text{kg/L})}{10M\,(\text{g})} \tag{26}$$

$$T(\mu\text{m}) = \frac{10^4 M\,(\text{g})}{A\,(\text{cm}^2)\cdot N\cdot D\,(\text{kg/L})} \tag{27}$$

See 1.j.2 for equations interrelating spreading rate, wet film thickness, and dry film thickness. See 1.j.3 for conversions between metric and U.S. units.

If the volatiles have a relatively low evaporation rate as with most architectural coatings, the film might be weighed rapidly before appreciable loss of volatiles, in which case Eqs 26 and 27 would still apply but with M as the wet film weight and N as unity. The disadvantage of this procedure is that it demands very skillful and speedy manipulation to minimize loss of volatiles before weighing. For that same reason, it is not applicable at all to coatings containing fast evaporating solvents.

With powder coatings, for which the spreading rate is normally expressed on a weight basis, Eq 26 becomes

$$H\,(\mathrm{m^2/kg}) = \frac{A\,(\mathrm{cm^2})\cdot N}{10M\,(\mathrm{g})} \tag{28}$$

Assuming negligible volatile content, the value of N in this equation can be taken as unity.

c. Photometric Measurements

The CIE-Y reflectance is measured because this function defines the human eye's quantitative response to the luminous character of light across the visual spectrum. This is valid for chromatic as well as nonchromatic colors, as reported by Tough [*19*], who found good correlation in a large series of colored paints between visual hiding power measurements and contrast ratio values based on CIE-Y measurements with a spectrophotometer. The end-point of 0.98 CR is effective with colors, although it appears that other end-points, for example CIELAB color difference: $\Delta E = 1.5$, would make some difference in the relative HP of various colored paints [*20*]. However, the simplicity of the 0.98 end-point and its history of validity and general agreement among various workers make it the best choice regardless of color (Ref *4*, p. 31). CIE-Y measurements can be made with the green filter of a tri-stimulus colorimeter or with a spectrophotometer. When properly standardized, results with the two instrument types should be the same. As a precaution, there should be coordination between correspondent laboratories with regard to instrumentation. In all cases, reflectance measurements must be made excluding surface reflection, which is implicit for instruments designed with 0°/45° geometry and optional with most other instrument types.

7. CURRENTLY USED TEST SUBSTRATES

The substrate is generally the major factor affecting the specific experimental details of a test procedure. It is selected or specified on the basis of its adaptability to the type of coating being tested and for its perceived advantages in the required or preferred test procedure.

a. Paperboard Charts

Substrates of this type are described in 4.d. Their employment with baking finishes is limited because of distortion and discoloration at high temperatures, but they are used widely with air-dried coatings for general hiding power observations. Black-and-white charts can be used for precision photometric hiding power measurements by taking appropriate steps to allow for weight variations in the substrate due to humidity and inherent random variations in the area weight of paper. These steps include the use of unpainted control charts and the averaging of multiple test results. Charts with combinations of gray and black, gray and white, and gradations of gray on a white background are used in visual hiding power tests to obtain what are considered to be more practical hiding power measurements.

b. Clear Plastic Film

Polyester is the preferred chemical type. Because of heat distortion, its use is generally confined to air-dried coatings. After the film has dried, a square of convenient size is cut and the area measured. Values of R_0 and R_w are read by placing the painted plastic film alternately on a black and a white background with the underside moistened with a suitable liquid (e.g., mineral spirits or dibutyl phthalate) to remove the air interface and establish good optical contact. The dry film weight is determined as the difference in the weight of the painted and unpainted substrate by stripping off the paint film with a strong solvent.

c. Glass Panels

Individual black and white glass panels are used to take advantage of the superior levelness of glass for casting of uniform films and because the hard, smooth surface permits rapid wet film thickness measurements with an ASTM-type of wet-film thickness gage (5.d). The same information is obtained less rapidly but with much better precision by scraping off and weighing a defined area of dry film and calculating as described in Section 6.b. In some tests, contrast ratios are calculated on the questionable assumption that separate film applications on black and white glass panels are identical in film thickness.

d. Painted Metal Panels

Panels of this type are generally used with coatings that are applied by spraying and cured by baking. The weight of the applied film is determined by weighing the panel before the coating is applied and again after drying. The spreading rate or film thickness is then calculated as described in 6.b. If desired, the dry film thickness can be determined without weighing, though with considerably less precision, by direct measurement with a magnetic or an eddy current thickness gage. Black-and-white panels are used for contrast ratio measurements or for visual observation of opacity. The use of all-black panels is described by Mitton for measuring the hiding power of baking enamels [*21*].

8. KUBELKA-MUNK (K-M) TWO-CONSTANT THEORY

a. Introduction

The light that enters a paint film is subjected to scattering and absorption as described in Section 3, and whatever is not absorbed by the film or substrate eventually reemerges as reflected light. In 1931 Kubelka and Munk [22] published equations defining the optical behavior of a translucent material in terms of two constants referred to as coefficients of scattering and absorption. Steele [23] in 1935 showed how these equations were adaptable to the measuring of paper opacity, and Judd et al. [24] in 1937 did the same in connection with coatings. Kubelka [25] in 1948 rearranged the original equations into new and simplified forms from which Switzer [26] in 1952 developed equations designed specifically for the study of hiding power by expressing the film thickness (or SR) as a function of the CR. Using these equations and their derivatives, the contrast ratio of a coating can be calculated for any spreading rate (or vice versa) from measurements made at only one and its photometric hiding power thereby determined by a single test application. This is in contrast with the more laborious procedure of obtaining CR values at two or more spreading rates for interpolation or extrapolation to the hiding power end-point. The calculations appear formidable but are readily accomplished with a suitably programmed computer. Graphs and tables are also available for this purpose, although not as convenient and accurate as a computer. The experimental steps are straightforward, and, as with most hiding power methods, the most difficult and time-consuming operation is to determine the experimental spreading rate (or film thickness) with sufficient precision. How that is accomplished is the essential difference between various Kubelka-Munk–based methods.

b. Equation Symbols

The symbols used here are based on ASTM Test Method for Hiding Power of Paints by Reflectometry (D 2805-88) as follows:

G = the substrate reflectance
For a white substrate $G = W$.
For a standard white substrate $G = W = 0.80$.
For a black substrate $G = B$.
For a standard black substrate $G = B \leq 1 \approx 0$.

R_G = the reflectance of a film applied over a substrate of reflectance G.

R_∞ = *reflectivity*—a property of the paint—the limiting reflectance of the paint film as it is increased in thickness. Also defined as the reflectance at complete hiding as evidenced by $R_0 = R_w$ over a black-and-white substrate of uniform film thickness.

C_w = the contrast ratio of a film applied at uniform thickness over a black-and-white substrate; thus, $C_w = R_0/R_w$,

$C_{0.80}$ = the contrast ratio over a standard black-and-white substrate, thus $C_{0.80} = R_0/R_{0.80}$.

C = abbreviation for $C_{0.80}$; the two are used interchangeably, thus $C = C_{0.80} = R_0/R_{0.80}$.

T = the film thickness in any stated unit, e.g., μm, mils.

H = the spreading rate in any stated unit, e.g., m²/L, ft²/gal, m²/kg, ft²/lb, cm²/g.

S = the scattering coefficient, a measure of the ability of the paint to scatter light, expressed in units reciprocal to T or the same as H.

K = the absorption coefficient—a measure of the ability of the paint to absorb light, expressed in the same unit(s) as S.

e = 2.718 28 . . . the exponential base for natural logarithms.

P = scattering power—a measure of the ability of a film to scatter light. A unitless film constant defined mathematically by the relationships: $P = ST$ or $P = S/H$.

Subscripts

x indicates an experimentally determined value, e.g., T_x, H_x, P_x.

c indicates a value calculated for a specified contrast ratio C, e.g., P_c, H_c.

0.98 indicates a value calculated for $C = 0.98$, e.g., $H_{0.98}$, $T_{0.98}$.

H indicates a value pertaining to a spreading rate, e.g., C_H, P_H, S_H.

T indicates a value pertaining to a film thickness, e.g., C_T, S_T.

a and b are simplifying functions of R_∞, defined by

$$a = \tfrac{1}{2}(1/R_\infty + R_\infty) \tag{29}$$

$$b = \tfrac{1}{2}(1/R_\infty - R_\infty) \tag{30}$$

From these definitions are derived the additional relationships

$$b = (a^2 - 1)^{1/2} \tag{31}$$

$$R_\infty = a - b = a - (a^2 - 1)^{1/2} \tag{32}$$

Note that R_∞, a, and b are three forms of the same constant, so that the determination of any one of them is equivalent to determining all three. Sometimes they are used together in the same equation.

Additional simplifying functions which can be expressed in exponential-logarithmic form, or using hyperbolic cotangents are

$$U = f(P, R_\infty) = b\left(\frac{e^{2bP} + 1}{e^{2bP} - 1}\right) = b \coth bP \tag{33}$$

and the converse of Eq 33

$$P = f(U, R_\infty) = \frac{1}{2b}\ln\left(\frac{U + b}{U - b}\right) = \frac{1}{b}\coth^{-1}\left(\frac{U}{b}\right) \tag{34}$$

in which

ln = sign of natural logarithms, viz., $\log_e x = \ln x$,

coth = sign of hyperbolic cotangents, defined by $\coth x = \dfrac{e^{2x} + 1,}{e^{2x} - 1}$ and

$\coth^{-1}$ = sign of inverse hyperbolic cotangents, defined by $\coth^{-1} x = \dfrac{1}{2}\ln\left(\dfrac{x + 1}{x - 1}\right)$.

Values of natural logarithms and hyperbolic functions are available in published tables and in calculators. Since the

tangent function is frequently provided without the cotangent, the relationships between the two are stated here as follows

$$\coth x = 1/\tanh x, \coth^{-1} x = \tanh^{-1} 1/x$$

c. Original *K-M* Equations

The original equations are as follows:

For nonopaque films

$$R_G = f(ST, R_\infty, G) = \frac{G/R_\infty - 1 + (1 - GR_\infty)e^{(1/R_\infty - R_\infty)ST}}{G - R_\infty + (1/R_\infty - G)e^{(1/R_\infty - R_\infty)ST}} \quad (35)$$

For opaque films

$$R_\infty = f(K/S) = 1 + K/S - (K^2S^2 + 2K/S)^{1/2} \quad (36)$$

whose converse and more useful form is

$$K/S = f(R_\infty) = (1 - R_\infty)^2/2R_\infty \quad (37)$$

Functional forms are shown in this discussion along with the corresponding explicit forms for a clearer perception of the variables. Sometimes the functional form will be used by itself for both brevity and clarity.

Equation 35 shows the reflectance of a paint film in terms of two basic optical characteristics of the paint: the scattering coefficient, S, and reflectivity, R_∞, and two values that are characteristic of the particular application: the reflectance G of the substrate and the thickness T of the film. Equation 36 shows that R_∞ could be replaced by K in Eq 35, but R_∞ is preferred because the resultant equation forms are much simpler and also because R_∞ can in some cases be measured directly.

d. Scattering Coefficient and Scattering Power

The product ST in Eq 35 is a unitless film constant referred to by Kubelka [*23*] and Judd [*22*] as the scattering power of the film and symbolized here by the letter P. Thus, given that $P = ST$ and employing simplifying forms of R_∞ and the function U of Eq 33, Eq 35 can be rewritten in the much abbreviated form

$$R_G = f(U, R_\infty, G) = f(P, R_\infty, G) = \frac{1 - G(a - U)}{a + U - G} \quad (38)$$

Since film thickness T and spreading rate H are reciprocally interdependent (see Eqs 3 and 7), it follows that $P = S_T T = S_H/H$, with the scattering coefficient (S_T or S_H) being expressed in a unit reciprocal to that of T (e.g., mil^{-1}, μm^{-1}) or in the same spreading rate units as H (e.g., ft^2/gal, m^2/L, ft^2/lb, m^2/kg, cm^2/g). A clarifying concept in which spreading rate units are mandatory is to consider scattering as an entity quantifiable in area units, with the scattering coefficient as the amount of scattering per unit quantity of coating or coating ingredient, and scattering power as the amount of scattering per unit area of film. Spreading rate units have the further advantage over film thickness and reciprocal film thickness of being directly relatable to gravimetric as well as volumetric quantities. Thus, for understandability, convenience, and standardization, it is preferable to use spreading rate units for scattering coefficients and hiding power and more specifically the metric spreading rate units m^2/L and m^2/kg. These are translatable into film thicknesses and U.S. units using the conversion equations in 1.j.3. Equations for the numerical conversion of scattering coefficients expressed in various units to standardized metric spreading rate units are given in Table 4.

e. General K-M Hiding Power Method

The experimental procedure, in brief, is to determine the reflectivity R_∞ of the paint and R_0 and H_x of a nonopaque paint film, from which the scattering coefficient S of the paint is calculated. From R_∞ and S is then calculated the spreading rate H_c at any specified contrast ratio C or vice versa, or more specifically the spreading rate $H_{0.98}$ when $C = 0.98$, which by definition is the hiding power of the paint. The *K-M* equations used in these calculations are derived from Eq 38 (the simplified form of Eq 35) and can be programmed for quick computer solutions.

(1) Determination of Reflectivity R_∞

A paint film is applied uniformly over a black-and-white substrate at normal spreading rate (or film thickness) and dried in the manner usual for the particular coating. After drying, the reflectance values R_0, R_w, and W are measured. If the contrast ratio $C_w = R_0/R_w$ is less than 0.96, the application is repeated as a second coat or at a somewhat higher film thickness. A porous film should not be recoated nor an impractically high film thickness applied in a single coat due to the possible effect on R_∞. If the original or recoated film hides completely, then $R_0 = R_w = R_\infty$. If not, calculate

$$a = f(R_0, R_w, W) = \frac{1}{2}\left(R_w + \frac{R_0 + W - R_w}{WR_0}\right) \quad (39)$$

and from Eq 32:

$$R_\infty = a - (a^2 - 1)^{1/2}$$

The preceding two equations may be programmed sequentially to give

$$R_\infty = f(R_0, R_w, W) \quad (40)$$

(2) Determination of R_0 *and* H_x

This requires the application of a uniform film at a spreading rate (or film thickness) such that the contrast ratio C_w is within the range of 0.96 to 0.985. These limits are established because too low a CR requires excessive extrapolation to the $C = 0.98$ end-point, and higher CR values become increasingly insensitive to spreading rate (or film thickness) variations. If the initial application is outside that range, the application is repeated at a higher or lower film thickness, as required.

TABLE 4—Unit conversion equations for scattering coefficients.

S (m^2/L)	=	S (ft^2/gal) ÷ 40.746
"	=	S (mil^{-1}) × 39.37
"	=	S (μm^{-1}) × 1000
"	=	S (mm^{-1}) × 1
S (m^2/kg)	=	S (ft^2/lb) ÷ 4.888
"	=	S (cm^2/g) ÷ 10
S (m^2/L)	=	S (m^2/kg) × D (kg/L)

The film may be applied on a black-and-white or an all-black substrate. If black-and-white, then the test application can be the same one used for determining R_∞ in 8.e.(1). If an all-black test surface is employed, the indicated contrast ratio range is still required, but since it can't be measured directly, it is calculated from

$$C_{0.80} = f(R_0, R_\infty) = \frac{R_0(1 - 0.80R_0)}{R_0 + 0.80(1 - 2aR_0)} \quad (41)$$

Having obtained a film within the specified contrast ratio range, R_0 is recorded and H_x is determined by a suitable method. Various techniques for determining the spreading rate are available, but the most precise is a weight-area-density-NVW method as discussed in Section 6.b, using applicable Eqs 26 or 27. The dry film weight M in those equations is usually obtained as the difference in the weight of the test area before and after application of the paint. Sometimes, as with black glass, it is obtained by removing a known area of film and weighing it directly. Such weighings can be performed on an analytical balance with great accuracy. The density D and nonvolatile N of the paint must of course also be determined if not already known.

With considerably less precision, the thickness of the dry film can be measured using a caliper or electronic gage on a metal panel, from which the spreading rate can be calculated using one of the following relationships

$$H\,(\mathrm{m^2/L}) = \frac{1000\,ND}{t\,(\mu\mathrm{m})\cdot d} \quad (42)$$

or

$$H\,(\mathrm{m^2/kg}) = \frac{1000\,N}{t\,(\mu\mathrm{m})\cdot d\ (\mathrm{kg/L})} \quad (43)$$

where

N = the nonvolatile fraction by weight (NVW) of the test paint,
D = the density of a liquid paint,
d = the density of the dry (or cured) film, and
t = the thickness of the dry (or cured) film.

(3) Calculation of $H_{0.98}$

Having determined R_∞ of the paint and R_0 and H_x of the test film, $H_{0.98}$ is obtained by the following sequence of calculations:

(a) The scattering power P_x of the test film is calculated from

$$P_x = f(R_0, R_\infty) = \frac{1}{b}\coth^{-1}\left(\frac{1 - aR_0}{bR_0}\right) = \frac{1}{2b}\ln\left(\frac{1 - R_0R_\infty}{1 - R_0/R_\infty}\right) \quad (44)$$

(b) The scattering coefficient S of the paint is calculated from $S = P_xH_x$.

(c) The scattering power P_c of a paint film at the contrast ratio $C = 0.98$ is calculated from

$$U_0 = f(C, R_\infty) = \left[\left(a + \frac{1 - C}{1.60\,C}\right)^2 - \frac{1}{C}\right]^{1/2} + \frac{1 - C}{1.60\,C} \quad (45)$$

and Eq 34

$$P = f(U, R_\infty)$$

which are solved sequentially to give

$$P_c = f(C, R_\infty) \quad (46)$$

(d) The hiding power $H_{0.98}$ is then calculated from $H_c = S/P_c$ where $C = 0.98$.

Calculation steps (a) through (d) can be combined into a single computer program to run as follows

$$\text{INPUT: } R_0, H_x, R_\infty, C\text{—OUTPUT: } S, H_c \quad (47)$$

Note that the same equations and program can be used to calculate the spreading rate H_c for any value of C, not just for $C = 0.98$.

Carrying the calculation sequence back to Eq 40 for a single test application on a black-and-white substrate, the combined program would be

$$\text{INPUT: } R_0, R_w, W, H_x, C\text{—OUTPUT: } R_\infty, S, H_c \quad (48)$$

with the reminder that the contrast ratio $C_w = R_0/R_w$ is required to be in the range 0.96 to 0.985 for these operations to provide reliable information.

(4) Contrast Ratio at a Specified Spreading Rate

Although this is not hiding power as such, it is frequently used as an alternative hiding power criterion. After Step (b) of 8.e.(3), calculate the scattering power P at the specified spreading rate H from: $P_H = S/H$, then calculate the contrast ratio C_H from Eq 33:

$$U_H = f(P_H, R_\infty)$$

and

$$C_H = f(U_H, R_\infty) = \frac{a + U - 0.80}{(a + U)[1 - 0.80(a - U)]} \quad (49)$$

which together give

$$C_H = f(P_H, R_\infty) \quad (50)$$

The computer program for this series of calculations would therefore be

$$\text{INPUT: } R_0, H_x, R_\infty, H\text{—OUTPUT: } S, C_H \quad (51)$$

Going back to Eq 40, for a single test application on a black-and-white substrate the combined program would be

$$\text{INPUT: } R_0, R_w, W, H_x, H\text{—OUTPUT: } R_\infty, S, C_H \quad (52)$$

A basic defect of this and other methods that employ contrast ratio as the criterion of HP is that CR values are only comparative as opposed to spreading rates, which have intrinsic and practical significance.

f. Judd Graph

Prior to the availability of modern computers, *K-M* equations were much too complex for a practicable hiding power test method. Judd [*24*] therefore laboriously worked out a general solution to Eq 35 in the form of a graph reproduced in Fig. 9. The graph relates the four variables R_0, $C_{0.80}$, R_∞, and P so that from any two of them the other two can be determined. It consists of two families of curves for constant values of R_∞ and P, plotted on the coordinates R_0 and $C_{0.80}$.

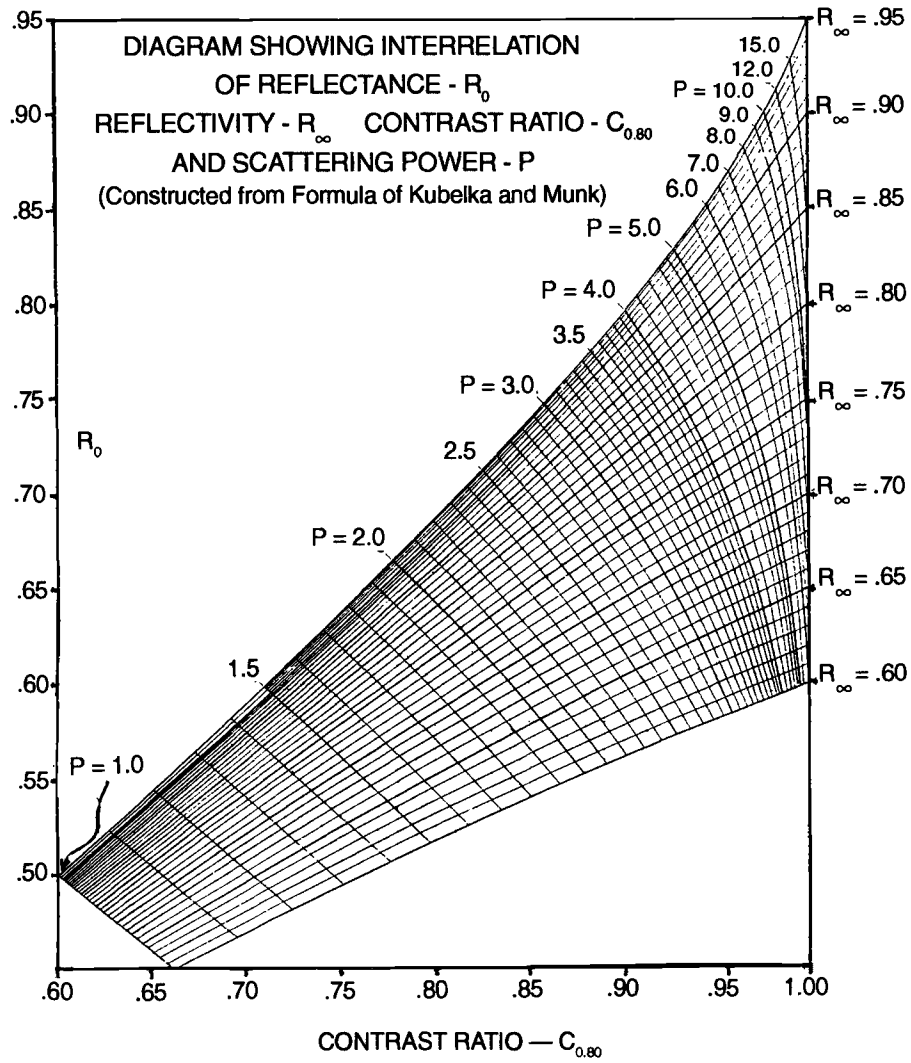

FIG. 9–Judd graph derived from Kubelka-Munk Eq 35.

The P curves were referred to in the original Judd graph as curves of SX (or ST). The portion pertinent to white paints ($R_\infty \geq 0.75$) has been enlarged and is shown in Fig. 10. Experimentally, R_0, R_w, W, and H_x are determined as in 8.e.1 and 8.e.2 for a film applied uniformly on a black-and-white test substrate. If W deviates from 0.80 by more than 0.01, $C_{0.80}$ is calculated using correction Eqs 1 or 2. P_x and R_∞ are determined at the graph point corresponding to $C_{0.80}$ and R_0, and the scattering coefficient of the paint calculated from $S = P_x H_x$. The value of $P_{0.98}$ is located at the intersection of the R_∞ curve with the vertical line for $C = 0.98$. The hiding power is then calculated from $H_{0.98} = S/P_{0.98}$. If desired, the spreading rate can be determined for contrast ratios other than 0.98 in the same way. Conversely, C_H may be determined for any specified value of H by first calculating: $P_H = S/H$, then finding the desired value of C_H at the intersection of the curves for the determined P_H and R_∞.

The Judd graph is also useful for depicting the basic optical properties of paints. It shows that paints with high S values are lighter over black backgrounds than paints of the same reflectivity with low S values. Also, if their S values and film thicknesses are the same, paints with high reflectivity are poorer in hiding than paints of low reflectivity. The latter fact may be demonstrated as follows: Suppose a portion of paint for which $R_\infty = 0.85$ is tinted with a black colorant to an R_∞ value of 0.78 and the untinted and tinted paints are applied at the same thickness such that $P = 5.0$. From Fig. 9, or more accurately from Fig. 10, it can be determined that the colorant addition has increased the contrast ratio to 0.965 from its original value of 0.945, representing a considerable increase in visual film opacity. To determine what this amounts to in terms of photometric hiding power, the P values of the untinted and tinted paints at the intersection of their R_∞ curves with the vertical line $C = 0.98$ are found to be 7.5 and 6.0, respectively. Since S is unaffected by tinting, the spreading rate change at $C = 0.98$ is calculated thus

$$\frac{H_{\text{tinted}}}{H_{\text{untinted}}} = \frac{P_{\text{untinted}}}{P_{\text{tinted}}} = \frac{7.5}{6.0} = 1.25$$

representing an increase of 25% in hiding power by tinting to a lower R_∞ value. This hiding increase was obtained at negligible monetary cost but at a sacrifice in paint quality in regard to brightness of appearance. For that reason, in evaluating a series of paints experimentally, a fair comparison requires that all R_∞ values be adjusted by tinting to that of its lowest reflectivity member. Examination of the Judd graph

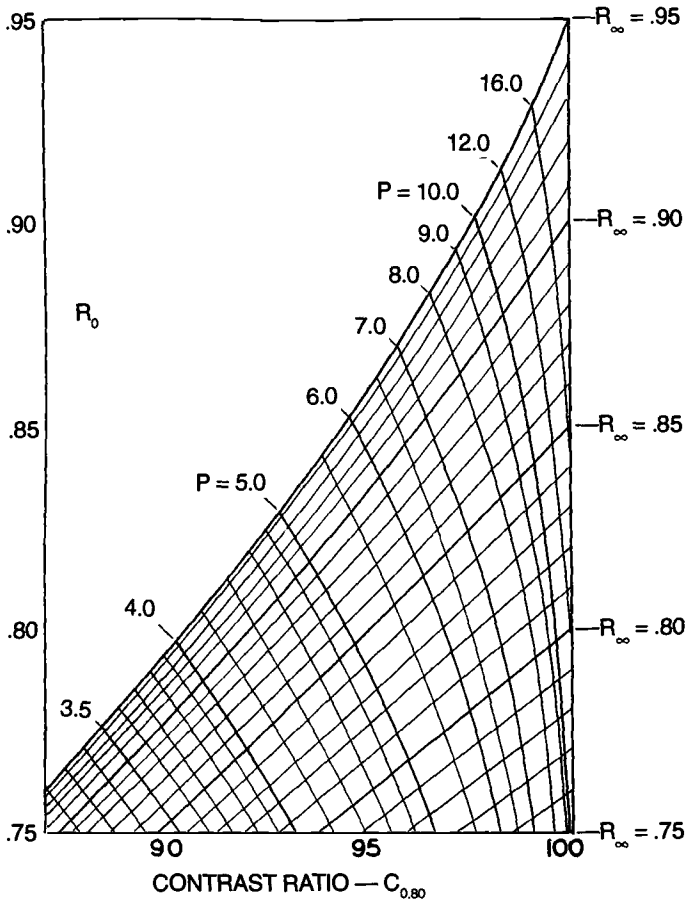

FIG. 10–Judd graph derived from Kubelka-Munk Eq 35—a portion of Fig. 9 enlarged.

shows that, after adjustment to the same R_∞ value, films of the different paints applied at the contrast ratio $C = 0.98$ all have the same $P_{0.98}$ value, and, since $H_{0.98} = S/P_{0.98}$, their hiding powers will be directly proportional to their scattering coefficients. Thus the scattering coefficient alone can be an adequate hiding power comparator, without actually tinting the individual paints.

g. Mitton Graph and Table [27]

As with the Judd graph, these provide precalculated solutions to *K-M* equations, but with much greater precision. They were designed for the experimental procedure described in 8.e, in which R_0 and H_x are determined for a film applied on an all-black test surface, and R_∞ is determined in a separate test application. The test surface of choice is black float glass because the extremely level nature of the surface permits the application of very uniform films with a doctor blade. Mitton also describes the use of all-black metal panels to test spraying/baking-type finishes [*21*]. The graph is derived from Eq 44: $P = f(R_0, R_\infty)$ and is plotted as a family of curves at constant R_∞ on coordinates of scattering power P and reflectance R_0. The ordinate is indicated as "*ST* (Factor *B*)," which is the same as P, and the abscissa as R_B, which is usually and in this case necessarily the same as R_0. It consists of a small-scale index graph (Fig. 11) divided into 31 sections, each then expanded to a much larger scale on a separate sheet. Figure 12 shows one of the expanded sections.

Associated with the Mitton graph is a table of Factor *A* values derived from Eq 46: $P_c = f(C, R_\infty)$, in which Factor $A_c = 1604.2/P_c$. Values of Factor A_c are given in this table for $C = 0.98$, 0.95, and 0.93, for all values of R_∞ from 0.08 to 0.98 (8 to 98%). The C value of most interest for hiding power calculations is 0.98, representing full photometric hiding as defined in Section 2.b. If desired, P_c is easily calculated from Factor A_c.

The graph and table are typically used as follows: After determining R_∞ and R_0 experimentally, the index graph is consulted in order to select the appropriate expanded graph on which the scattering power P_x of the experimental paint film is to be found. Factor $A_{0.98}$ is determined from the table for the measured value of R_∞. At this point either the film thickness T_x or spreading rate H_x of the test film associated with R_0 is determined. If, as Mitton intended, T_x is determined in mils, then the scattering coefficient S is calculated in reciprocal mils from $S = P_x/T_x$, and the hiding power is calculated from the equation

$$H_{0.98}\,(\text{ft}^2/\text{gal}) = S\,(\text{mil}^{-1})\cdot A_{0.98}$$

The preceding simple relationship holds when S is expressed in reciprocal mils and hiding power in ft²/gal. If the spreading rate in m²/L is determined instead of the film thickness, then after determining P_x and R_∞, the scattering coefficient is calculated as: $S\,(\text{m}^2/\text{L}) = P_x \cdot H_x\,(\text{m}^2/\text{L})$ and the hiding power calculated from

$$H_{0.98}\,(\text{m}^2/\text{L}) = \frac{S\,(\text{m}^2/\text{L})\cdot A_{0.98}}{1604.2} = \frac{S\,(\text{m}^2/\text{L})}{P_{0.98}}$$

At a later date Mitton commented that graphical and tabular aids for Kubelka-Munk calculations had become unnecessary with the advent of inexpensive programmable calculators [*28*]. Nevertheless, the Mitton graph and table continue to be used in a number of important test methods, and both the Judd and Mitton graphs are useful for instructional purposes.

h. Typical Kubelka-Munk Hiding Power Results

Tables 5, 6, and 7 are based on the testing of various commercial paints and pigments. They are intended to illustrate magnitudes of hiding power and scattering coefficient values encountered in *K-M* hiding power measurements. The scattering coefficient values are intended to supplement and clarify, by specific examples, the relationships shown in Table 4. With regard to pigments (Table 7), it is of course dispersions that are actually measured and the values for the pigments then calculated from their concentrations in the dispersions. For example

$$\frac{H_{\text{pigment}}\,(\text{m}^2/\text{kg})}{H_{\text{coating}}\,(\text{m}^2/\text{L})} = \frac{S_{\text{pigment}}\,(\text{m}^2/\text{kg})}{S_{\text{coating}}\,(\text{m}^2/\text{L})} = \frac{1}{\text{Pigment Conc. (kg/L)}}$$

The values in Table 7 should be considered as comparative because the hiding power of pigments can vary widely depending on the conditions of measurement (Ref *4*, p. 34), being effected by PVC, effectiveness of dispersion, the presence of other pigments in the same dispersion, and the nature of the vehicle. Even within a specific chemical class it can vary considerably depending upon the particular method of

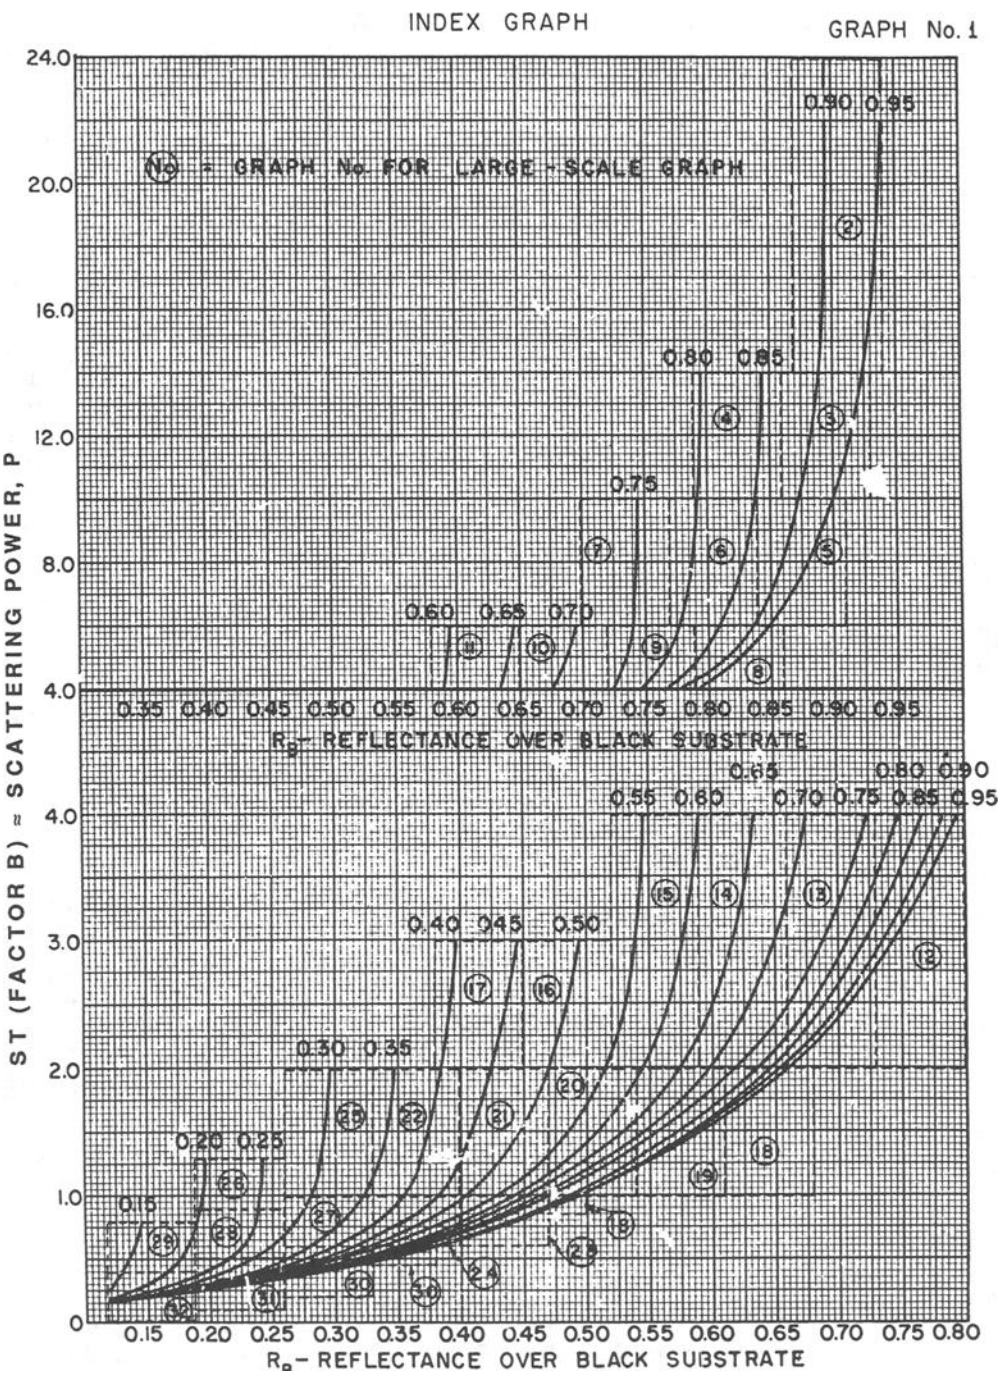

FIG. 11—Mitton graph of Kubelka-Munk Eq 44.

manufacture employed. Nevertheless, it is frequently useful to determine pigment hiding power values for a comparison of their efficiency under specified conditions.

i. Theoretical Problems and Practical Considerations

The validity and usefulness of the Kubelka-Munk equations in hiding power calculations are predicated on the constancy of the scattering coefficient S over a suitably wide film thickness range. Judd [*24*] studied this question in connection with water-borne paints and vitreous white enamels and concluded that at practical film thicknesses S is constant within experimental error. The writer in his laboratory obtained essentially constant S values within a wet film thickness range of 100 to 50 μm (10 to 20 m^2/L, 400 to 800 ft^2/gal) for white alkyd gloss, latex gloss, and latex flat paints. Moreover, the effect of any variation of S with film thickness that might occur is minimized in experimental practice by casting films with contrast ratios fairly close to the 0.98 CR hiding endpoint, as called for in 8.e.(2). This is not difficult to do.

Refractive indices and resultant scattering coefficients vary with the wavelength of light. Thus the effective scattering coefficient of a paint is actually an average for all of the

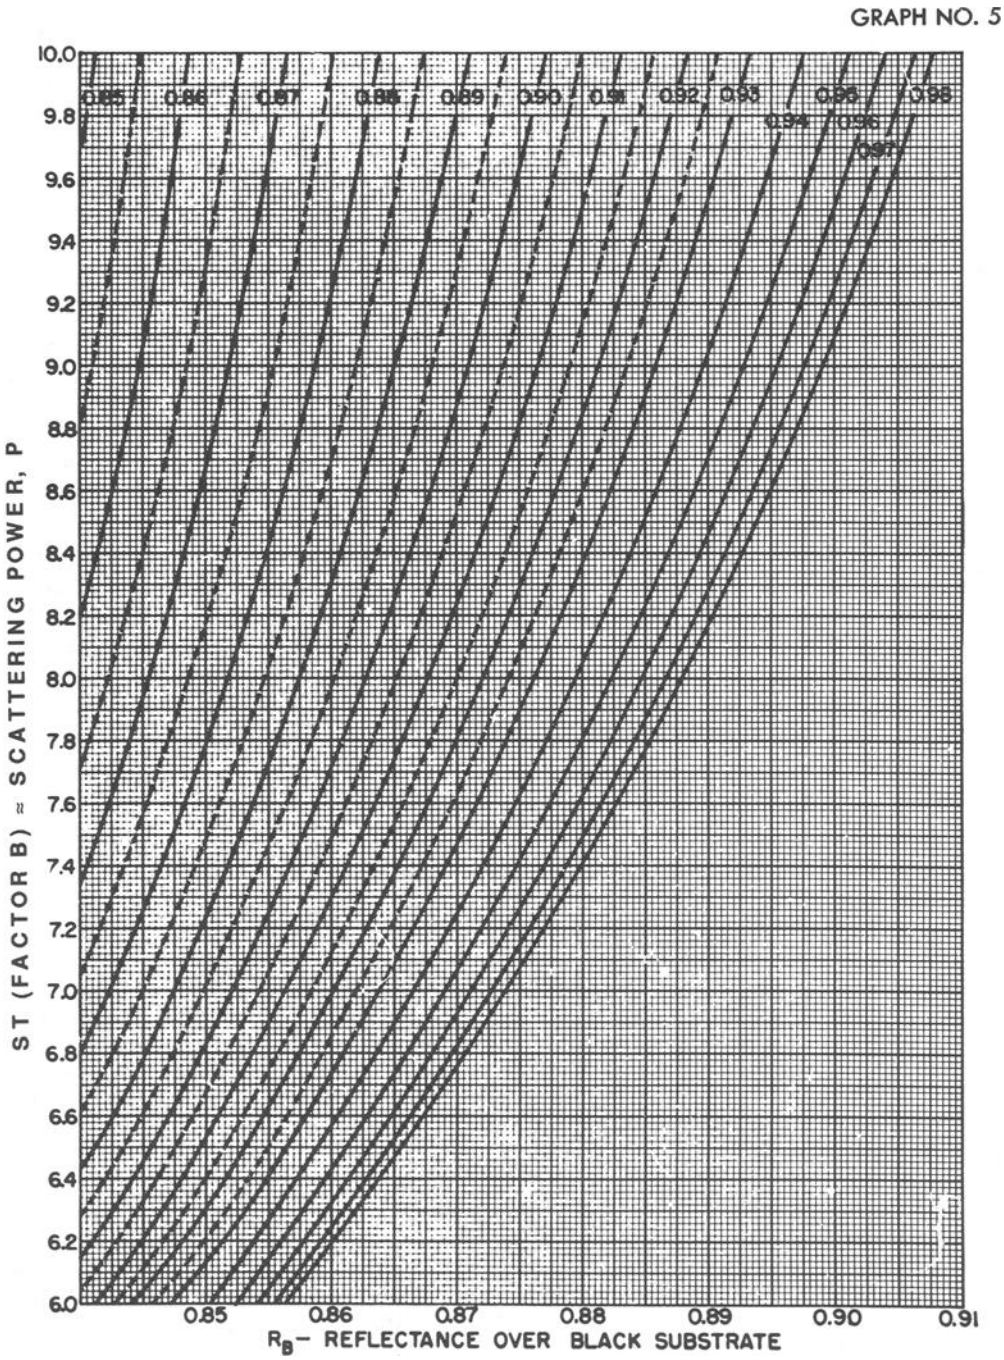

FIG. 12–Mitton graph—expansion of Sector 5 in Fig. 11.

encountered wavelengths. With nonchromatic paint films, the wavelength composition of the light flux remains constant and therefore so does the scattering coefficient upon which constancy the validity of *K-M* equations is predicated. Chromatic paint films, however, absorb light selectively and therefore change the composition of broad-band illuminants with a resultant change in the effective scattering coefficient. This would in theory appear to disqualify chromatic paints from Kubelka-Munk hiding power calculations. In practice, however, the equations are used successfully for that purpose (Ref *29*; Ref *4*, p. 31), which is undoubtedly related to the previously noted fact that the experimental measurements are made fairly close to the hiding power end-point (C = 0.98), so that the Kubelka-Munk extrapolation and thus any associated error is relatively small.

As discussed by Mitton (Ref *4*, p. 27), Kubelka-Munk theory has been questioned because it is "phenomenological" rather than based on fundamental theoretical considerations, and the measurements and equations omit needed corrections for surface reflection that are theoretically substantial. However, in experimental practice the errors are generally small despite the theoretical defects. Simpson took note of this in his comment that when uncorrected values of S and K are inserted back into the uncorrected *K-M* equations, "it would

appear that an approximately correct answer is obtained" (Ref *2*, p. 111).

j. Calculation of Hiding Power from Tinting Data

Initially the S and R_∞ values of a standard white paint are determined in accordance with the procedure described in 8.e. The K value of the paint can then be calculated from Eq 37: $K/S = (1 - R_\infty)^2/2R_\infty$.

From 8.d, S and K can be considered as concentrations of "scattering" and "absorption" per unit weight or volume. The K value of a black tinter is determined by adding a measured ratio to the standard paint sufficient to reduce the reflectivity to about 0.40. The K value of the tinted paint is its initial K value plus the tinter contribution, thus

$$K_2 = K_1 + XK_t \quad \text{(a)}$$

from which

$$XK_t = K_2 - K_1 \quad \text{(b)}$$

and dividing through (b) by the common value of S

$$XK_t/S = K_2/S - K_1/S \quad \text{(c)}$$

in which

K_t = the absorption coefficient of the tinter,
X = the ratio of tinter to paint,
K_1 = the initial K value of the paint,
K_2 = the K value of the paint after tinting, and
S = the scattering coefficient of the paint.

The ratios K_2/S and K_1/S are calculated from measured values of R_∞ for the tinted and untinted paints using Eq 37: $K/S = (1 - R_\infty)^2/2R_\infty$. If the standard paint is an untinted white with a reflectivity no lower than 0.93, then its absorption contribution K_1 is considered negligible compared with that of the tinter, in which case K_1/S is dropped from Eq (c) to give

$$XK_t/S = K_2/S \quad \text{(d)}$$

The absorption coefficient K_t of the tinter can be calculated from Eqs (c) or (d) since all other terms in these equations are known.

Having determined K_t, the S-value of a test paint can be determined using the same tinting procedure and equations as before, but this time calculating unknown S from known K_t instead of vice versa. With the values S and R_∞ of the test paint having thus been determined, its hiding power $H_{0.98}$ can be calculated as in 8.e.(3)(c) and (d) without the tedious requirement of measuring the spreading rate.

Experimental evidence for the validity of this procedure is given by Mitton and Jacobsen [*32*], who, equating the tinting

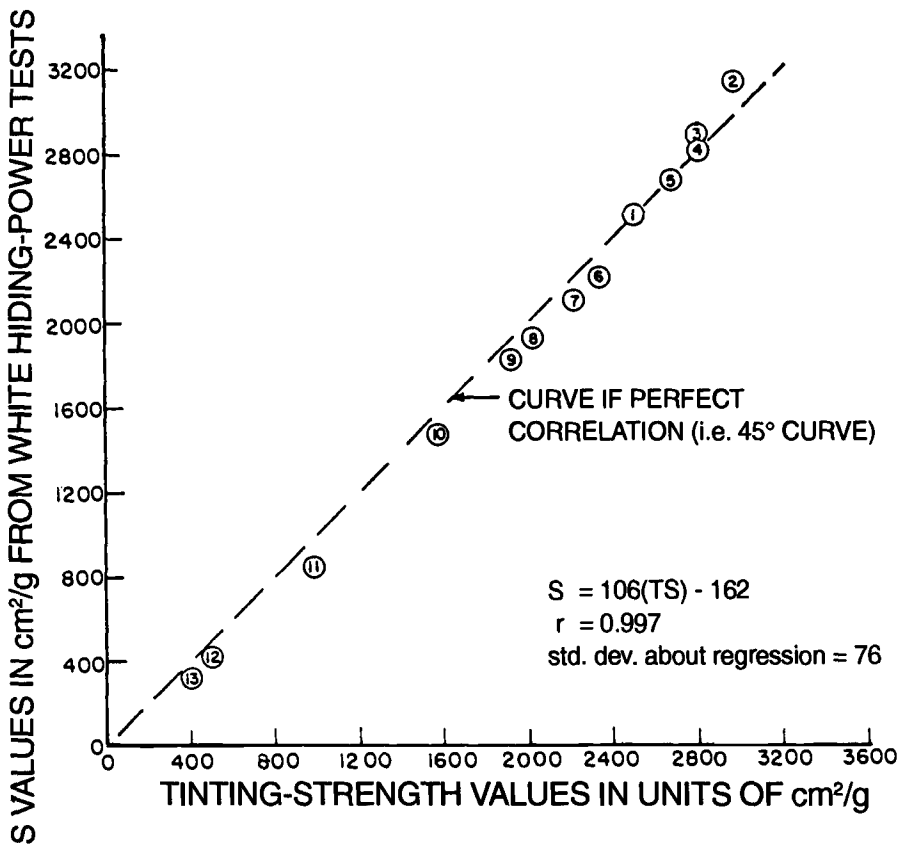

FIG. 13—Scattering coefficients determined by tinting and by hiding power tests.

strength of a white pigment with its scattering coefficient, measured S (cm²/g) for a number of white pigments by direct hiding power measurement and by the tinting procedure. As shown in Fig. 13, the correlation between the two methods is very close. If this simplified method is to work, the K value of the black tinter must be the same in any paint being tested. Also, the tinter must not change the degree of dispersion of the white pigment so as to cause a change in its S value. These conditions are not always met, so that it is safest to apply the method only under favorable circumstances, when interaction of tinter and paint are known to be negligible.

k. Determination of Relative Hiding Power of Untinted White Paints from Tinting Data

For this purpose there is no need to determine the K value of the tinter as in 8.j. An equal ratio of black tinter is added to Comparison Paints A and B, sufficient to reduce their R_∞ values to about 0.40. The R_∞ values of Paints A and B are measured before and after tinting and the four corresponding K/S values calculated from Eq 30. Then, as in Eq (c) of 8.j, for Paint A:

$$XK_t/S_A = K_{A2}/S_A - K_{A1}/S_A \qquad \text{(a)}$$

for Paint B:

$$XK_t/S_B = K_{B2}/S_B - K_{B1}/S_B \qquad \text{(b)}$$

Next, dividing Eq (b) into Eq (a), X and K_t cancel to give

$$S_B/S_A = (K_{A2}/S_A - K_{A1}/S_A) \div (K_{B2}/S_B - K_{B1}/S_B) \qquad \text{(c)}$$

If the comparison paints are both untinted high reflectance whites then, as pointed out in 8.j, the untinted K-values can be considered negligible and Eq (c) becomes

$$S_B/S_A = K_{A2}/S_A \div K_{B2}/S_B \qquad \text{(d)}$$

As stated at the end of 8.f, at the same reflectivity R_∞, the HP values of Paints A and B will be in the same ratio as their scattering coefficients.

9. FACTORS AFFECTING WHITE HIDING POWER

As shown in Tables 1 and 7, rutile titanium dioxide is by far the most effective of the white hiding pigments in producing light scattering and hiding power, which is true on a cost as well as a weight basis. This fact has effectively eliminated the use of other white hiding pigments except for special properties or considerations. The important variables that determine the scattering and hiding efficiency of a titanium dioxide pigment in a paint are: (1) its mean crystal and particle size, (2) the state of pigment dispersion, (3) its concentration in the paint film, and (4) film porosity.

a. Crystal and Particle Size

By decreasing the particle size of the pigment, the number of particles and surfaces for light reflection and refraction increase, and the light scattering ability of a given quantity of pigment will therefore tend to be enhanced. However, if the particle size is too small in relation to the wavelength of light, the wave front passes around rather than through it, so there is no light scattering, and the dispersion is transparent. Obviously, there is some intermediate optimum size related to the wavelength of light at which maximum scattering efficiency is obtained. The wavelength of the visible spectrum ranges from approximately 0.4 to 0.7 μm, peaking in luminosity at 0.55 μm. The mean crystal size for maximum opacity ranges from approximately 0.20 to 0.30 μm depending on both the PVC and the fraction of the pigment consisting of single crystals. Commercial grades of titanium dioxide developed for high-gloss finishes exhibit a single-crystal content of about 20% and have a mean crystal size between 0.22 and 0.24 μm. The adverse effect of lesser crystal size in such formulations is shown in Table 8 [*33*].

b. Pigment Dispersion

The process of obtaining a satisfactory dispersion involves the wetting of the pigment by the dispersion medium to displace air, breakdown of larger particles by milling, and stabilization after the dispersion has been obtained. With alkyd media, standard grades of titanium dioxide disperse easily and develop full hiding with very little milling. Thus, the main reason for milling alkyd dispersions is to reduce or eliminate oversize particles that effect the appearance of the film. With latex paints, milling can have an important effect on opacity depending on the grade of pigment employed [*33*], but the appearance factor is also an important consideration, particularly with semigloss and gloss finishes.

A major factor affecting the efficiency of TiO_2 in the completed formulation is the phenomenon referred to as "flocculation," which is the formation of large particle groups or "floccules" due to weak forces of cohesion. Floccules are easily broken down but can spontaneously and quickly recur in the wet paint or drying paint film. Despite their weak bonding, floccules have the optical effect of increasing the mean particle size, thereby decreasing the scattering efficiency of the pigment. An auxiliary phenomenon related to increased particle size is the preferential scattering of longer wavelengths. Balfour and Hird took advantage of this phenomenon to quantify pigment flocculation by measuring back-scattered infrared radiation (wavelength 25 μm) from a dried paint film to obtain what they refer to as a "flocculation gradient" [*34,35*].

TABLE 8—Scattering coefficient of a 20% PVC TiO_2-alkyd paint film versus crystal size of pigment.

S, μm^{-1}	Mean Crystal Size, μm
0.76	0.24
0.73	0.20
0.64	0.16

c. Pigment Concentration

In Section 3.c it was pointed out that a very large single crystal of a white hiding pigment is actually transparent. Without undertaking a theoretical analysis, it is to be expected that as the concentration of pigment increases and its particles become more crowded, they approach the optical condition of a very large particle with resultant loss of scattering efficiency and hiding power. The "crowding" effect was studied by Stieg [*36–38*], whose results were used by Mitton (Ref *4*, pp. 34–35) to draw curves of hiding power $H_{0.98}$ versus PVC for pure rutile and anatase titanium dioxide in alkyd enamels. These are shown in Fig. 14, in which HP is expressed in ft^2/lb of nonvolatile matter. If the paint is formulated at 50% nonvolatile by volume, the hiding power results would be half that shown in the figure, but the shape of the curves would be unchanged. Note the maximums in the curves at 25 to 30% PVC, above which hiding power actually begins to decrease with increasing concentration of pigment. When calculated in terms of ft^2/lb of pigment, the results appear as shown in Fig. 15, clearly indicating the drastic decrease in TiO_2 efficiency due to crowding.

Stieg [*36*] found empirically that the relationship between TiO_2 hiding power and PVC, as shown in Fig. 15, could be expressed by the equations

$$\text{rutile: } H_{0.98}\,(\text{ft}^2/\text{lb}) = 370\text{-}410\,(\text{PVC})^{1/3} \quad (53)$$

$$\text{anatase: } H_{0.98}\,(\text{ft}^2/\text{lb}) = 290\text{-}330\,(\text{PVC})^{1/3} \quad (54)$$

The PVC values in these equations are decimal fractions. Expressed in metric units, the equations become:

$$\text{rutile: } H_{0.98}\,(\text{m}^2/\text{kg}) = 75.7 - 83.9\,(\text{PVC})^{1/3} \quad (55)$$

$$\text{anatase: } H_{0.98}\,(\text{m}^2/\text{kg}) = 59.3 - 67.5\,(\text{PVC})^{1/3} \quad (56)$$

The question has been studied [*36,39*] of whether extenders added to a gloss or semigloss paint film might tend to increase the spacing of the TiO_2 pigment and thereby its scattering efficiency. The physical picture that emerges is of large particle-size extenders acting as massive intrusions having no effect on the original TiO_2 spacing, and of fine particle-size extenders dispersing uniformly so as to increase TiO_2 spacing, but no differently in this respect than an equal volume of binder. Consequently, when binder is replaced by an equal volume of large particle-size extender, TiO_2 efficiency decreases, whereas with small particle-size extenders, TiO_2 efficiency has been found to remain essentially the same and in no case improved.

d. Film Porosity

The preceding relationships pertain to pigment concentrations at which there is sufficient binder to wet the pigment completely and form a continuous phase, which means below the critical pigment volume concentration (CPVC). Above the CPVC, the dried film becomes porous, containing entrapped air that increases pigment-scattering efficiency by effectively lowering the refractive index of the surrounding medium. The air itself, as particulate matter in contact with the higher refractive index binder, contributes to light scattering. Thus, if the curves of Fig. 14 were extended to a sufficiently high PVC, the hiding power of the film would begin to rise again

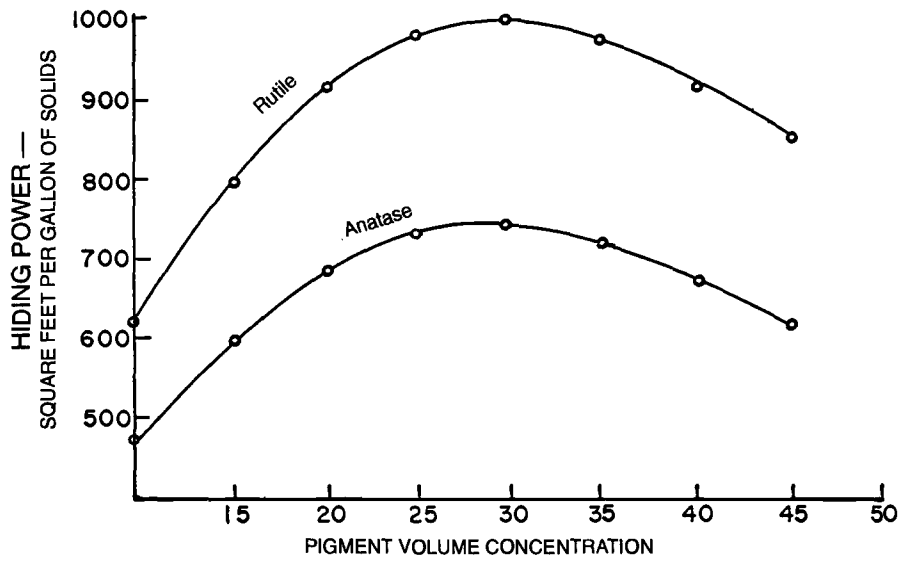

FIG. 14–Hiding power $H_{0.98}$ (ft²/gal) of solids at various PVC levels.

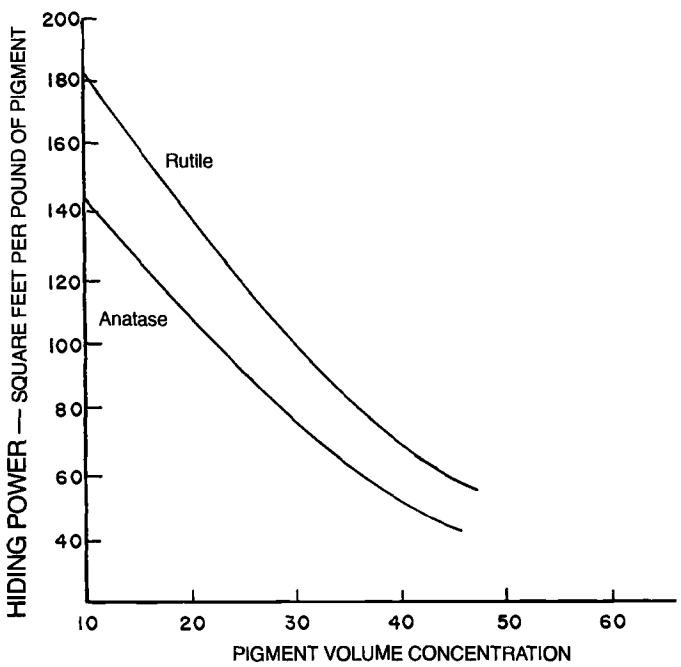

FIG. 15–Hiding power $H_{0.98}$ (ft²/lb) of pigment at various PVC levels.

due to the opacification effect of film porosity. Obviously this is an extremely impractical use of expensive titanium dioxide with no relation to actual formulation practice. However, porosity does in practice make a major contribution to hiding power in the important interior flat wall paint sector. In paints of that type, inexpensive inert white pigments are included in the formulation along with titanium dioxide for the esthetic purpose of producing a flat finish and to contribute hiding power by means of porosity. Stieg and Ensminger [*38*] showed that with paints over the CPVC that contain both TiO_2 and extender, hiding power is in a straight-line relationship with the Porosity Index (P.I.), with the slope of the line depending on the percentage of prime pigment and the nature of the extender. The Porosity Index is calculated from the equation

$$\text{P.I.} = 1 - \frac{\text{CPVC}(1 - \text{PVC})}{\text{PVC}(1 - \text{CPVC})} \tag{57}$$

The low-cost hiding power obtained from porosity is unfortunately accompanied by a deterioration in the quality of the film as manifested by poor scrub, soilant, and stain resistance. This is due to an insufficiency of binder, resulting in an air phase continuum that gives ready capillary access to staining materials.

10. MICROVOIDS FOR WHITE HIDING POWER

Through the use of encapsulated preformed microvoids, it has been found possible to obtain some of the hiding power benefit of entrapped air while avoiding or minimizing the deleterious effect of film porosity. The microvoids are supplied as a water dispersion of hollow beads having a plastic outer shell and water-filled core. Incorporated into a latex paint, the water in the core evaporates during the drying of the film and is replaced by air that functions as light-scattering particulates shielded from staining penetrants by the surrounding plastic shell. Because the microvoids alone are not able to produce the desired level of opacity in a film of normal thickness, the inclusion of titanium dioxide pigments in the paint formulation along with microvoids is essential. One widely used microvoid bead product is referred to as "opaque polymer" and employs a shell of thermoplastic polystyrene. Another type is a vesiculated bead in which titanium dioxide and water-filled "vesicles" are associated in a cross-linked polyester/styrene matrix. By using such products to partially replace titanium dioxide pigment, raw material cost savings have been demonstrated with no loss in film integrity or hiding power [*35,40*].

a. ASTM Methods

D 344: Test Method for Relative Dry Hiding Power of Paints by the Visual Evaluation of Brushouts

This is essentially the same as the Krebs Method described in 4.d, differing only in requiring black-and-white instead of grey-and-white charts and in permitting checkerboard or other suitable contrast designs as well as the diamond-stripe pattern. Modern charts are 0.1 m^2 in area (1.076 ft^2) instead of 1 ft^2 as specified originally. Provision is made for reporting results in m^2/L as well as ft^2/gal.

D 2805: Test Method for Hiding Power of Paints by Reflectometry

This was adopted in 1969 and is actually a combination of two earlier methods, D 1738 and D 2614, that differed only in technique. It conforms with the general Kubelka-Munk method described in 8.e but is designed specifically for air-dried coatings. Originally it provided for the use of either black glass or charts for determining H_x and R_0. In later versions black glass is mandatory. R_∞ is determined by a separate application as described in 8.e.(1). The need for two test applications does not represent a significant extra effort since only the application on black glass requires the time-consuming spreading rate determination. The latter is accomplished by placing a template of predetermined area on the dry film, scraping off and discarding the film outside the confines of the template, then carefully scraping off the remaining film in the defined test area and weighing it on an analytical balance. The spreading rate is then calculated from the density and nonvolatile content of the paint using Eq 26. Having obtained the experimental values: R_0, H_x, and R_∞, the scattering coefficients and hiding power $H_{0.98}$ of the paint are calculated from these values using the Kubelka-Munk sequence shown in 8.e.(3) thus: $P_x = f(R_0, R_\infty)$, $S = P_x H_x$, $P_c = f(C; R_\infty)$, $H_c = P_c/S$ for $C = 0.98$. These calculation steps can be carried out individually or combined into the previously described computer program identified as Eq. 47: INPUT: R_∞, R_0, H_x, C—OUTPUT: S, H_c.

The method also provides for calculating the contrast ratio C_H at a specified spreading rate H, using the same experimental results but with a slightly different equation sequence as described in 8.e.(4), thus: $P_x = f(R_0, R_\infty)$, $S = P_x H_x$, $P_H = S/H$, $C_H = f(P_H, R_\infty)$. This sequence is summarized in the computer program identified as Eq 51: INPUT: R_0, H_x, R_∞, H—OUTPUT: S, C_H.

Earlier versions of D 2805 and its predecessor standards included or referenced the Mitton tables and graphs described in 8.g for solving the *K-M* equations. The method can be adjusted by appropriate experimental modifications to the measurement of baked enamels on black-painted metal panels as discussed in 7.d, or to other types of coatings and test substrates.

D 5007: Test Method for Wet-to-Dry Hiding Change

This is a rapid visual test designed to measure percent change in hiding power during drying. The paint is drawn down on a black-and-white test chart using a special multinotch applicator (Fig. 16) having eight notches with clearances in geometric progression ranging from 67 to 264 μm (2.65 to 10.4 mils). The clearance corresponding to an agreed visual endpoint (see 2.a) is estimated immediately after application and again after drying. The ratio of the two clearances multiplied by 100 gives the percentage change in hiding power:

$$\frac{\text{CLEARANCE}_{\text{WET ENDPOINT}}}{\text{CLEARANCE}_{\text{DRY ENDPOINT}}} = \frac{\text{WFT}_{\text{WET ENDPOINT}}}{\text{WFT}_{\text{DRY ENDPOINT}}} = \frac{\text{SPREADING RATE}_{\text{DRY ENDPOINT}}}{\text{SPREADING RATE}_{\text{WET ENDPOINT}}}$$

The equation assumes that, for any one drawdown, the ratio of clearance to WFT for the several notches does not deviate appreciably. On that basis WFT variations due to application technique or paint rheology would not affect the final test result. This is not a precision test but provides significant information of a practical nature with minimal effort.

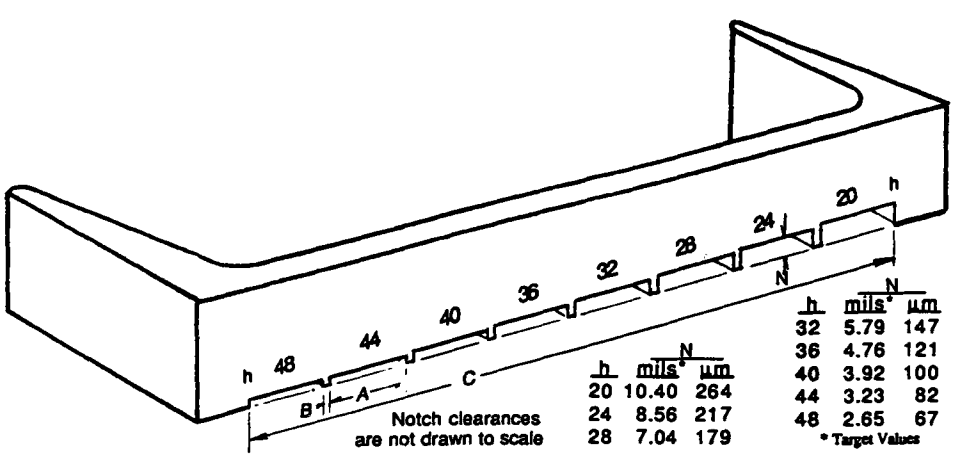

FIG. 16–Multi-notch applicator for ASTM D 5007.

D 5150: Test Method for Hiding Power of Architectural Paints Applied By Roller

This is a visual comparison method designed for use with interior wall finishes and intended to provide practical information from tests performed on a convenient laboratory scale. The test substrate is a large, sealed paper test chart (Fig. 17) with a series of stripes numbered 1 through 6 on a white background. The stripes range in shade from very light grey to black and were selected so that the color difference ΔE^*_{ab} between each successive stripe and the white surround is in a geometric progression from 2 to 64 CIELAB units. The dimensions of the test area are 24 by 36 in. = 6 ft^2 (610 by 914 mm = 5575 cm^2), sufficiently large to simulate practical application of paints with a roller. The paint is applied at a specified, controlled spreading rate, and the hiding power is reported as the stripe number of the darkest stripe perceived as being completely obscured. The concept of this test is that in practical applications the levelness of the paint film and hence its effective opacity is affected by the rheological properties of the paint. Thus, in practice paints tend to have lower hiding power than indicated by more customary test methods in which films are applied with maximum uniformity using a blade-type applicator. Relative practical hiding power among paints can be influenced for that same reason.

b. U.S. Federal Test Method Std. 141

Method 4121, Contrast Ratio at a Specified Spreading Rate

This pass-fail test was previously described in some detail in 5.f. Paint films are applied on black-and-white charts by brush or drawdown, and spreading rates are determined by a typical weight-area-density procedure, discussed in 6.b. CR values are plotted at several spreading rates to obtain graphically the CR at a specified spreading rate. For the test paint to pass, the CR at the specified spreading rate must have a specified minimum value.

Method 4122, Contrast Ratio at a Specified Dry Film Thickness on Black and White Glass Panels

An applicator is selected to obtain precisely the desired dry film thickness, the latter being measured with a micrometer to the nearest 0.0001 in. Separate drawdowns are made on black and white glass panels. Reflectances R_B and R_W are measured and the CR calculated. This is a simplistic concept in view of the undoubted difficulty in obtaining, measuring, and then repeatedly applying a precise predetermined dry film thickness.

c. ISO (International Standardization Organization) Methods

ISO 2814, Contrast Ratio (CR) at a Nominal Spreading Rate (SR) of 20 m^2/L on Black-and-White Charts or Polyester Film

A paint film is applied with a 100-μm clearance applicator to give a nominal wet film thickness of 50 μm, corresponding to a spreading rate of 20 m^2/L. Black and white substrate reflectances are measured and the contrast ratio calculated without a determination of actual spreading rate. Films cast on a clear polyester are measured, as described in 7.b, by placing the film alternately on black and white glass. Because different paints and application techniques with the same applicator give films differing significantly in thickness, the method is satisfactory only as a rough guide for paints of the same type and color evaluated by one operator.

ISO 3905, Contrast Ratio (CR) at a Spreading Rate (SR) of Precisely 20 m^2/L on Black and White Charts

This method, like ISO 2814, is intended to measure the CR at 20 m^2/L, but the *SR* in this case is determined carefully. Drawdowns are made with three applicators to obtain no-

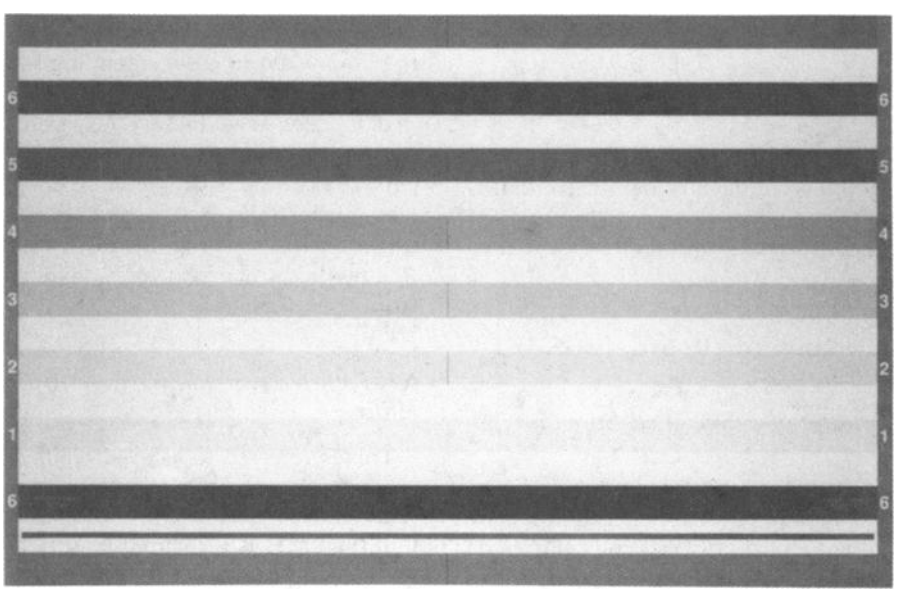

FIG. 17—Large gray scale chart (6 ft,^{2} 5575 cm^2) for roller application tests per ASTM D 5150.

minal wet film thicknesses of 40, 50, and 60 μm corresponding to SRs of 25, 20, and 16.67 m^2/L. After drying, the CR values are measured and the SR values determined by a typical weight-area-density method as discussed in 6.b. The dry film weight is determined as the difference between the painted and unpainted chart, with considerable precautions taken, as discussed in 7.a to avoid error due to nonuniform chart weight. A graph of CR versus SR is prepared on square-ruled paper from which the CR at exactly 20 m^2/L is determined by interpolation. The method is restricted to paints with a reflectance value of at least 25%. Weaknesses of this method are: (a) it fails to correct for possible variations in the reflectance of the white substrate, as discussed in 1.f; (b) the specified SR of 20 m^2/L corresponds to a wet film thickness of only 50 μm (2 mils), at which thickness irregularities in the surface of paper test charts can have an appreciable effect.

ISO 3906, Contrast Ratio (CR) at a Spreading Rate (SR) of Precisely 20 m^2/L on Polyester Film

This method is essentially the same as ISO 3905, differing only in the use of polyester film instead of black-and-white charts. Like ISO 3905, the method fails to correct for deviations in the white substrate from the ideal reflectance of 80%. However, the problem of surface irregularity is largely overcome due to the superior levelness of the plastic film. Since true hiding power is a spreading rate, neither this method nor ISO 3904 or ISO 3905 measure hiding power as such.

ISO 6504, Kubelka-Munk Method for White and Light-Colored Paints

This is in accordance with the general *K-M* hiding power method described in 8.e. It calls for an all-black substrate which can be glass or polyester film over black glass. The Mitton graph and table described in 8.g are included, which makes it very similar to early versions of ASTM D 2805.

d. British Standards Institute, BSI 3900

Part D4. Comparison of Contrast Ratio of Paints of the Same Type and Color—This method is technically identical with ISO 2814 (11.c).

Part D6. Contrast Ratio at 20 m^2/L Using Polyester Film—This method is technically identical with ISO 3906-1980 (11.c).

Part D7. True Hiding Power (SR at C = 0.98) by the Kubelka-Munk Method—This method is technically identical with ISO 6504 (11.c) and in accordance with early versions of ASTM D 2805 and the general *K-M* hiding power method described in 8.e.

e. Canadian General Standards Board, (CGSB) 1-GP-71

Method 14.1, Visual Hiding at a Specified Spreading Rate

The test substrates are black-and-white or black-and-gray checkerboard charts with an area of 0.1 m^2. The appropriate chart is specified according to a list of CGSB color numbers, with black-and-gray being used for lighter colors. The paint is applied by brush or drawdown. In brush application the SR is controlled accurately by weighing container and brush before and after application, with a specified volume being delivered to the chart surface by syringe. With drawdowns, presumedly identical applications are made on glass and charts and the WFT determined on glass by means of an Interchemical (ASTM D 1212) wet film thickness gage. For the test paint to pass, the dry paint film is required to completely obscure the contrast pattern of the chart.

Method 14.2, Spreading Rate Determined at Full Visual Hiding (for Quick-Drying Coatings)

Successive thin coats are applied by spraying onto black-and-gray or black-and-white charts until visual hiding of the dry film is complete. The SR is calculated from the difference in weight of the coated and uncoated chart. This can be expressed in m^2/kg of dry film or m^2/L of the original liquid coating.

Method 14.7, Contrast Ratio on Black and White Glass Panels at a Given Spreading Rate or Dry Film Thickness

This is modeled after the NYPC method described in 5.d. WFT is determined with an Interchemical gage or DFT with a micrometer. The target film thickness is bracketed experimentally to obtain two points on a CR versus reciprocal film thickness graph and the CR at the target thickness determined by interpolation. The experimental CR values are corrected for $W = 0.80$ before plotting the graph.

f. French Standards Association (AFNOR)

NF-T30-075, Spreading Rate at a Contrast Ratio (CR) of 0.98

Paint films are cast on clear polyester at several thicknesses and CR values determined after drying by measuring reflectances over a black-and-white substrate. Dry films just below and above 0.98 in CR are measured by weight or micrometer to obtain experimental spreading rates in m^2/kg or m^2/L and results interpolated to obtain the spreading rate at exactly CR = 0.98. The introductory text points out that this method measures true hiding power in preference to ISO 3905 and 3906 (11.c) which simply compare CR values at 20 m^2/L. It also refers to the experimental film thickness not being limited to 50 μm as in the ISO methods. No provision is made in this method to correct for deviations of the white substrate from $W = 0.80$.

NF-T30-076, Spreading Rate at Complete Visual Hiding

This is referred to as a "simplified" method. Several films are cast on polyester to obtain one that shows full hiding when placed over a black-and-white background. The dry film thickness is measured by difference with a micrometer and the hiding power calculated in m^2/L. Potential users should consider whether this method, though simple in concept, might be excessively burdensome in execution.

g. German Standards Institute (DIN)

DIN 53162, Hiding Power of Air Drying Nonchromatic Paints

This is a Kubelka-Munk method which is essentially the same as ISO 6504, but includes auxiliary test procedures for measuring paint density and nonvolatile content. The Mitton nomograph and table (8.g) are employed.

DIN 53164, Relative Scattering Power of White (TiO_2) Pigments

This method measures the Kubelka-Munk scattering coefficient S of a TiO_2 pigment and reports its value as a percentage of the scattering coefficient of a reference pigment measured in the same way. The determination of S is based on the solution of Eq 44: $P = f(R_0, R_\infty)$ using the Mitton nomograph. The method calls for the test pigment to be dispersed in an alkyd or a plasticized polyvinyl chloride vehicle. R_∞ is measured from a thick, full hiding film of the dispersion and R_0 from a nonopaque film applied on a black plastic substrate. The spreading rate H_x of the pigment is determined in a unique way, by igniting a known area of film on plastic and weighing the residue. This method is basically the same as DIN 53162 and other *K-M* methods (8.e), with the difference that only relative values are reported. There is no attempt to report actual scattering coefficients or to calculate hiding power in physical units, although this could easily be done on the basis of the accumulated data.

Mass Color and Tinting Strength of Pigments

by Julio I. Aviles[1]

DEFINITIONS

The mass color (MC) of a coating is defined in ASTM Terminology Relating to Paint, Varnish, Lacquer, and Related Products (D 16) as:

> "the color, when viewed by diffuse reflected light, of a pigment-vehicle mixture of such thickness as to obscure completely the background. Sometimes called over-tone or mass-tone."

Mass color is produced by the reflected light (R_∞ at infinite thickness) of an opaque coating and depends on the pigment concentration, degree of dispersion, coating thickness, and the light absorption (K) and scattering (S) of pigments and binders. Mass color is applicable to both chromatic and achromatic pigments.

Other definitions of interest, taken from ASTM Terminology of Appearance (E 284), are as follows:

- Brightness is an "aspect of visual perception whereby an area appears to emit more or less light."
- Chroma is the attribute of color used to indicate the degree of departure of the color from a gray of the same lightness. Chromatic is a term meaning "perceived as having a hue; not white or black."
- CIE 1931 standard colorimetric system is "a system for determining the tristimulus values of any spectral power distribution using a set of reference color stimuli X, Y, A and the three CIE color-matching functions $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, $\bar{z}(\lambda)$ adopted by the CIE in 1931."
- Colour Index is a listing of colors by name and number by The Society of Dyers and Colourists, London, 1987. It is available from the American Association of Textile Chemists and Colorists, P.O. Box 12215, Research Triangle Park, NC 27709.
- Hue is "the attribute of color perception by means of which a color is judged to be red, orange, yellow, green, blue, purple, or intermediate between pairs of these, considered in a close ring."
- Lightness is "(1) the attribute of color perception by which a nonself-luminous body is judged to reflect more or less light." "(2) the attribute by which a perceived color is judged to be equivalent to one of a series of grays ranging from black to white."
- Masstone is a pigment-vehicle mixture that contains a single colorant only. This definition includes certain colorants that may contain more than one pigment but are tested and used as if they contain only a single pigment.
- Saturation is "the attribute of a visual sensation that permits a judgment to be made of the proportion of pure chromatic color in the total sensation." Saturation can also be described in a mathematical manner as in ASTM E 284.
- Scattering is "the process by which light or other electromagnetic radiant flux passing through matter is redirected over a range of angles."
- Shade is "a color produced by a dye or pigment mixture including black dye or pigment."
- Tint is "a color produced by the mixture of white pigment or paint with a chromatic pigment or paint."
- Tristimulus values are "the amounts of three specified stimuli required to match a color." In the CIE system, these stimuli are assigned the symbols X, Y, and Z.

TINTING STRENGTH

Tinting strength is a measure of the effectiveness with which a unit quantity of a colorant changes the color of a material (ASTM E 284). It may be thought of as a pigment's "coloring power." For those colorants that both scatter and absorb, the scattering and absorption tinting strengths must be specified. ASTM D 284 defines scattering tinting strength as "the relative change in the scattering properties of a standard black material (with no scattering colorant present) when a specified amount of a white or chromatic scattering colorant is added to it" and absorption tinting strength as the relative change in the absorption properties of a standard white material when a specified amount of an absorbing colorant, black or chromatic, is added to it."

Pigment concentration is important to coating strength and cost, and therefore tinting strength can be an important relative economic value factor in selecting one paint over another. There is no particular value of tinting strength that can be stated as desirable unless an end use is stated. In certain cases a high value is desirable and in others a low value is needed to achieve a desired color/strength effect. In a general sense, tinting strength is determined by dilution of a test paint and a reference paint with a standard "mixing white paint" in the case of chromatic paints or a standard "tinting color" in the case of white paints, drawing down the resulting pastes on a suitable substrate, and then instrumentally measuring tristimulus values or visually comparing the specimens. The latter comparison technique has lower precision than the former. Details for the preparation of a standard

[1]Senior technical service representative, Kronos Inc., Wyckoffs Mill Road, Hightstown, NJ 08520.

Copyright© 1995 by ASTM International

mixing white paint are described in ASTM Test Methods for Relative Lightfastness of Pigments Used in Artists' Paints (D 4303) or a commercial titanium-dioxide white artists' paint may be used. It should be understood that the mixing white paint must be made with the same vehicle type—acrylic, alkyd, or oil—as the paint to be tested.

In color tints, differences in gloss and haze may be mistaken for a lighter tint or lower tinting strength than really exists. In grays, these factors may be interpreted as higher white pigment strength than exists. Instruments cannot compensate for specular gloss or haze differences between a sample and a standard, and this can result in erroneous tint strengths. It is possible to equalize gloss differences between the specimens by top coating with a clear coating. Evaluation through the clear coating reveals the true tinting strength differences between sample and standard.

Tinting strength results can also be affected if the lightness, chroma, and saturation of the sample differ significantly from those of the standard, since this involves matching two color variables, lightness and chroma or lightness and saturation, by adjusting only the amount of pigment used [*1,2*].

Chromatic Paints

ASTM Test Method for Determining the Relative Tinting Strength of Chromatic Paints (D 4838) is a method used for determining the absorption tinting strength of a chromatic (define) test paint relative to that of a paint of the same chemical type. The method is intended for comparison of paints that contain the same chemical type vehicle (acrylic, alkyd, or oil) and single-pigment colorants of the same Colour Index name and number. Knowledge about the amount of pigment and other components of the paint is not necessary.

The color measuring instrument can be either a spectrophotometer that provides 1931 CIE tristimulus values X, Y, Z for CIE standard illuminant C, or a tristimulus colorimeter providing either such tristimulus values or colorimeter readings R, G, B. Other related test methods useful in following ASTM D 4838 are ASTM Test Method for Computing the Colors of Objects by Using the CIE System (E 308) and ASTM Practice for Obtaining Spectrophotometric Data for Object-Color Evaluation (E 1164).

ASTM Test Method for Color and Strength of Color Pigments with a Mechanical Muller (D 387) is used for comparing the color and strength of a pigment with a reference standard of the same type. The test method is not to be used with white pigments. The pigments are dispersed in a suitable vehicle with a mechanical muller. Opaque drawdowns are made on white paper charts that have a black band and a surface that is impervious to paint liquids. These are then compared either visually or instrumentally for color and strength differences.

White Paints

ASTM Test Method for Relative Tinting Strength of White Pigments by Reflectance Measurements (D 2745) is a procedure for determining the relative tinting strength of white pigments by reflectance measurements made on black tints. It is only applicable for comparing a test pigment with a reference standard. The method is conducted by dispersing the pigment in an agreed on solvent-free vehicle and then letting it down with additional vehicle that has been tinted with a lamp black that has been predispersed in a vehicle similar in nature to the test vehicle. Refined or low-bodied linseed oil should not be used. Both dispersion and let-down are achieved with an automatic, mechanical muller. Tristimulus values are determined with a colorimeter.

ASTM Test Method for Relative Tinting Strength of White Pigments by Visual Observation (D 332) is a procedure for determining the relative tinting strength of white pigments by visual evaluation of blue tints. It is only applicable for comparing a test pigment with a reference standard. Specified amounts of white pigment and a blue tinting pigment that conforms to ASTM Specification for Ultramarine Blue Pigment (D 262) are dispersed together in a refined linseed oil with an acid number of about 4 using a glass hand muller or an automatic muller. The pastes are drawn down together on a panel and visually evaluated for tinting strength. A numerical rating of tinting strength is obtained by preparing dispersions with the standard white pigment and more or less of the tinting pigment and comparing them until the lightness of the test paste is matched. The weight of the tinting pigment is used to calculate the relative tinting strength.

PIGMENT DISPERSION

Mass color and tinting strength require that the pigments be well dispersed in the binder to achieve maximum tinting strength. Ideally, it would be desirable to break down pigment agglomerates to individual particles, i.e., to an ultimate dispersion state. However, in actual practice this would be difficult, if not impossible, to achieve. Therefore, pigments under investigation for MC and TS must be processed in the same manner and receive the same level of mechanical work. Mechanical mullers, Fig. 1, which are instruments that have two circular, usually ground, glass-grinding surfaces that contain the pigment and vehicle, are used for dispersing the two components. (A satisfactory muller is supplied by the Hoover Color Corp., 13 Cordier St., Irvington, NJ 07111.) Development of tinting strength is dependent on the force applied to the glass plates, the number of revolutions used, and the mass of pigment and of vehicle used. If muller conditions, pigment, and vehicle have not been agreed on by purchaser and seller, the mandatory dispersing conditions given in the Annex of ASTM D 387 should be used to achieve the maximum level of tinting strength. These conditions include:

- Determination of the appropriate ratio of color pigment to dispersing vehicle for the standard and test pigments.
- Determination of appropriate masses of pigment and vehicle to use.
- Preparation of a standard tint by application of 100 lb to the muller plates, introducing the appropriate mass of pigment/vehicle, and mulling the paste for 100 revolutions in two stages of 50 revolutions each. This is then repeated on three more specimens of the standard mixture except the mulling is carried out for 200, 300, and 400 revolutions in stages of 50 revolutions.
- Each of the four specimens is compared one to the other for tinting strength, and the minimum number of revolutions

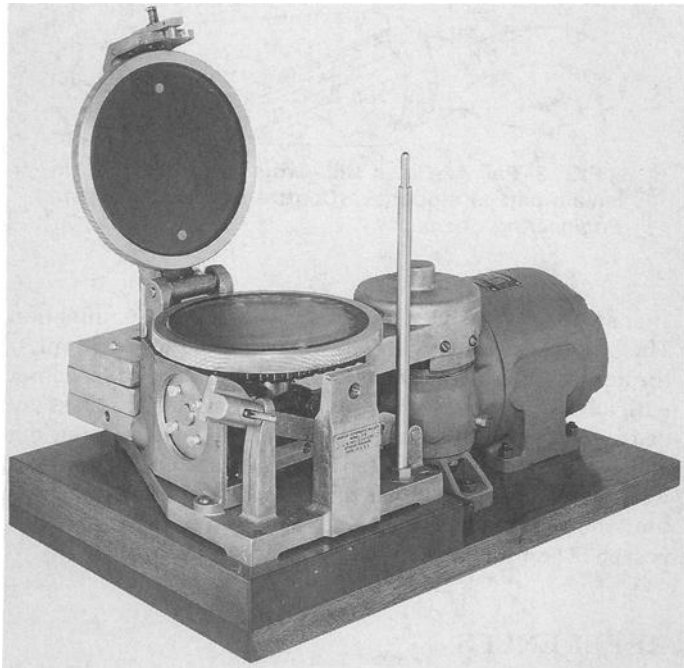

FIG. 1—Hoover Automatic Muller. *Automatic* means motor driven. (Courtesy of Hoover Color Corp.)

needed to develop maximum or full tinting strength is determined.

Parameters to record and the dispersing conditions for three pigments used in an interlaboratory test to determine the precision of this standard method are given in Table 1.

PIGMENT-DISPERSION TECHNIQUES

It should be kept in mind that the techniques described in this chapter pertain to preparing specimens for determination of tinting strength, mass color, etc., and are not meant for pigment dispersion in general. The general topic of pigment dispersion is discussed elsewhere in this manual as well as in numerous references [3–7]. There is a vast amount of literature that deals with the surface treatment of organic pigments to improve ease of dispersibility, and interested readers are encouraged to seek such information in the classic work of Hayes [*8*] as well as others [*9–11*]. Detail about the surface treatment of inorganic pigments is also in the literature [*12–14*]. Much of the following information is abridged and modified from the chapter with the same title in the previous edition of this manual [*15*].

Spatula and Hand Muller

Grinding pigment/vehicle combinations can be done with a spatula or a hand muller by rubbing or mulling the materials over a 3 by 12-in. (8 by 30-cm) strip area on a glass plate, Fig. 2. The rubbing is done by pushing the muller up one side and pulling it down the other side of the strip area so all color particles receive the same amount of rubbing. One rub is one up and down course. Early studies by Ayers [*16*] indicated that a muller gave more reliable results than a spatula and that the rubbing surface may vary a great deal without affecting the results. Stutz's [*17*] results during investigation of the tinting strength of white pigments also found a muller superior to a spatula. It was also found that a weighted or unweighted muller can be used without affecting the results.

AUTOMATIC MULLERS

Automatic or mechanical mullers have two circular glass-grinding surfaces that contain the pigment/vehicle paste. The grinding surfaces are usually constructed of ground glass with one stationary and weighted to exert a pressure of 100 psi (440 N) and the other rotary with rotation effected by a motor. Because rotation is about the disk centers, paste at the center can receive less mulling than paste located near the edges. To compensate for this effect, it has been found helpful to spread the paste in a ring approximately halfway between the edge and center. The revolutions per mulling cycle can be adjusted in increments of 1 to 999. Mechanical muller advantages include very good development of tinting strength, possibility to rapidly mull small quantities of materials, and efficient processing of a large number of samples.

The Annex of ASTM D 387, briefly described above, has a specific way to operate an automatic muller when determining tinting strength or mass color.

Laboratory Miniature Media Mills

There are commercial horizontal or vertical laboratory media mills that can process up to a quart of millbase. For small grinds, a media mill can be simulated with a laboratory dispenser equipped with a fiber or Teflon® 1⅝-in. disk, a 200-mL tall-form beak, and media. Equal volumes of millbase to media are used. Grinds may be 60.0 g for carbon black and some organics to 160.0 g for inorganic pigments. The millbase must be prepared carefully to eliminate gross and oversized agglomerates. Peripheral impeller speed should be 2000 ft (610 m) per minute, and the mixture should be ground for a set time or to a set dispersion level such as Hegman value 7.0+. Advantages of media mills include development of the

TABLE 1—Interlaboratory pigment dispersing parameters and specific conditions obtained for maximum tinting strength (data taken from ASTM D 387).

Parameter	Pigment Type		
	Yellow Iron Oxide	BON Red	Pthalocyanine Green
Force applied, lb (N)	100 (440)	100 (440)	100 (440)
Total no. revolutions	100 (2 × 50)	200 (4 × 50)	400 (8 × 50)
Mass of color pigment, g	1.0	0.6	0.75
Mass of dispersing vehicle, g	1.7	1.4	1.8

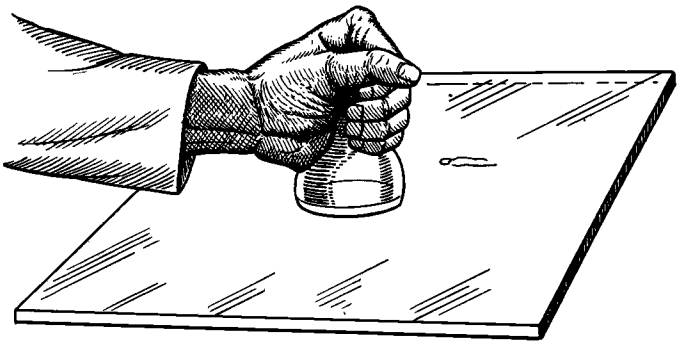

FIG. 2–Rubbing pigment and vehicle with glass muller and slab.

highest mass color and tinting strength, simulation of actual factory grinding conditions, and low cost.

Laboratory Roller Mill

Small three-roller mills have been found useful for grinding small, laboratory-size batches of paint. Rolls of such mills are about 4 in. (10.16 cm) in diameter and 8 in. (20.82 cm) in length. Batches as small as 5 g have been prepared in such mills.

Pall Glass Mill

Metal-free, small quantities of pigment paste have been prepared with the Pall Glass Mill [*18*], which is depicted in Fig. 3. It is a heavy ground-glass stopper in a heavy glass joint. The mixed, unground materials (1 to 8 g) are placed in the joint, and the stopper/plunger is inserted. The stopper is rotated with a small motor at about 150 r/min. In this mill, grinding pressure ranges from 20 to 30 psi. The Pall Glass Mill is said to be an improvement over hand mulling because it saves time and because it results in greater development of tinting strength.

PIGMENT CONCENTRATION

Paste viscosity has an effect on grinding efficiency, and it determines the level of mass color and tinting strength that is developed. Ayers [*16*] investigated iron oxides, and the results indicated that color developed faster as paste viscosity increased. A low-viscosity paste had a reflectance of 26% at a wavelength of 700 nm, whereas high-viscosity paste was darker and redder with a reflectance of 23%. There is a point above which viscosity has no effect.

MIXING TIME OF LIQUID COLORS

One of the properties of oil or universal liquid colorants is the ease with which they can be incorporated into white paints. A method for testing the speed of incorporation has been described by Paul and Diehlman [*19*]. This method involves use of a mechanical rotating bottle that contains a white paint, the liquid colorant, and a grinding media. When the test was first developed, No. 11 lead shot was used; however, today glass beads, zirconia grinding media, and steel

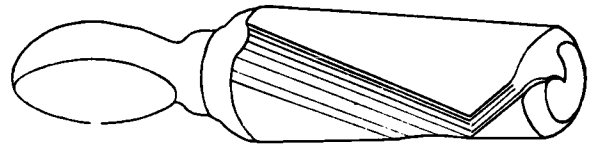

FIG. 3–Pall All-Glass Mill. Grooved plug rotates in female part of stopcock. (Courtesy of *Industrial and Engineering Chemistry.*)

shot are among the media used to avoid lead contamination. The bottle is charged with 550 g of grinding media, 2 mL of the liquid colorant, and 75 mL of white paint. It is then closed with a cork, concave on the inner end to match the glass end of the bottle, and placed in the holder of the rotating machine. The bottle is then tilted and rotated slightly by hand to wet the container walls. The mill is then mechanically rotated until the paint is homogenous in that no streaking of the color is seen. The time in seconds for mixing is determined.

Part 11:
Physical and Mechanical Properties

44

Adhesion

by Gordon L. Nelson[1]

ORGANIC COATINGS ARE APPLIED to a variety of substrate materials (woods, metals, plastics, ceramics) for decorative, protective, and functional applications. In each case, it is imperative that the coating adheres well to the substrate. Accordingly, adhesion assessments should be an integral part of coating development. This may seem a straightforward task, but coating adhesion is, in fact, extremely complex and often poorly understood. The growing use of plastics to replace metals and other "traditional" materials renders the issue even more complex [*1–2*].

The objectives of this chapter are to review briefly salient concepts of the adhesion process and to discuss currently accepted standard test methods.

FUNDAMENTAL CONCEPTS

While the very definition of "adhesion" is of some controversy [*1*], adhesion may be loosely defined as the attraction between dissimilar bodies for one another. ASTM D 907 on Terminology of Adhesives defines adhesion as "The state in which two surfaces are held together by interfacial forces which may consist of valence forces or interlocking action or both." In discussing adhesion assessment, one must consider the issue from two different aspects: *basic* adhesion and *practical* adhesion. Basic adhesion signifies the summation of all interfacial, intermolecular forces, whereas practical adhesion is used to represent the forces or work required to disrupt the adhering system [*3*]. The next section will be devoted to theories and concepts of basic adhesion and will of necessity be brief. The perspective will be from that of a polymeric coating on a plastic substrate [*2*]. Metal and metal oxide substrates will be discussed where appropriate. The reader is referred to Refs *4–7* for a more thorough discussion.

BASIC ADHESION

Work of Adhesion

Bonding between polymeric coatings and substrates may be viewed as the union of two contiguous polymer phases, one a solid and the other a liquid which solidifies to form a thin film. The reversible separation of the two phases may be expressed by the work of adhesion

$$W_a = Y_1 + Y_2 - Y_{12} \tag{1}$$

where W_a is the work of adhesion, and Y_1 and Y_2 are the surface tensions of the two phases. The maximum force per unit area, σ^2, to effect this process is the ideal adhesive strength [*8*]

$$\sigma^2 = [16/9\,(3)^{12}]\,(W_a/Z_0) \tag{2}$$

where Z_0 is the equilibrium separation between the two phases, usually about 5 Å. The average value W_a for polymers is typically 50 ergs/cm^2, yielding a theoretical value for σ^2 of 15 000 psi (103 mPa). For practical purposes this value is never attained, primarily due to the fact that perfect intermolecular contact is most unlikely. In fact, this is at least an order of magnitude higher than the practical adhesive strength usually observed. This deviation from ideality has led to the promulgation of several theories of adhesion, none of which are universally recognized [*9*]. This is not unexpected, since most theories deal exclusively with the mechanisms of bond formation and disregard the fact that bond strength is ultimately a function of both the degree of bond formation, the nature of the bond (chemical and physical), and the rheological properties of the bonding phases. The strength of an adhesive bond is, in fact, a function of all of these factors. Summary paragraphs about basic theories of adhesion follow below.

Fracture Theory

The area of interfacial bonding between coating and substrate will, in most instances, contain voids or defects. The result is deviation between the ideal adhesive strength and the practical limit.

Good [*10*] and Williams [*11*] have applied the theory of cohesive fracture to coating fracture. The concept that fracture propagates from the weakest point, a defect, is fundamental to fracture mechanics. The strength of a bond, in terms of the energy required to induce fracture, is described as a function of the defect size and the energy dissipated by irreversible processes (plastic deformation, light emission, and electric discharge). The general equation given is

$$f = k\,(EF/d)^{1/2} \tag{3}$$

where f is the fracture stress, $k = (4/\pi)^{1/2}$, E the elastic modulus of the material, d the defect length, and F the fracture energy or total work per unit area of fracture surface, which is dissipated. Accordingly, the fracture energy

$$f = W_a + W_i \tag{4}$$

[1]Dean, College of Science and Liberal Arts, Florida Institute of Technology, 150 West University Blvd., Melbourne, FL 32901-6988.

Copyright© 1995 by ASTM International

where W_a is the work of adhesion and W_i is the total work for the irreversible processes. For all practical purposes W_i is much greater than W_a, therefore [*12–13*]

$$f = W_i \tag{5}$$

Weak Boundary Layer Theory

Proposed by several workers [*14–16*], the weak boundary layer theory maintains that true interfacial fracture does not occur, and that fracture usually occurs *cohesively* in a weak boundary layer (WBL), which may be near the interface between coating and substrate. Experimental evidence has perhaps disproved the first point [*10*], that true interfacial failure can occur, but it has been shown that the second is valid in some instances [*17-18*].

Of practical importance to WBL investigations is the locus of fracture, which can occur in one or more of the zones in Fig. 1. For a strong bond, the boundary layer (layers) must be rheologically sound and chemically durable. The zone of failure may, of course, be studied by SEM, TEM, and FT-IR. In fact, thin layers of coating have been noted where interfacial failure was only thought to occur on visual examination.

Wetting—Contact Theory

The wetting-contact theory states that van der Waals attractive forces alone provide sufficient coating/substrate bond strength given perfect molecular contact, and that the extent of contact and resulting bond strength are functions of wetting energetics [*20–28*]. No one denies the importance of wetting in adhesion, i.e., the lower the contact angles, the more the interfacial area of contact, which generally yields improved adhesion (Fig. 2).

However, thermodynamic wetting is a necessary but not sufficient condition for the establishment of coating film adhesion. Wetting is a kinetic phenomenon as well. Furthermore, this model does not consider the effects of weak boundary layers or the effects of defects or fracture mechanics. What is the effect of surface contamination on the contact angle?

Diffusion Theory

Voyutskii and others [*29–33*] have proposed that coating adhesion between high polymers arises from interdiffusion.

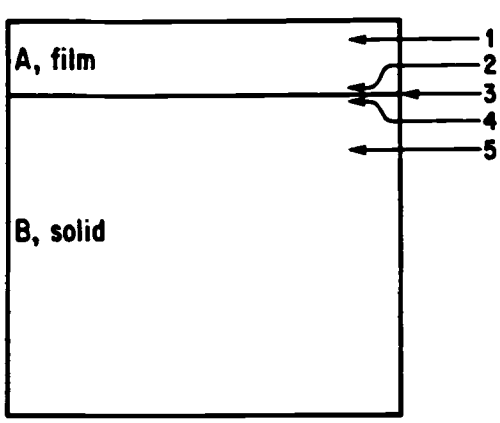

FIG. 1–Weak boundary layer theory. Possible zones of failure (after Good [*19*]).

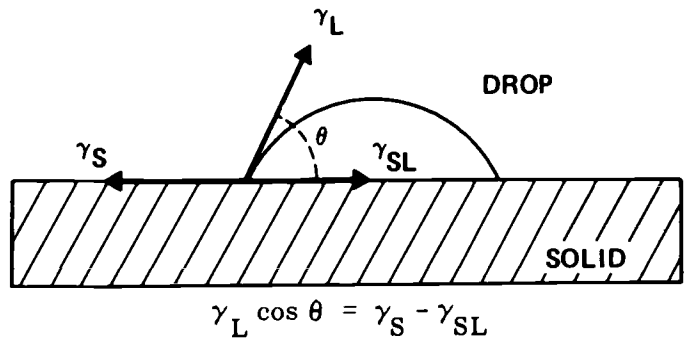

FIG. 2–Contact angle.

This has been validated somewhat by the observation that adhesive strength is a function of polymer molecular weight, structure, and contact time.

Key to this theory is the concept that no clear-cut interfacial boundary exists, but rather that an interphase exists which consists of polymer chain segments from both contiguous phases. The theory has been criticized for giving insufficient weight to the contribution of van der Waals attractive forces. Nevertheless, for the case of solvent-borne organic coatings applied to plastic substrates, this phenomenon is intuitively appealing.

Interdiffusion of coating and substrate polymer molecular segments is a function of polymer-polymer compatibility. An interphase forms as a result of the blending of the two phases. Although polymer pairs are generally incompatible, Helfand and others [*34–38*] have utilized statistical thermodynamics to predict that interdiffusion also occurs as a result of the tendency for free energy at the interface to minimize. A useful equation which describes interfacial thickness as a function of the Flory-Huggins interaction parameter as derived from Hansen solubility parameters is [*36,38*]

$$a_i = 2\,(m/x)^{1/2} \tag{6}$$

Where a_i is the interfacial thickness expressed as the cross sectional area of a lattice cell, m is a lattice constant directly proportional to nearest-neighbor contacts, and x is the Flory-Huggins interaction parameter. By this equation, interfacial thickness increases by interdiffusion as the solubility parameter difference between the two phases decreases. Although experimental verification is scarce, adhesive strength has been shown to decrease with increasing disparity in the solubility parameters of the two phases [*39*].

It is important to note that diffusion should occur in the latter stage of bond formation, the first stage being wetting to establish contact. Additional support for the theory comes from the observation that adhesive strength between certain high polymers increases with time [*30*]. This theory, however, cannot be applicable to systems involving one or more hard solids (metals, glass, or metal oxides).

Chemical Adhesion

The bond strength of covalent bonds is one to two orders of magnitude greater than van der Waals attractive forces. There have been numerous applications where interfacial chemical bonds have been employed to promote adhesion. Dramatic increases in bond strength have been reported [*40*].

Coupling agents such as chrome complexes [41], silanes [42], and titanates [43] have been used effectively. Organic functionalities, including isocyanates, carboxyls, amides, amines, hydroxyls, and epoxides [43–44], have been reacted interfacially to enhance adhesion.

Adhesive strength has been shown to increase with functional group concentration as expressed by

$$f = kC^n \tag{7}$$

where f is the adhesive strength, C the functional group concentration, and k and n are positive constants [45]. There, however, appears to be an upper limit for functional group concentration above which adhesion may tend to decrease [46–47].

Mechanical Adhesion

In mechanical adhesion substrate roughness is thought to provide a mechanical locking of the coating to the substrate. However, if there is not intimate contact between the coating and the substrate, then increased roughness should lead to a *decrease* in adhesion by producing uncoated voids. In the practical application of electroless metals on polymer substrates, etchants are used which create deep channels, increasing adhesion. Other examples are anchor coats for PTFE, adhesion to porous anodic films on aluminum, and hot melt polyolefin coatings on metals. Mechanical adhesion is also important for porous substrates such as wood, cloth, and paper. Since good adhesion can be obtained on smooth surfaces such as glass, questions can be raised about the general validity of the mechanical adhesion mechanism. It should also be noted that mechanical abrasive treatment of a solid surface may also yield macroradicals and active secondary chemical products, which if they do not come into contact with atmospheric oxygen, may interact with components of the coating. This has been shown for certain adhesives. Active radicals or functionality would yield adhesion, better described as mechanico-chemical adhesion than just mechanical [7,48–49].

Electrostatic Adhesion

In the theory of electrostatic adhesion, when two dissimilar materials are brought into contact, a charge transfer takes place which results in the formation of an electrical double layer, much like a capacitor. Work would then be required to separate the two charged layers. This is thought to be particularly applicable to metal-polymer bonds. Indeed, ionizing discharge has been shown to affect a copper to acrylic bond but not copper on salt (NaCl) or glass. This theory would not be applicable to two nonpolymer systems [49–50].

Acid-Base Adhesion

In the acid-base adhesion theory, it is said that the strength of the adhesive bonds is increased significantly by acid base interactions between coating and substrate. Appropriate modification of surface acidity or basicity of the substrate should increase adhesion. Modification of surface acidity or basicity of inorganic solids can increase mechanical properties (modulus, extension to break, and toughness) of coatings on these substrates. It has also been claimed that the reverse is true, however [51–52].

Combination of Phenomena

The preceding theories interpret adhesion in terms of single phenomena, each of which undoubtedly plays some role in interfacial bonding between coating and substrate. One should be cautioned, however, against exclusive use of a single theory to explain the adhesion of a given system. A more logical approach has been proposed by Allen [53]

$$\psi = a\psi_A + b\psi_B + c\psi_C + \ldots \tag{8}$$

which suggests that a combination of phenomena is more realistic, that is, that basic adhesion is the summation of *all* interatomic or intermolecular interactions at the interface. One would think that systematic studies could be made to assess the contribution of a given variable to the adhesion process, with the others being held constant. This would reveal useful information as to factors critical to coating adhesion for a particular system. Unfortunately, being able to accomplish that task is questionable given that adhesion assessment not only involves factors of basic adhesion but variation in application of the applied external stress (tensile, shear, or peal) and many other factors.

It can be concluded that adhesion is an interfacial phenomenon in which both physical and chemical forces operate when surfaces develop to form an interface. Adhesive strength is a measure of the degree to which the two surfaces are attracted. This is a function of wettability, relative surface energetics of both phases, and of the kinetics of wetting. For integrity of a bond at the interface between a coating and a substrate, one needs to consider the following factors:

1. Thermodynamics and kinetics of the formation of the bond.
2. The forces acting near the interface in both the coating and the substrate.
3. The cohesive forces within the coating layer.
4. Internal stresses in the coating layer.
5. The behavior of the coating layer under stress.

To understand basic adhesion one must understand the surface chemistry, surface physics, surface architecture, coating polymer chemistry and physics, polymer rheology, coating internal stresses, fracture mechanics, and effects of changes in the environment. In fact, it has been noted that spontaneous loss of adhesion can occur due solely to internal strain of the coating [54–56].

Effects of Substrates

Additional Chemistry

The adhesion of organic coatings to metals is at a high level of development in the practical sense. The contribution of surface energy, chemical functionality, surface irregularities, and contaminants (oxides, adsorbed water, etc.) have been identified.

On the other hand, coating adhesion to plastic substrates has presented additional complexities. Polymer surfaces are often more difficult to wet and bond because of low surface energy, incompatibility, chemical inertness, or the presence of contaminants (oils, lubricants, plasticizers, etc.), and weak

boundary layers. Surface modification techniques have been developed to enhance adhesion. In the absence of surface preparation, coating adhesion is felt to be a function primarily of van der Waals and/or polar-dipolar attractive forces, mechanical adhesion (from surface irregularities), and interdiffusion. This latter contribution to adhesion has been studied using scanning electron microscopy. In Fig. 3 is presented a scanning electron micrograph of a thermoplastic acrylic coating applied to modified polyphenylene oxide (a blend of PPO and polystyrene), an important engineering thermoplastic. The first coating contains 60% of the recommended amount of solvent. The interface formed is sharp and well-defined. In this instance, adhesion appears to be due largely to mechanical and attractive forces. Figure 4 shows the same substrate and coating, which in this case contains 100% of the recommended amount of solvent. The sharp interface seen in Fig. 3 is no longer present, an intermediate zone or interphase having formed in its place. Diffuse interface formation of this magnitude is undoubtedly unique to coatings applied to plastics. Bond strength will be a function of formulation, solvent content, and drying time [*2*].

Organic coatings are complex formulations; thus, the polymer chemistry at the developing coating substrate interface will clearly be impacted by the solid surface, whether plastic, metal, or inorganic, that is, the polymer interface may be somewhat different than the bulk coating (i.e., a boundary layer). Fully developed coatings may also be porous or permeable, thus aging and weathering may impact adhesion, as water, oxygen, and other agents penetrate to the polymer coating solid interface [*7,57*]. Indeed, some coatings that have acceptable adhesion while dry may fail badly when tested under high humidity or after immersion in water for several hours.

It has been shown for polyolefin-metal adhesion that oxidation of the polymer attached to the surface occurs through action of oxygen absorbed by the metal and the polymer. The appearance of oxygen-containing groups in the otherwise inert polymer should promote an increase in the extent of interaction with the metal. Adhesion in this case would also be increased by oxygen donor fillers [*7,57*].

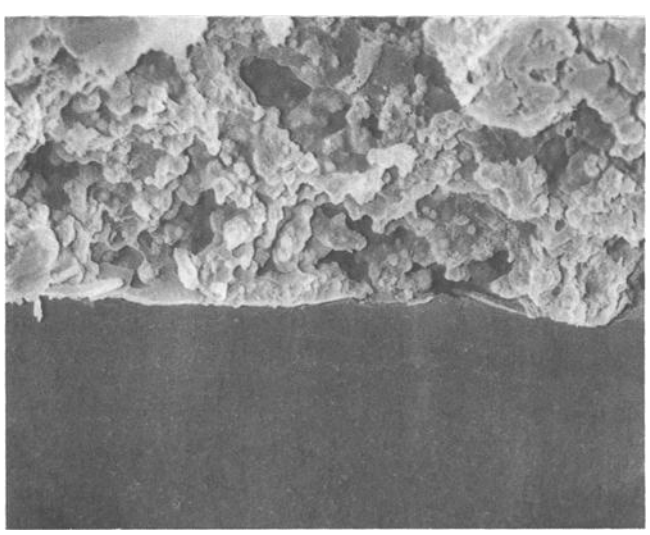

FIG. 3–SEM of sharp interface.

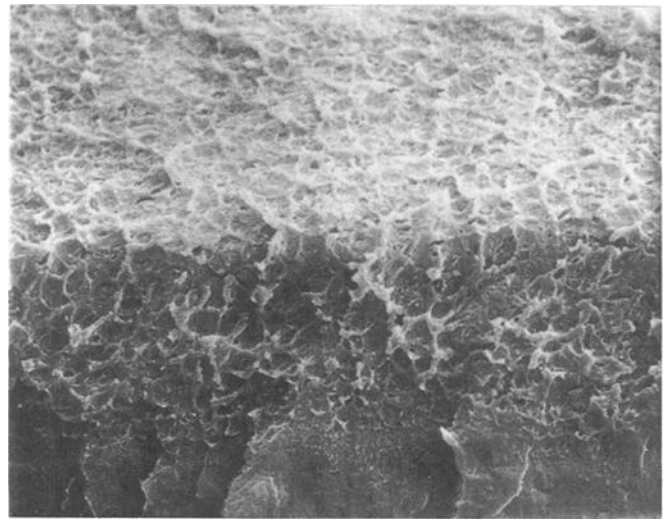

FIG. 4–SEM of diffuse interface.

All metals (except gold) are known to exist with an oxide film on their surfaces. The volume of oxide formed may be smaller than the metal reacted, and consequently the oxide film is porous and nonprotective (alkali and alkaline earth metals) or the volume may be larger and therefore protective (transition metals and aluminum). However, in the latter case, migration of metal cations from the surface leaves vacancies which aggregate to form cavities. Treatment of a metal before coating to produce a preferred or controlled bonding surface is therefore common [*7,57*]. From the above discussion, it is clear that chemical interaction between coating and solid can occur even when not recognized or anticipated.

Finally, change in substrate may impact adhesion. Weathering failures such as blistering and scab corrosion are often regarded as adhesion failures by coatings development chemists. Delamination of coatings in the absence of substrate corrosion can also be produced by weathering. A common problem involves the interfacial chalking of an epoxy primer and a topcoat that has a high UV light transmission. In the presence of UV light, moisture, and oxygen, the epoxy primer is degraded at the interface between the primer and topcoat, leading to delamination of the topcoat from the primer.

Delamination of clear or semitransparent exterior wood coatings can also occur by UV, water, and oxygen attacking the wood substrate. Delamination of the intact coating results when the wood substrate coating interface is destroyed. The solution to this problem is to add organic and inorganic UV absorbers to the coating to protect the wood substrate from degradation.

PRACTICAL ADHESION

Given the complexities of the adhesion process, can adhesion be measured? As Mittal [*3*] has pointed out, the answer is both "yes" and "no." It is reasonable to state that at the present time no test exists which can precisely assess the actual physical strength of an adhesive bond. But it can also be said that it is possible to obtain an indication of relative adhesion performance.

Practical adhesion test methods are generally of two types: *implied* and *direct*. Implied type tests include indentation or scribe techniques, rub testing, and wear testing. Criticism of these tests arises when they are used to quantify the strength of adhesive bonding. But this, in fact, is not their purpose. An implied test should be used to assess coating performance under actual service conditions. Direct measurements, on the other hand, are intended expressly to measure adhesion. Peel, lap-shear, and direct tensile are common examples. Meaningful tests of this type are highly sought after, primarily because the results are expressed by a single discreet quantity, the force required to fracture the coating/substrate bond under prescribed conditions [*2*].

Test Methods

In practice, a battery of tests is used to evaluate adhesion by inducing bond rupture by different modes. Criteria deemed essential for a test to warrant large-scale acceptance are: use of a straightforward and unambiguous procedure, relevance to its intended application, reproducibility, and quantifiability, including a meaningful rating scale for assessing performance. Test methods used for coatings on metals are: peel adhesion or "tape testing," Gardner impact flexibility testing, and adhesive joint testing including shear (lap joint) and direct tensile (butt joint) testing. These tests do not, in fact, strictly meet the criteria listed, but an appealing aspect of the above tests is that in most cases the equipment/instrumentation is readily available or can be obtained at reasonable cost [*2*].

A wide diversity of test methods has been developed over the years. In this chapter only selected test methods developed through the consensus process will be discussed in detail. The reader should recognize, however, that numerous test methods have been developed which measure aspects of adhesion [*7,58–61*] and that there generally is difficulty in relating these to basic adhesion phenomena.

The Tape Test

By far the most used test to access coating "adhesion" is the peel test. In use since the 1930s, in its simplest version, a piece of adhesive tape is pressed against the paint film. The test consists of observing whether the film is peeled off when the tape is removed. The method can be refined to measure the force required for film removal. In other tests, crosses or a cross-hatched pattern are cut into the coating, a tape applied and removed, and the coating removal assessed against an established rating scale. The currently widely used version was published in 1974 as ASTM D 3359, Standard Test Methods for Measuring Adhesion by Tape Test. Two test methods are covered.

These test methods cover procedures for assessing the adhesion of coating films to metallic substrates only by applying and removing pressure-sensitive tape over cuts made in the film. Method A is primarily intended for use at job sites, while Method B is more suitable for use in the laboratory. The cross-hatch test, Method B, is not considered suitable for films thicker than 5 mils (125 μm). Both test methods are used to establish whether or not the adhesion of a coating to a substrate is at a generally adequate level. They do not distinguish between higher levels of adhesion for which more sophisticated methods of measurement are required. In multicoat systems, adhesion failure may occur between coats so that the adhesion of the coating system to the substrate is not determined. In Test Method A an X-cut 1.5 in. (3.8 cm) long is made in the film (to the substrate) with a sharp cutting device. A 1-in. (2.5-cm)-wide pressure sensitive tape is applied over the cut and firmly adhered with a pencil eraser and then removed, and adhesion is assessed qualitatively on a 0 to 5 scale.

In Test Method B, a lattice pattern with either six or eleven cuts in each direction is made in the film (to the substrate), pressure-sensitive tape is applied over the lattice and then removed, and adhesion is evaluated by comparison with descriptions and illustrations.

For Test Method A, the following rating scale is used:

- 5A No peeling or removal.
- 4A Trace peeling or removal along incisions.
- 3A Jagged removal along incisions up to 1/16 in. (1.6 mm) on either side.
- 2A Jagged removal along most of incisions up to 1/8 in. (3.2 mm) on either side.
- 1A Removal from most of the area of the X under the tape.
- 0A Removal beyond the area of the X.

For Test Method B, 3/4 in. (1.9 cm) cross-cuts are made.

For coatings having a dry film thickness up to and including 2.0 mils (50 μm), eleven cuts are spaced 1 mm apart.

For coatings having a dry film thickness between 2 mils (50 μm) and 5 mils (125 μm), six cuts are spaced 2 mm apart.

For films thicker than 5 mils (125 μm), Method A is used instead of Method B. For Test Method B, adhesion is rated according to the following scale (as illustrated in Fig. 5.):

- 5B The edges of the cuts are completely smooth; none of the squares of the lattice is detached.
- 4B Small flakes of the coating are detached at intersections; less than 5% of the area is affected.
- 3B Small flakes of the coating are detached along edges and at intersections of cuts. The area affected is 5 to 15% of the lattice.
- 2B The coating has flaked along the edges and on parts of the squares. The area affected is 15 to 35% of the lattice.
- 1B The coating has flaked along the edges of cuts in large ribbons, and whole squares have detached. The area affected is 35 to 65% of the lattice.
- 0B Flaking and detachment worse than Grade 1.

Repeatability within one rating unit is generally observed for coatings on metals for both methods, with reproducibility of 1 to 2 units. The method is widely used and is viewed as "simple" as well as low in cost.

Peel Adhesion Testing on Plastic Substrates

ASTM D 3359 has drawn fire when used for substrates other than metal, such as plastics. The central issues are that the test lacks reproducibility and does not relate to its intended application. Both concerns are well founded. Poor reproducibility is a direct result of several factors intrinsic to the materials employed and the procedure itself. More importantly, in this instance the test is being applied beyond its

Classification	Surface of cross-cut area from which flaking has occurred. (Example for six paralled cuts)
5B	None
4B	3B	
2B	
1B	0B	Greater than 65%

FIG. 5–Classification of adhesion test results. From ASTM D 3359.

intended scope. ASTM D 3359 was designed for relatively ductile coatings applied to metal substrates, not for coatings (often brittle) applied to soft plastic parts [*1*].

Nevertheless, the tape test enjoys widespread popularity. The tape test is economical to perform, lends itself to job site application, and most importantly, after decades of use, people feel comfortable with it. Unfortunately, the often unique functional requirements of coatings on plastic substrates dictate that the tape test as written may not be a satisfactory measure of practical adhesion performance.

When a flexible adhesive tape is applied to a rigid coated substrate surface and then removed, the removal process has been described in terms of the "peel phenomenon," as illustrated in Fig. 6.

Peeling begins at the "toothed" leading edge (at the right) and proceeds along the coating-adhesive interface. It is reasonable to assume that any coating removal is due to a tensile force generated along this interface, which would be a function of the rheological properties of the backing and adhesive layer materials and the strength of the bond between the adhesive layer and the coating surface. Note, however, that in actuality this force is distributed over a discreet distance (0 to A on Fig. 6), which relates directly to the properties described [*63*], not concentrated at a point (0 on Fig. 6) as in the theoretical case, though tensile force is greatest at the origin for

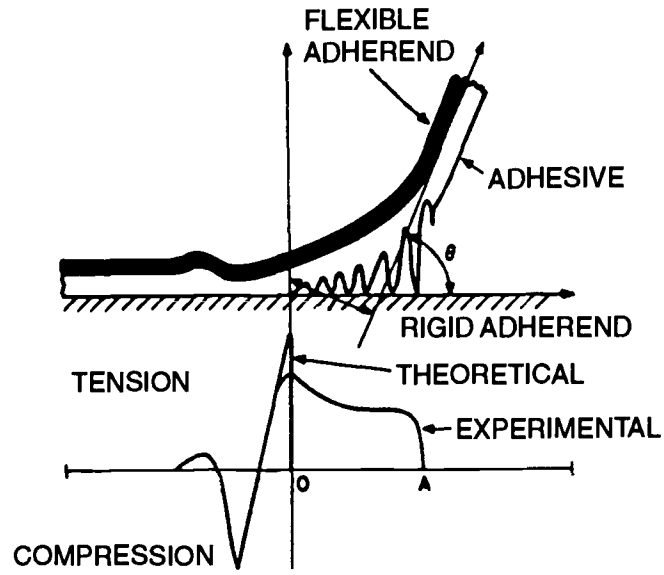

FIG. 6–Peel profile [*62*].

both. It is worthwhile to note the significant compressive force which arises from the response of the tape-backing material to being stretched, which precedes the tensile force. Both tensile and compressive forces are involved in tape testing.

Close scrutiny of the tape test with respect to the nature of the tape employed and certain aspects of the procedure itself reveal several factors, each or any combination of which can dramatically affect the results of the test as discussed below.

The Tape Controversy

Given the withdrawal of the originally specified tape, 3M-710, ASTM D 3359-91 no longer specifies a specific tape. Differences in tapes can lead to different results for reasons noted above since small changes in backing stiffness and adhesive rheology cause large changes in the tension area. It is also important to note that tapes, like most products, are manufactured to meet minimum standards. A given lot may surpass these criteria and be suitable for general market distribution, but a source of serious and unexpected error for tape testing [*63*]. There was, in fact, a commercially available tape test kit which included a tape with adhesion variations of up to 50% claimed by the manufacturer [*64*]. And, of course, tapes age on storage. Bond strengths change over time.

While there are tapes available which would appear to deliver consistent performance, a given tape does not adhere equally well to all coatings. For example, the peel removal force of the tape previously recommended by ASTM (3M-710) was examined with seven coatings. It was found that while peel was indeed consistent for a given coating, it varied by 25% between the highest and lowest ratings among coatings. This observation could be the result of several factors, notably coating composition and topology, but the bottom line is that no single tape is likely to be suitable for testing all coatings. It is also useful to note the tape test does not give an absolute value for the force required for bond rupture, but serves only as an indicator that some minimum value for bond strength was met or exceeded [*1,2*].

Procedural Problems

The tape test is operator intensive. By design it was made as simple as possible to perform and requires a minimum of specialized equipment and materials which must meet certain specifications. Therefore, the burden of accuracy and reproducibility relies largely upon the skill of the operator and his/her ability to perform the test in a consistent manner. Key steps which directly reflect the importance of operator skill include the angle and rate of tape removal and the visual assessment of the tested sample. It is not unexpected that different operators might obtain different results [*1,2*].

Peel Angle and Rate

The standard requires that the free end of the tape be removed rapidly at as close to a 180° angle as possible. But if peel angle and rate vary, the force required to remove the tape can change dramatically. Nearly linear increases were observed in peel force approaching 100% as peel angle was changed from 135 to 180°, and similar large differences can be expected in peel force as peel rate varies. These effects are related in that they both reflect certain rheological properties of the backing and adhesive which are molecular in origin, but the most useful conclusion is that these phenomena can make large contributions and must be minimized to assure reproducibility [*65*].

Visual Assessment

The final step in the test is visual assessment of coating removed from the specimen, and this can be subjective in nature. This assessment can vary among individuals evaluating the same specimen [*65*].

Performance in the tape test is based on the amount of coating removed compared to a relative scale. But it was found that the exposure of substrate can be due to factors other than coating adhesion, arising from the requirement that the coating be cut (hence the synonym "cross-hatch adhesion test"). Justification for the cutting step is reasonable; cutting provides a free edge from which peeling can begin without having to overcome the cohesive strength of the coating layer. This might be suitable for coatings applied to metal substrates, but for coatings applied to plastics, the cutting process can lead to false indications of poor adhesion. This is due to the unique interfacial zone mentioned earlier. For coatings on soft plastics, how deep should this cut penetrate? Is it possible to cut only to the interface?

If microscopic examination of panels is included, in several instances it is clearly evident that coating removal results from substrate failure at or below the interface, not from adhesive failure between coating and substrate. At the same time, it is also observed that cohesive failure within the coating layer is a frequent occurrence. The latter observation is significant in that the tape test assessment criteria make no provision for it [*1,2*].

Direct Tensile Testing

A long-used approach to coating adhesion testing is the direct tensile test, perhaps "conceptually" the simplest of all methods for measuring adhesion. A dolly or stud is bonded to the coating film. The normally applied force which is required to remove the film is measured. If failure occurs at the substrate-film interface, this force is taken to be the "force of adhesion." An obvious limitation is, of course, the strength of the adhesive bond of the stud to the cured coating. Such methods have been available since the 1930s. Many of these test methods have unfortunately suffered from their own lack of reproducibility. This is not unexpected since the forces involved are not quite as simple as appearance would have it [*5,66*].

It is essential that the force is applied strictly in the direct normal to the sample and that no bending moment is active across the test area. Deviations from symmetry in the test arrangement, poor alignment, deviations from homogeneity and of thickness of the adhesive (coating), and random variations in the strength of the bond between film and substrate affect test results [*5,66*].

The stress at locations where the adhesive film is thinner will be higher than the average stress and will be transmitted to the film under test. Another factor may be peeling during test, which is not easily identified or analyzed.

The adhesive used to bond a stud to the coating has the potential to influence the coating film properties by penetration through the film into microcracks and possibly into the substrate [*66*]. Test adhesive flexibility may also be an issue, as well as the flexibility of the substrate, if the sample is unrestrained.

There exist now within ASTM both laboratory and field versions of direct tension tests for coatings. Test Method for Measuring Adhesion of Organic Coatings to Plastic Substrates by Direct Tensile Testing, ASTM D 5179, while limited to organic coatings on plastics, uses a restrained sample and commonly available tension test apparatus. The second, Method for Pull-Off Strength of Coatings Using Portable Adhesion-Testers, ASTM D 4541, defines a class of portable pull-off adhesion testers for field evaluation of coating adhesion. ASTM D 5179 is the successor to numerous attempts to develop a reproducible coating tension test and was approved in 1991. It will be discussed first.

ASTM D 5179

This test covers the laboratory determination of adhesion of organic coatings to plastic substrates by mounting and removing an aluminum stud from the surface of a coating and measuring the force required to break the coating/substrate bond with a tensile tester. The test method provides an inexpensive test assembly which can be used with most tensile test machines. The method is used to compare the pull-off strength (commonly referred to as adhesion) of coatings to various plastic substrates, thus allowing for a quantitative comparison of various coating/substrate combinations.

A carefully prepared aluminum stud is bonded directly to a coated, cured panel using a cyanoacrylate adhesive. The adhesive is allowed to cure for 2 h at room temperature. Adhesive buildup is removed from around the stud. The specimen is then subjected to test on a tensile tester equipped with an upper coupling adapter and a restraining device (Fig. 7) to provide for sample alignment and minimal substrate flexing. The sample bearing the stud is installed in the restraining device, with only the stud pertruding. The tensile machine crosshead is lowered so the upper coupling adaptor can be attached to the specimen.

When testing thin substrates, a piece of plastic is placed in the restraining device behind the specimen to insure a rigid

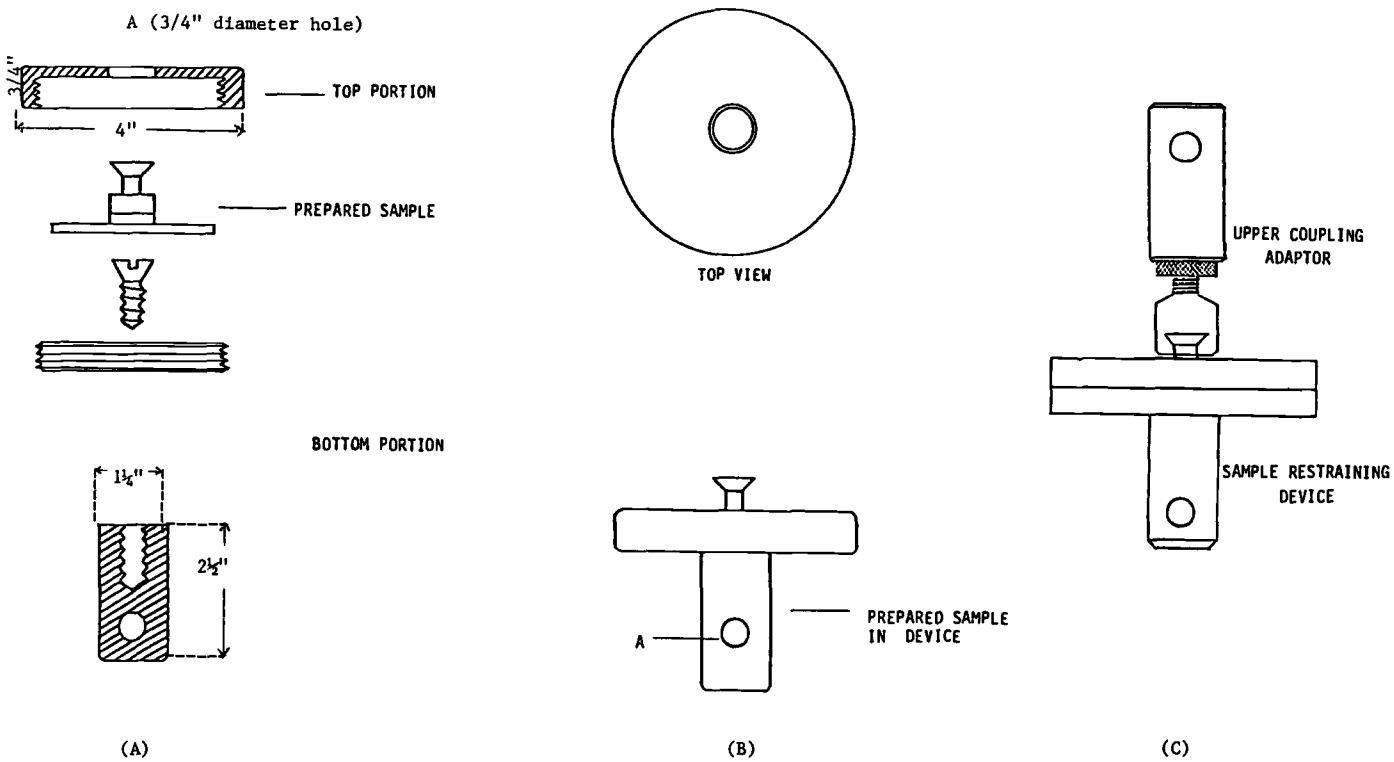

FIG. 7–Direct tensile restraining device. From ASTM D 5179.

assembly. The tension test is conducted, and pull strength recorded. Each specimen is rated according to type of coating failure, as follows:

- A Adhesive failure of the coating from the substrate.
- C Cohesive failure in the coating.
- AC Combination of adhesive failure at the coating/substrate interface and cohesive failure in the coating.
- S Adhesive failure at the stud.
- CS Combination of adhesive failure at the stud and cohesive failure in the coating.

For multilayer coatings, failure between the layers is noted and labeled as CM. Five specimens of each coated substrate are tested one day and five on a second day. If one specimen differs significantly from the other four tested at the same time, fails because of an uneven (nonplanar) stud, or for another reason performs unlike the other four, a replacement specimen is tested. The stud and specimen are carefully examined. The adhesive should have been applied uniformly to the entire stud surface. Coating should have pulled off uniformly over the *entire* stud surface either with adhesive failure from the substrate (A) or cohesive failure in the coating (C). If failure is less than 90% A or C (or CM), if the adhesive has failed at the stud, a retest, exercising particular care in the specimen and stud preparation is performed. Pull strength for the ten runs on each coating substrate combination are averaged and reported.

The precision and bias are primarily dependent upon the accuracy of the force measurements, the alignment of the device, and the care exercised in stud and specimen preparation and in the care in testing. A ten-laboratory round robin on ten samples gave an average standard deviation of 29% for reproducibility and 22% for repeatability. A range of pull strengths of two orders of magnitude has been observed (Table 1) for diverse coating-plastic combinations.

ASTM D 4541

This test method defines a class of portable adhesion testers for measuring the pull-off strength of coatings. The method covers a procedure and apparatus for evaluating pull-off strength by determining either the greatest perpendicular force (in tension) that a surface area can bear before a plug of material is detached or whether the surface remains intact at a prescribed force (pass/fail). Failure will occur along the weakest plane within the system comprised of the test fixture, adhesive, coating system, and substrate and will be exposed by the fracture surface. The method maximizes tensile stress as compared to the shear stress applied by other methods such as scratch or knife adhesion, and results are not comparable. It is recognized that the pull-off strength reflects both material and instrumental parameters and therefore provides a relative, not absolute, measure of adhesion. The pull adhesion testers defined are portable and capable of applying a concentric load and counter load to a single surface so that coatings in the field can be tested even though only one side is accessible. Measurements are limited by the strength of adhesion bonds between the loading fixture and the specimen surface or the cohesive strength of the substrate. The pull-off test is performed by securing a "loading fixture" (dolly or stud) normal (perpendicular) to the surface of the coating with an adhesive. After the adhesive is cured, the testing apparatus is attached to the loading fixture and aligned to apply tension normal to the test surface. The force applied to the loading fixture is then gradually increased (in less than 100 s) and monitored until either a plug of coating material is

TABLE 1—Representative pull strength for organic coatings on plastics.

Sample No.	Coating	Substrate	Failure Mode	Pounds Per Square Inch[a]
1	Lacquer	Polyester/polycarbonate	C	58

PPO = polyphenylene ether

detached or a specified value is reached. The nature of the failure is assessed as to the percent of adhesive or cohesive failure, and the actual interfaces and layers involved are identified. The pull-off strength is computed based on the maximum indicated load, the instrument calibration data, and the original surface area stressed (Fig. 8).

This method is general and is applicable to any portable apparatus meeting the standard's basic requirements for determining the pull-off strength of coatings. Four apparatus are commonly recognized to meet the requirements of the standard.

It is known that the rigidity of the substrate affects pull-off strength results and is not a controllable test variable in field measurements as defined by this standard. For example, steel substrates of less than 1/8 in. (3.2 mm) thickness show reduced pull-off strength results compared to 1/4-in. (6.4-mm)-thick panels.

Errors in measurement in this test result from alignment of the apparatus that is not normal to the surface, poor definition of the area stressed due to improper application of the adhesive, poorly defined glue lines and boundaries, holidays in the adhesive caused by voids or inclusions, improperly prepared surfaces, and sliding or twisting of the fixture during the initial adhesive cure. Also, scratched or scored samples may contain stress concentrations leading to premature fractures. Interlaboratory data have been obtained for four commercial test apparatus and are presented in Table 2.

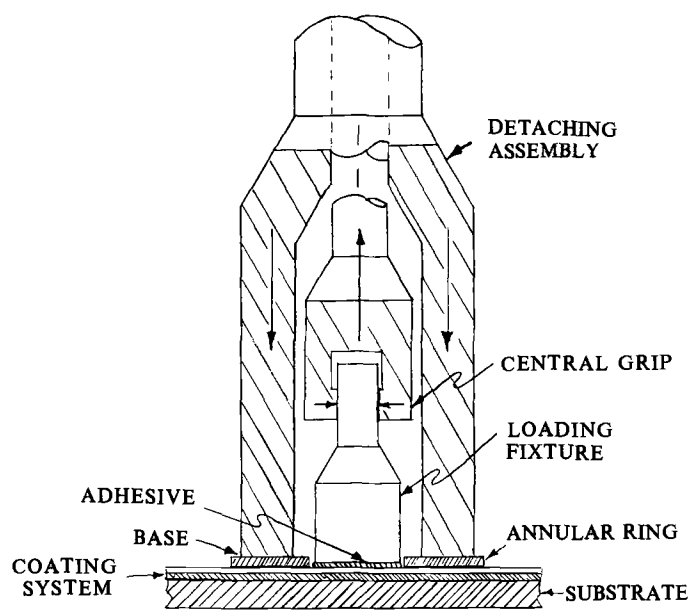

FIG. 8—Portable adhesion tester. From ASTM D 4541.

ISO 4624

Similar pull-off test methodology has been approved through the International Standards Organization, and the parameters involved have been carefully studied. ISO 4624, "Pull-off Test for Adhesion," was approved in 1978. ISO 4624 specifies two different tests assemblies (A and B of Fig. 9)

Test Assembly A (Sandwich Method) consists of a substrate painted on one or both sides, with test cylinders (studs) with a specified diameter bonded coaxially to the coated test surface and on the reverse. Test Assembly B consists of a rigid substrate coated on one side, with one test cylinder (stud) applied to that side only. While the latter is the more practical, Test Assembly A on stress analysis shows a smoother stress distribution than B. Test Assembly B shows strong stress peaks at the coating layer periphery. The result is that the Test Assembly B shows 20 to 60% lower breaking strength results than the sandwich method for several organic coatings on metal [*67*].

For Test Assembly B, breaking strength values have been shown to be a function of the diameter of test cylinders (studs) as well as their geometry. On the range of 10 to 28 mm diameters, a factor of two in breaking strength was seen with a peak at about 14-mm diameter. It was observed that tensile forces only affected the central part of the test area. Even test cylinders of the same diameter, but different shapes, gave different results, up to 45% lower. It has been noted that while uniform tensile stress can only be approached, the length of the test cylinder (stud) should be no less than half its diameter. When this is done, similar results are achieved regardless of cylinder diameter [*67*].

TABLE 2—ASTM D 4541 interlaboratory data.

Instrument	Patti	Elcometer	Hate	Dyna
Loading Fixture Diameter	13 mm	20 mm	19 mm	50 mm
Paint Sample		(mean of 3 results)		
A	1160	586	1185	201
B	1099	674	1157	185
C	1033	827	1245	190
D	1678	888	1686	297

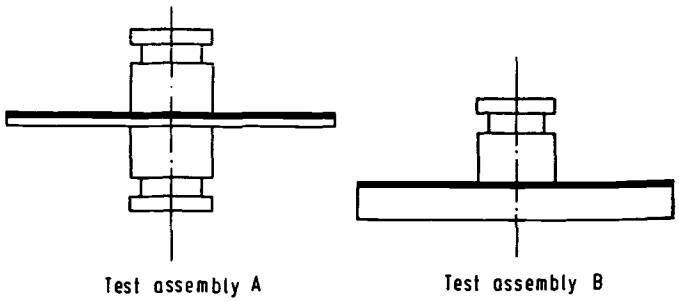

FIG. 9–ISO 4624 test assemblies.

Perhaps it is only coincidence, but it is interesting to note in Table 2 for apparatus meeting ASTM D 4541 that the loading fixture diameter and geometry differ significantly and at least partially account for the greater than a factor of 4 variation in test results, with the apparatus having a 50-mm loading fixture diameter showing the lowest numerical results.

Substrate thickness (flexibility) has a significant effect upon results. In a study of steel panels in the range of 2 to 30 mm thick, breaking strength increased to a thickness of 15 mm using Test Assembly B. A comparison of results with the sandwich method for substrates above 15 mm thickness, however, still showed breaking strength values about one third higher for Test Assembly A. These observations can be explained in terms of differences in stress distribution. Thinner substrates show increased stress intensity at the periphery, which is distinguishable up to 15-mm thickness [*67*].

ISO 4624 specifies that tensile stress shall not be increased at a rate greater than 1 MPa/s, so that failure occurs within 90 s of initial stress application. An investigation of the rate of tensile stress increase in the range 0.15 to 1.2 MPa/s yielded indistinguishable results [*67*].

Sample parameters are important. Coating thickness (and adhesive thickness) is a key factor. The energy stored in a 5-mil (125-μm) coating, by virtue of its internal strain, increases as the coating thickness increases and at a particular thickness can be sufficient to overcome the work of adhesion at the interface (spontaneous peeling). The variation is largest at thicknesses below 125 μm (5 mils), which of course is the area of most practical application. It was also observed that at the lowest coating thickness for the coatings studied, cohesive failure occurred in the uppermost parts of the coating, leaving a very thin film of coating on the test cylinder (stud). With thicker coatings, the fracture propagated deeper into the coating. Through study of the locus of failure, one can also study the effects of environmental conditions (aging, solvents, moisture) and of coating resin cure [*67*].

Clearly, stress distribution changes, as altered by test apparatus and sample parameters, can alter results dramatically. Pull-off strength (breaking strength) is therefore a relative number. Comparisons must be made carefully in concert with an examination of the locus of failure. Practically speaking, while absolute values are only approached, relative values and studies of the locus of failure are sufficient for most purposes.

ASTM D 2197

Used to a lesser extent than the preceding methods is ASTM D 2197, Test Methods for Adhesion of Organic Coatings by Scrape Adhesion.

This test method covers the determination of the adhesion of organic coatings such as paint, varnish, and lacquer when applied to smooth, flat (planar) panel surfaces. The materials under test are applied at uniform thickness to planar panels, usually sheet metal of uniform surface texture. After drying, the adhesion is determined by pushing the panels beneath a rounded stylus or loop loaded in increasing amounts until the coating is removed from the substrate surface.

The method is most useful in providing relative ratings for a series of coated panels exhibiting significant differences in adhesion. The balanced-beam, scrape-adhesion tester (Fig. 10) consists of a balanced beam to which is secured a platform for supporting weights and a rod at an angle of 45° that holds the scraping loop. The rod is set so that the scraping loop contacts test surfaces directly below the weights. The loop is a 1/16-in. (1.6-mm)-diameter rod bent into a "U" shape with an outside radius of 0.128 ± 0.002 in. (3.25 ± 0.05 mm) hardened to Rockwell HRC 56 to 58 and chromium plated and polished.

At least 1/2 in. (1.3 cm) at the end of a test panel is uncoated. The surface of the substrate must be hard enough so that it is undamaged by the scraping loop. The test procedure is as follows. A test panel on the sliding platform is placed so that it may be moved away from the operator and the uncoated portion is toward the main beam support. Weights are placed on the weight support using an initial amount estimated to be appropriate for the particular coating. The beam is lowered until the loop rests on the uncoated portion of the specimen and the full load is applied; then the sliding platform is slowly pushed away from the operator 1 to 2 s/in. for a distance of at least 3 in. (76 mm). If the coating is removed, the testing is continued using successively smaller loads (0.5-kg increments) until the coating is not removed. If the coating is not removed by the initial scrape, the testing is continued, using successively larger loads (0.5-kg increments) until the coating is removed or until the maximum load of 10 kg has been applied. A new area of the test surface is used each time a scrape is made. When the critical load has been approximately located, the test is repeated five times at each of the three loadings: above, below, and at the load determined in the first trial.

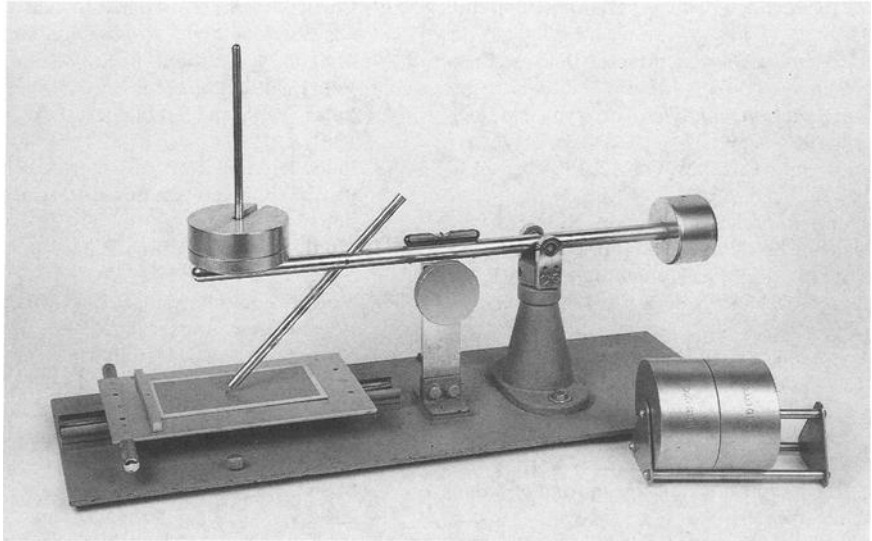

FIG. 10—Balanced-beam scrape adhesion tester.

For each applied load, the number of times the coating was removed or adhered is tabulated. The load where the scrape results change from mainly adhering to mainly removed, ignoring the first 1/2 in. (13 mm) of the scratch if the coating was removed, is the adhesion failure end point.

Other ASTM Standards

Other ASTM standards which pertain to aspects of adhesion measurements of films and coatings include the following:

ASTM B 533	Standard Test Method for Peel Strength of Metal— Electroplated Plastics.
ASTM B 571	Test Methods for Adhesion of Metallic Coatings. (This method includes bend, burnishing, chisel-knife, draw, file, grind-saw, heat-quench impact, peel, push, and scribe-grind tests).
ASTM C 313	Test Method for Adherence of Porcelain Enamel and Ceramic Coatings to Sheet Metal.
ASTM C 988	Test Method for Adherence of Porcelain Enamel Cover Coats Direct-to-Steel. (This test method is a drop weight deformation test).
ASTM D 3281	Standard Test Method for Formability of Attached Organic Coatings with Impact-Wedge Bend Apparatus. (This test method is for factory-applied organic coatings on strip metal. Adhesion loss is determined using cellulose adhesive tape.)
ASTM D 3730	Guide for Testing High-Performance Interior Architectural Wall Coatings. (This guide includes a pull-strength test for adhesion assessment).
ASTM D 4145	Test Method for Coating Flexibility of Prepainted Sheet. (This method includes a tape pull-off test).
ASTM D 4146	Test Method for Formability of Zinc-Rich Primer/Chromate Complex Coating on Steel. (This method is a tape test after dome-shaped deformation).
ASTM F 518	Practice for Determining the Effective Adhesion of Photoresist to Hard-Surface Photomask Blanks and Semiconductor Wafers During Etching.
ASTM F 692	Method for Measuring Adhesion Strength of Solderable Films to Substrates.

Additional tests exist for electrodeposits, and bending, burnishing, and wrapping tests for coatings on wire. Tests for adhesives have also been applied to coatings as well. Use of reverse impact tests, lap and butt joint tests, and tensile shear tests have been reported [*1*].

CONCLUSIONS

Basic adhesion is the summation of multiple phenomena. Ideal adhesion is probably neither obtainable nor measurable experimentally. Practical techniques do, however, allow sufficient assessment of relative adhesion for most purposes, if used with care and knowledge. Workers need to understand both basic adhesion concepts and the factors affecting practical adhesion for systems of their interest if they are to make improvements in real world products.

Abrasion Resistance*

by Mark P. Morse[1]

THE PROBLEM OF RESISTANCE TO ABRASION exists all around us: on floors, walls, furniture, automobiles, farm implements, construction equipment, military gear, appliances, shoe soles, and so on. Because resistance to abrasion is a basic factor in the durability of a coating, its measurement is of practical importance to both producer and consumer.

Abrasion is caused by mechanical actions such as rubbing, scraping, or erosion from wind and water. It can take two general forms: marring or wearing.

DEFINITIONS

Mar abrasion consists of permanent deformations that have not ruptured the surface of a coating. The resistance of a coating to marring is its ability to withstand scuffing actions that tend to disfigure or change the appearance of its surface. Some examples of potential causes of marring of organic coatings are: (a) sliding an object across the surface of furniture; (b) rubbing of a belt buckle, button, zipper, or rough fabric on an automobile finish; (c) sliding a toy across a wall or a refrigerator door, etc.

Wear abrasion is caused by mechanical action that removes material from the surface of a coating. In many cases, the removal is gradual or progressive due to repetitive mechanical action.

RELATIONSHIP TO OTHER PHYSICAL PROPERTIES

Abrasion resistance is not a unique or isolated property of a material but is rather related to other physical characteristics such as hardness, cohesive and tensile strength, elasticity, and toughness. Also, from the standpoint of retaining its protective or decorative function, the thickness of a coating can be an important factor.

Hardness, Elasticity, and Tensile Strength

Abrasion resistance is related to hardness, yet the relationship is not simple. A first thought might be that the harder a coating, the better would be the abrasion resistance; however, this is not always true. Steel is much harder than rubber, for example, but steel "tires" on an automobile, in addition to not giving a smooth ride, would not last long on concrete roads in comparison to the service life of a good rubber tire. The ability of a material, such as a rubber tire, to undergo elastic deformation and recover or "to ride with the blow" is associated with good abrasion resistance.

The energy transferred to an elastic material by an impacting object is largely returned to the object, though redirected, instead of being expended in the destruction (separation and removal of material) of the impacted surface. From a fundamental viewpoint, this is a consequence of the smaller deceleration and hence smaller force generated, since force is equal to the product of mass and acceleration, when the impact is with a material that will deform or "give" with the impacting object. If the deformation caused by the object is not elastic, the material will yield and flow, causing damage. Therefore, soft materials with a low tensile strength are not abrasion resistant.

The fact that elastic materials are often abrasion resistant does not mean that hard materials are not abrasion resistant. Theoretically, however, if one is given two materials of equal tensile strength, the material of lower modulus should have the best abrasion resistance. The deceptive factor here is that a hard material usually has a much higher tensile strength than a soft material. Thus, when a rubber is compared with steel, materials with orders of magnitude difference in tensile strength are being considered. The fact that rubber is abrasion resistant emphasizes that the value of a low modulus of elasticity and adequate tensile strength are factors that play a role in obtaining good abrasion resistance.

In theory, a very hard material that has a hardness and cohesive strength adequate to completely resist any impact force it might encounter would not be dependent on rubber-like elasticity to reduce or dissipate impact stresses. It would be more abrasion resistant than the best elastic but weaker material [*1*].

CORRELATION WITH END-USE PERFORMANCE

From the discussion above, it is apparent that the measurement of abrasion resistance involves measuring a complex combination of interrelated properties among which there is no direct relationship. The task of devising a test methodology that will correlate with end-use performance is, therefore, complex and difficult but not impossible to develop. If the test method subjects the material under test to a composite of destructive forces similar to those met in service, then

*This chapter is an abridged and modified version of the chapter with the same title, written by A. Gene Roberts, found in the previous edition of this manual.

[1]Consultant, 71 S. Shelburne Road, Springfield, PA 19064.

Copyright© 1995 by ASTM International

the test method will correlate—or predict—the service performance of the material in at least a qualitative or relative ranking respect.

When accelerated tests are being considered, even tests that rank materials in the same sequence as actual service tests, a quantitative correspondence with actual service is seldom expected or obtained. Actual end-use tests, while the most reliable in providing an indication of a material's probable long-term durability, suffer from the difficulties of ensuring equivalent usage and measurement, especially when the comparison of different materials is attempted. Because of such difficulties and because service tests are usually very time consuming, a wide variety of test machines have been developed to provide an accelerated indication of the abrasion resistance of coatings and related materials such as vinyl flooring, linoleum, and wall coverings. In a comprehensive review article by Harper [*2*], there is a list of no less than 49 different abrasion-causing machines. An investigation by the International Study Committee for Wear Tests of Flooring Performance [*3*], in which seven commercial, organic flooring materials were systematically tested on 21 abrasion machines of 17 different types, indicated that very few of these machines were capable of providing a reliable comparison of the abrasion resistance of widely different materials that could be correlated with end-use performance. In addition, the different machines did not correlate very well with each other.

On the basis of a round robin conducted in 1956 by ASTM with six different clear floor coatings evaluated by six different abrasion test methods [*4*], only two of the methods were found to correlate with actual end-use performance and to have the reproducibility necessary for acceptance as ASTM standards. These were ASTM Test Method for Abrasion Resistance of Organic Coatings by Falling Abrasive (ASTM D 968) and ASTM Test Method for Abrasion Resistance of Organic Coatings by Air Blast Abrasive (ASTM D 658). The jet abrader, Method 6193 of Federal Test Method Standard No. 141C, which became available after the testing, appears to correlate well with the two cited ASTM methods and with various types of end-use performance. In addition, the jet abrader offers greater speed and precision of measurement [*1*]. Even today, with other tests also available, these tests are still important and widely used. However, more recent comparative testing (see **COMPARISON OF WEAR ABRASION TESTERS**) indicates ASTM D 658 is superior to ASTM D 968 and that ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (ASTM D 4060) is superior to both of these tests as regards precision and sensitivity in differentiating between coatings.

MECHANISM OF ABRASION

The success of the particle impingement types of abrasion testers in correlating with service performance is perhaps not surprising when one considers the abrading mechanism. Whether or not a particular type of abrasion test correlates with end-use performance depends not only on a similarity of abrading mechanisms in both cases, but also on the extent to which that mechanism is maintained during the course of the abrasion test. It is on the latter factor that many methods fail.

Rubbing (friction) and scraping methods obviously wear away the test surface in a different manner than methods in which abrasive particles are contacted with the surface. One aspect of the mechanistic difference lies in the angle of contact with the surface. Abrasive particles striking the surface of a coating at nearly normal incidence tend to compress, scar, and cut into the coating. As a result, minute portions of the coating eventually should be crosscut and displaced. On the other hand, the rubbing and scraping types of abrasion that take place at near grazing incidence would tend to undercut and to shear through very thin layers of the coating in successive, irregular slices that ultimately wear it away. Different devices might incorporate various degrees of these basic processes, depending on the angle and force of particle attack.

Apart from the nature of the above mechanisms, it should be apparent that whatever the mechanism, it is not maintained uniformly in friction methods. Such methods suffer from changes in the abrading conditions as the testing proceeds, either because of heating of the specimen or clogging of the abradant or other.

If an abrasion test using the direct impingement of particles is chosen so the undesirable frictional effects are avoided, there may be doubt about whether the method correlates well with a type of service in which the coating is, for example, walked upon. Yet, the previously mentioned ASTM round robin of abrasion tests carried out with floor coatings clearly established the validity of particle-impingement-type tests for evaluating this type of end-use service life.

Until the mechanism of abrasion is more completely studied and understood, industry must continue to rely to a large extent on experimentation and even intuition when devising abrasion test methods. In addition, properly designed test programs must be employed to determine the extent to which a given method correlates with actual end-use performance [*1*]. A side variety of useful abrasion testing procedures are described in sections that follow.

LOOSE FOR FALLING ABRASIVE METHODS

Falling Abrasive Test

This widely used abrasion test method has both ASTM and federal counterparts. Originally developed at Gardner Laboratory [*5*], the method has been studied and further developed by others [*6*]. ASTM D 968 employs an apparatus, Fig. 1, that is simple and inexpensive compared with other more complicated instruments, and the test results correlate reasonably well with various types of service [*4*]. However, the method is laborious and time consuming since large quantities of abrasive must be handled due to the slow rate of abrasion, particularly when the material under test is abrasion resistant.

Over the years a variety of abrasives have been used in the basic apparatus. These abrasives include sand, emery, and various grades of silicon carbide (Carborundum). Sand, although having the disadvantage of a slow abrasion rate, is readily available and has given reproducible results at low cost. Therefore, it has been the abrasive of choice in the standard methods. Only sand and silicon carbide are used in

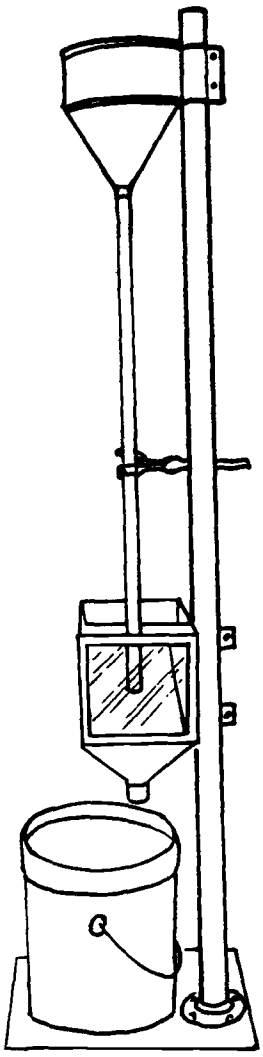

FIG. 1—Falling sand abraser (courtesy of Paul N. Gardner Co.).

ASTM D 968, which specifies that a natural silica sand graded to a particular sieve size and known as Ottawa sand is the standard sand abrasive and a silicon carbide of particular sieve size is the other standard abrasive. Abrasion resistance is expressed in terms of the volume of abrasive required to wear through a unit thickness of the coating with the abrasive falling from a specified height through a guide tube. The substrate is supported at a 45° angle to the vertical.

Pebble Abrasion Wear Test

This test method was originally developed as an adhesion test for floor finishes, but it is more properly classified as an abrasion test. The coatings to be investigated are applied to the walls of a hexagonal iron box; 6 lb (2.72 kg) of flint pebbles are placed in the box, and then the box is rotated so that the pebbles strike the coatings. A rotational speed of 38 rpm applied for 2 h (1 h in each direction) is sufficient to differentiate most floor coatings. The apparatus for this test is not commercially available.

Gloss Reduction Test

Some methods of gloss reduction utilize the impingement of a definite quantity of abrasive coupled with measurement of gloss. A modified version of ASTM D 986 was used by Sward [*5*] to measure the effect of abrasion on paints, varnishes, and lacquers. A large guide tube of 2.5-in. (6.35 cm) diameter was used to make an abraded area large enough for gloss determinations. Ottawa sand of 20 to 30 mesh was used as the abrasive. To distribute the sand uniformly throughout the cross section of the guide tube, a wire spider web was inserted just below the outlet tube in the stream of falling sand.

ABRASIVE BLAST METHODS

Air Blast Abrasive (Bell Laboratory Abrasiometer)

ASTM D 658 employs a particular size of silicon carbide abrasive that passes from a hopper through a guide tube and impinges onto the specimen. The abrasive flow is facilitated with an air blast [*7*]. The abrasion rate is markedly greater than that obtainable with a free-falling abrasive as is used in ASTM D 968. This device, which was originally known as the Bell Laboratory abrasiometer, was adopted for use in ASTM D 658 after the good results obtained in the round robin test described under **CORRELATION WITH END-USE PERFORMANCE.** The test requires rather cumbersome test equipment and the need to replace the abrasive after it has been used five times. In addition, the abrasive must be sieved after each use to remove any large particles of coating that may have chipped off during the test. This testing device is not commercially available; however, details for its construction are available at ASTM Headquarters in Philadelphia.

A view of that part of the abrasive blast device which contains the abrasive guide tube, nozzle, and specimen stage is presented in Fig. 2. The controlled air that enters the nozzle has passed through an array of regulating devices: filters, pressure reduction valve, mercury pressure leg, air equalizing chamber, flow meter, and manometer. When it is adjusted to a standard air pressure, air flow, and abrasive flow, the device is capable of good precision.

The specimen is mounted at a 45° angle to the nozzle, which is lowered to touch the test surface. Then the air flow is adjusted to the specified pressure, and the stream of abrasive is released and allowed to flow until the coating is worn through to the substrate. The end point is considered to be reached when a worn spot about 2 mm in diameter appears in the center of the wear pattern. The abrasion resistance (abrasion coefficient) is calculated as the weight in grams of abrasive required per mil of coating.

A device similar to the Bell Laboratory abrasiometer was designed by Koch at Hercules [*8*]. The main difference between the two devices is in nozzle design.

Roberts Jet Abrader

With this abrader, which is pictured in Fig. 3 and available from Kamaras Instruments, Garrett Park, MD, abrasion resistance is evaluated in terms of the time required for a closely controlled jet of fine abrasive to penetrate through the

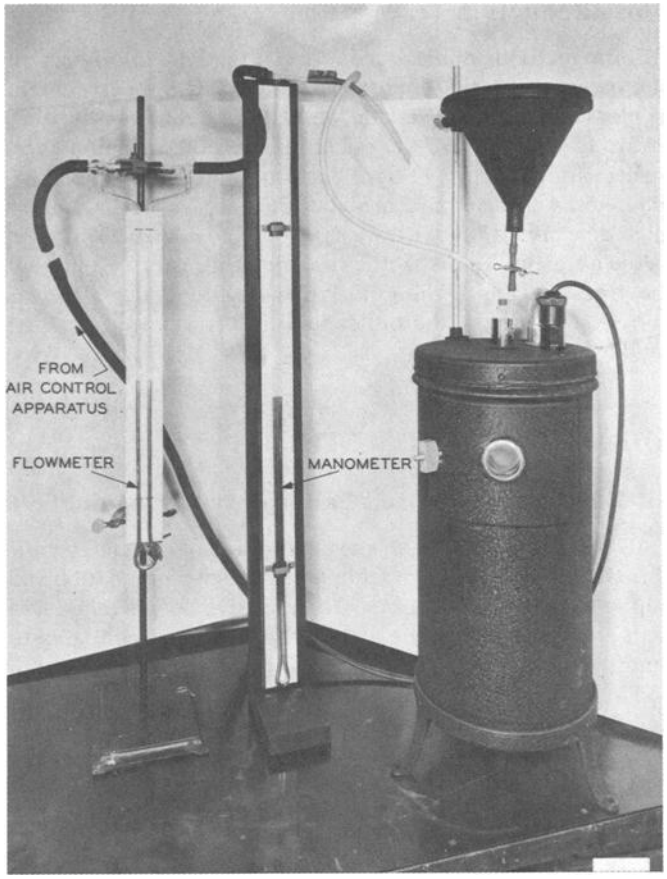

FIG. 2–Abrasion test apparatus (ASTM D 658).

FIG. 3–Roberts Jet abrader (courtesy of Kameras Instruments).

coating to the substrate. The first disclosure of bare substrate is taken as the end point, and it is visually signalled by an abrupt change in gloss or color. The high speed of the abrasive jet particles used in this test results in a rapid abrasion rate that permits most coatings to be tested in a matter of seconds.

The jet abrader method avoids the adverse heating, gumming, and abradant-clogging effects associated with the rubbing and friction methods. The small scale of operation permits the economical use of continuously fresh abrasive, and it allows a large number of tests to be made on a single 15.2 by 7.6-cm specimen. This method makes practical the use of a reference panel for instrument calibration and affords the opportunity for interlaboratory standardization of instruments and results.

A prototype jet abrader was developed at the National Bureau of Standards (NIST) [*9,10*]. The abrading conditions are set from outside the test chamber, and the abrasive flow is controlled by adjusting the voltage to the vibrator on which the abrasive storage chamber is mounted. The amplitude of vibration determines the amount of abrasive that sifts into the gas (carbon dioxide) stream.

Abrasion resistance is usually expressed in terms of time per unit thickness (seconds/mil), but coatings of the same thickness may be compared on the basis of total abrasion time. Abrasion time is proportional to coatings thickness up to about 6 mils. At greater thickness, the abrasion rate begins to decrease due to hindrance of abrasive particles in the abraded pit. Very thick coatings on the order of 100 mils may be evaluated as small specimens on which weight loss for a given abrading time is determined. This test procedure is detailed in Method 6193 of Federal Test Method Standard No. 141C. Any panel of uniform coating thickness can serve as a reference panel if it has a convenient abrasion time. A suitable reference panel can be made by bonding plastic film of uniform thickness to a rigid substrate by means of a very thin coat of adhesive.

Gravel Projecting Machine

This machine, which is commonly termed a gravelometer, is a device designed to evaluate the resistance of automotive and railway finishes to abrasion by flying gravel and road ballast. ASTM Test Method for Chip Resistance of Coatings (ASTM D 3170) has a description of such a device and provides a procedure for its use. Figure 4 illustrates the interior components of a device that meets specification given in ASTM D 3170. A test chamber is provided in which a coated panel is supported vertically and blasted with a stream of particular gravel. One pint of this gravel is introduced into an air stream having a pressure of 70 ± 2 psi (4.92 ± 0.14 kg/cm^2) over a 10-s period. Tests are usually conducted in a cold room to simulate winter-like driving conditions. At the completion of the test, the coated panel is visually rated for degree of chipping by using a photographic reference standard provided with D 3170. SAE Method J400 describes the test procedure used for evaluating the chip resistance of automotive coatings.

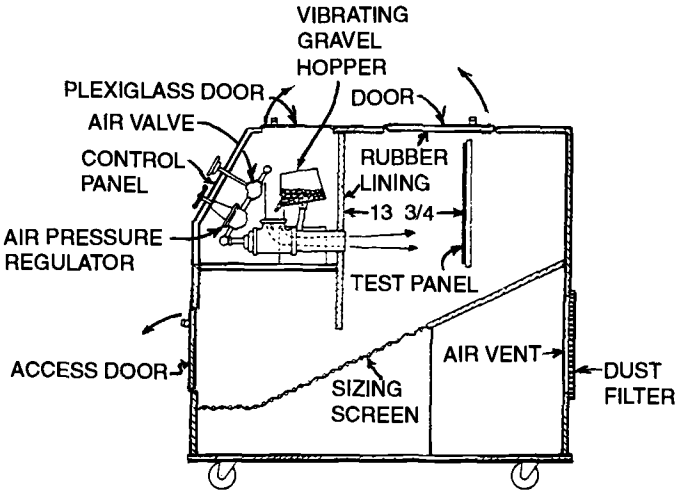

FIG. 4–Interior of a gravelometer (courtesy of the Q-Panel Company).

METHODS USING ROTATING DISKS

Bell Laboratory Rotating Disk Abrasion Test

In this method, a circular panel coated with the finish is rotated while submerged [*11*] in a bed of sand. The apparatus is illustrated in Fig. 5. A turntable to which the 4-in. (10.2 cm)-diameter specimen is mounted is contained within the hopper. Ottawa sand of 20 to 30 mesh is added to the hopper until the specimen is covered to a depth of 5 in. (12.7 cm). The disk is then rotated at speeds of 750 to 1000 rpm for several thousand revolutions as specified. During the test, the sand is circulated through a device that cleans and cools it. The amount of film material lost during a test is a measure of abrasion resistance. It is expressed as a "wear factor" that is the product of the radius of film remaining on the disk and the number of revolutions in thousands.

FIG. 5–Bell Laboratory rotating disk abrasion tester. Specimen rotates while buried in sand. (Courtesy of Bell Telephone Laboratories.)

Wolf Abrasion Method

This early method [*12*] was the forerunner of other more elaborate instruments such as the Camp and the Taber devices. A leather disk on the end of a rod is moved in a circular manner on the film being tested. The abrasion factor is given as the loss in grams per 100 cm^2 of surface.

Camp Abrasion Tester

For this test, the coating is applied to a 10.2 by 10.2-cm metal panel, and the panel is fastened to a horizontal turntable that rotates at a speed of 30 rpm beneath a weighted, circular, rubber, ink eraser (Eberhard-Faber No. 1071) that acts as the abrader [*13*]. The eraser abrader is attached to a side arm on a lever at an offset angle that causes a 0.64-cm-wide path to be worn in the film. A counter records the number of revolutions required to wear through the film. The machine is made automatic by placing a copper trailer behind the abrading disk. This trailer activates a circuit-breaking relay when it contacts the metal panel exposed by wearing away of the film. Tests can be checked within 500 revolutions in a total of 5000 to 8000 revolutions. Most coatings fail within the range of 2000 to 46 000 revolutions. The eraser abrading disks are changed after each 5000 revolutions.

FDC Wear Test

This test was devised to determine the resistance of cellulose nitrate furniture lacquers to abrasion [*14*]. It measures the loss of weight when the lacquer film is abraded by nylon fabric. The machine used, which is shown in Fig. 6, is the modified carpet abrasion machine of the Wool Industries Research Association of England. A 10.2 by 10.2-cm lacquered glass panel is attached to the plate carrier, with lacquered side down. During the test, it rotates at 37 rpm while in contact with the nylon-covered abrading head, which is also rotating at the same speed and in the same direction. However, the centers of the plate and the head are offset, which results in uniform abrasion of the film. After a specified number of revolutions and conditioning, the weight loss is determined and is taken as the abrasion resistance of the specimen.

Schiefer Abrasion Testing Machine

(This machine is available from Frazier Precision Instruments Co., Inc., 925 Sweeney Dr., Hagerstown, MD 21940.) The machine was designed for measuring wear resistance of textiles such as rugs and fabrics [*15–18*], but it offers a potentially useful means for evaluating the wear abrasion of organic coatings. It has two unique features: (a) a uniform abrasion pattern and (b) interchangeable steel and Carboloy abradent disks with crosscut and rod patterns that reduce heating and clogging (Fig. 7).

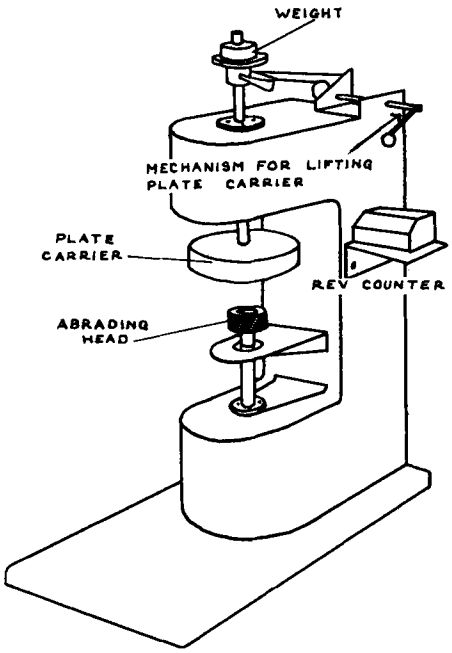

FIG. 6–FDC wear tester. Nylon fabric on rotating head is used to abrade furniture lacquer rotating on offset axis (courtesy of Furniture Development Council, England).

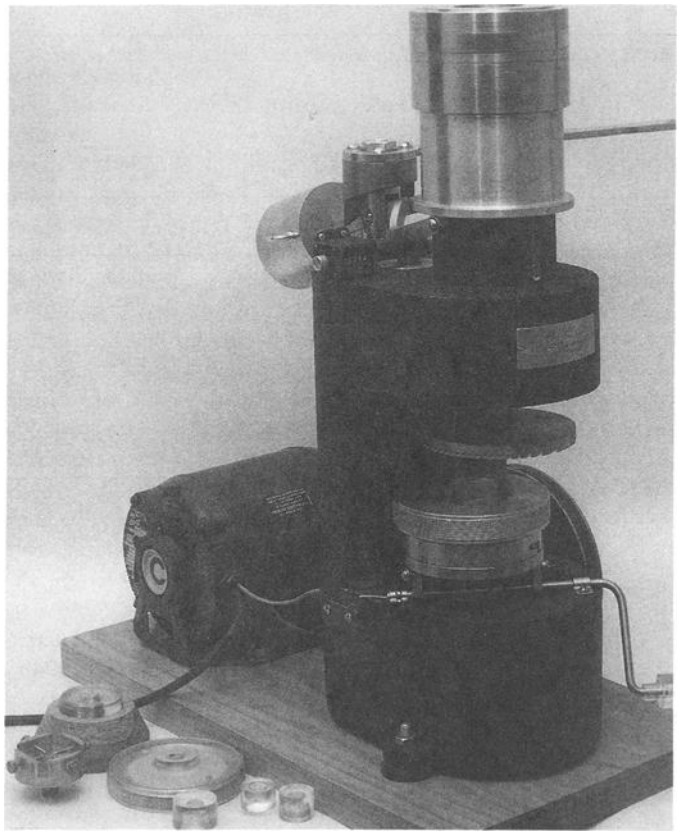

FIG. 7–Schiefer abrasion testing machine (courtesy of Frazier Precision Instrument Company).

To conduct a wear abrasion test, the specimen is mounted on a motor-driven rotating plate where it is abraded uniformly in all directions by the motion of the offset rotating abradent mounted directly above it. Both specimen and abradent rotate in the same direction with approximately the same angular velocity, 250 rpm, each about its own axis. The axes are spaced 1 in. (2.54 cm) apart and are parallel. The abradent is loaded with a standard weight.

METHODS USING ROTATING WHEELS

Taber Abraser

This apparatus, Fig. 8, is widely used for evaluating the wear abrasion resistance of organic coatings. A procedure for its use is given in ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (ASTM D 4060), in Method 6192 of Federal Test Method Standard No. 141C, and in ISO/DIN Methods 3494 and 4584. ASTM D 4060 utilizes a specimen in the form of a 4-in. (10.2-cm)-diameter disk or a 4-in. (10.2-cm) square mounted on a turntable that is rotated at a fixed speed under a weighted abrading wheel. "Calibrase" resilient abrading wheels are designated CS-10 and CS-17 with the latter being the most abrasive. Because of the slow hardening of the rubber bonding materials in this type wheel, a wheel should not be used if it has aged longer than one year. Before each test and after every 500 cycles (revolutions), the abrading wheel is resurfaced with an abrasive disk that is placed on the turntable. A vacuum pickup is used to remove any loose particles generated during actual tests. Wear abrasion resistance is expressed in terms of (a) Wear Index, which is the weight loss per specified number of revolutions (usually 1000) under a specified load (500 or 1000 g), and/or (b) wear cycles per mil, which is the number of cycles required to wear through a 1-mil thickness of coating and is reported as the number of revolutions per mil. In an ASTM round robin, Taber abraser tests with a series of organic coatings produced abrasion resistance values that exhibited a within-laboratory coefficient of variation of 10% and an interlaboratory coeffi-

FIG. 8–Taber Abraser (courtesy of Taber Industries).

cient of variation of 30%. Another study of the reliability of test results was conducted by Hill and Nick in 1966 [*19*].

TESTS BASED ON RECTILINEAR MOTION

Straight-Line Reciprocating Machines

These machines, as shown in Fig. 9, pull a sled or boat back and forth over the surface of a coated panel. The sled surface can be a brush, a sponge, rubber, or sandpaper. A sled travel of at least 10 in. (25.4 cm) is provided by the machines, and they can provide reciprocating cycles ranging from 35 to 60 per minute.

Both dry and wet surface tests may be performed with these machines. For dry surface tests, wear abrasion resistance is reported as: (a) number of cycles to reach a certain visual end point, (b) degree of abrasion observed after a specified number of cycles, and (c) number of cycles required to abrade through the coating to the substrate.

Procedures for conducting wet adhesion (scrub resistance) tests on interior paints are described in ASTM Test Method for Wet Abrasion Resistance of Interior Paints (ASTM D 4213) and in Method 6141 of Federal Test Method Standard 141C. In these test procedures, coating films are applied to a plastic substrate and allowed to dry. A sponge surface is mounted on the sled. Both the sled and the coating surface are wet with a soap solution of specified composition. Wet abrasion resistance is reported as: (a) computed rate of erosion of the wet coating film and (b) number of cycles required to wear through the coating film to the substrate or to produce breaks in the film.

RCA Tape Tester

This device is available from Norman Tool and Stamping Co., 15415 Old State Rd., Evansville, IN 47711. It is being actively used for evaluating the abrasion resistance of appliance finishes and of coatings on television set controls. It is reported to have greater sensitivity than the Taber Abraser in determining differences in the abrasion resistance of coatings. The machine abrades a 2 by 2-in. (5.1 by 5.1 cm) coated panel surface by passing computer or polyester tape over the surface. A fresh tape surface is presented for each cycle of abrasion. Weights ranging from 55 to 275 g are applied to the tape depending on the nature of the coating under test. Abrasion resistance is reported either as the number of cycles required to produce the onset of visible scuffing or as the number of cycles required to wear through to the substrate.

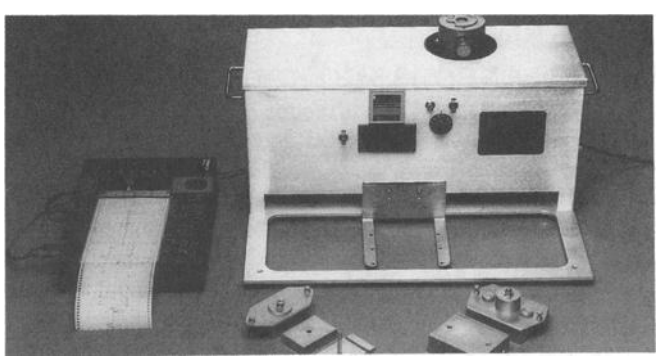

FIG. 9—Reciprocating abrasion tester. WA-2168 Model D12VFI machine with cut-out base, recorder, and several test accessories in foreground. (Courtesy of Paul N. Gardner Co.)

COMPARISON OF WEAR ABRASION TESTERS

ASTM Subcommittee D-01.23 conducted a round robin to determine the comparative precision, sensitivity, and correlation of four wear abrasion testing procedures. The procedures were (a) air blast silicon carbide (ASTM D 658), (b) falling sand (ASTM D 968), (c) falling silicon carbide (ASTM D 968), and (d) Taber Abraser (ASTM D 4060). The wear abrasion resistance of four coatings with significantly different apparent resistances to abrasion were tested with each device. The results obtained from these tests are recorded in ASTM Report RR D01-1037, which is available at ASTM Headquarters.

From the results, it was concluded that the air blast silicon carbide test and the cycles per mil Taber abraser test had better sensitivity in differentiating coating abrasion resistances than the other test procedures. The falling sand test, air blast silicon carbide test, and Taber abraser cycles per mil test ranked the coatings in the same order as the expected performance. The falling silicon carbide test reversed the ranking of two of the coatings. The precision exhibited by the four test procedures are as given in Table 1.

TEST FOR MAR ABRASION RESISTANCE

(See also above-described Gloss Reduction test.)

Balanced Beam Tester

A useful test for determination of mar resistance involves the use of a balanced beam scrape tester. ASTM Committee D-01.23 has developed a proposed test procedure using such a tester, which consists of a balanced beam equipped with a loop stylus attached to the end of a rod set at an angle of 45°. The test is carried out by placing a coated test panel on a movable platform and a weight on the beam. The stylus is lowered gently onto the coated surface, and then the platform is pushed against the stylus at a rate of ¼-in. (6 mm) per second for a distance of at least 3 in. (75 mm). At the end of each stroke the stylus is raised off the coated panel and the

	Coefficients of Variation	
	Within Laboratory	Between Laboratories
Taber Abraser (ASTM D 4060)	4%	16%
Air Blast Silicon Carbide (ASTM D 658)	7%	10%
Falling Sand (ASTM D 968)	9%	35%
Falling Silicon Carbide (ASTM D 968)	11%	45%

panel is moved slightly to the side to provide a new test surface. The coating is examined for marring. If none is visually observed in the initial scrape, successively greater weights are added to the beam until marring is apparent. If marring is produced in the initial scrape, testing is continued using successively lighter weights until the coating is not marred. The weight required to just produce visible marring is taken as the mar resistance value. Details about the balanced beam tester and its operation can be found in ASTM D 2197, Test Methods for Adhesion of Organic Coatings by Scrape Adhesion, ASTM D 2248, Practice for Detergent Resistance of Organic Finishes, and MIL-P-7788A.

Princeton Scratch Tester

This apparatus is similar to the balanced beam tester, but instead of having a moveable specimen table, the beam assembly itself moves on a V-shaped track with the coated panel remaining immobile. The stylus is held at a 90° angle.

Impinging Abrasive Method

An impinging abrasive method is described in ASTM Test Method for Mar Resistance of Plastics (ASTM D 673) and in Method 1093 of Federal Test Method Standard No. 406. Although this test was designed for determining the mar resistance of plastics, it has a potential for determining this property of organic coatings.

The test consists of allowing a stream of silicon carbide to fall on the specimen and then determining the degree of marring by gloss measurements. The apparatus consists of a hopper that dispenses the abrasive through small openings as it rotates at 7 rpm. Abrasive flow is about 225 g per minute.

Taber Abraser Mar Test

The Taber Abraser can be used to evaluate the mar resistance of organic coatings. A mild abrading is produced by using wheels covered with paper. Mar resistance is reported as the number of cycles of rotation required to just produce a barely visible scuffing or loss of gloss.

Coin Mar Test

This test consists of dragging the edge of a coin across the surface of a coated panel and visually determining the degree of marring produced. The procedure can be used as a "pass/fail" test or for comparing the mar resistance of coatings on a relative basis. Results will vary from laboratory to laboratory due to the particular coin used and the pressure used for contact.

Fingernail Test

In this test, the back of a fingernail is dragged across the surface of a coating and the degree of marring is visually observed. The procedure can be used as a "pass/fail" test or for comparing the mar resistance of coatings on a relative basis.

RAIN OR WATER EROSION

Rain erosion resistance of aircraft coatings has been studied in two types of testing machines [*20*]—whirling arm and jet. In the whirling arm tester, specimens having an airfoil contour are fastened to the leading edges of the two arms of a propeller-like blade that is rotated at angular velocities equivalent to flying speeds of up to 700 mph. Simultaneously drops of water fall on the whirling arms. Both the simulated air speed and the quantity of "rainfall" can be varied and closely controlled. In the jet-type tester, a high-pressure jet of water impinges on the specimen. A rotating slotted disk in the path of the water jet breaks the stream of water into individual drops to simulate rainfall.

In both of the above methods, having the water in the form of individual drops is a basic principle of the test. This is because the erosion that occurs on the leading edges of the airfoils on high-speed aircraft flying through rain is often the result of cavitation produced by the high-energy impacts of a multitude of individual droplets. At very high velocities, the water droplets, in effect, behave as tiny solid projectiles.

TRAFFIC PAINT TESTS

The Dorry tester uses a crushed quartz abrasive that is fed onto a grinding plate against which the coating, face down on its paper base and weighted with 100 g of sand, is abraded.

The Hickson tester is a heavy duty, permanently mounted machine in which a motor-driven solid rubber tire is rotated against a braked rotating concrete disk on which the test paint has been applied. The test correlates quite well with the service performance of traffic paints.

The New Jersey Zinc Company (presently Zinc Corporation of America) tester is a portable machine in which a pair of rubber-tired wheels revolve in a layer of sand on the test platform.

Another tester, the abradometer, is a large machine that utilizes a motor-driven wheel set at a slight shear angle to a large wheel on the rim of which up to 46 specimens are mounted. A brake load is applied during the test.

In the Payne abrasion machine, five specimens at a time oscillate through a 25-mm distance while being abraded with an abrasive wheel.

MISCELLANEOUS METHODS

Brief mention is made to several less-well known tests that may be of interest. In The Sproul-Evans apparatus [*21*] the specimen is rotated in a cylinder containing silicon carbide powder. A procedure by Wellinger [*22*] involves using a rod coated with the test paint and rotated in a container of sand. A sensitive method for measuring the tread wear of automobile tires involving the use of a nonhazardous radioisotope of iodine was developed by Outbridge [*23*]. Conceivably, this technique could be used to evaluate the abrasion resistance of coatings. Marks and Conrad [*24*] developed an abrasion comparator apparatus that utilizes high-velocity emery particles

FIG. 10—PEI abrasion tester. Specimen in chamber on gyrating table is abraded by glass or stainless steel sphere in a slurry of abrasive particles. (Courtesy of National Bureau of Standards.)

propelled by high-pressure air to evaluate the resistance of plastics—particularly aircraft glazing—to abrasive particles. Haze due to abrasion is measured with aid of a light integrating sphere.

Although the PEI abrasion tester was designed and developed by the Porcelain Enamel Institute to measure the abrasion resistance of porcelain enamels, this tester has also proven to be useful in determining the wet abrasion resistance of organic coatings. It is specified to be used in ASTM C 448, Test Methods for Abrasion Resistance of Porcelain Enamels. The tester, which is pictured in Fig. 10, has a gyrating table with positions for nine specimens. Abrasive-retaining rings and lids are clamped over the specimen to form individual test chambers. Each chamber is charged with glass or stainless steel spheres, and a slurry of abrasive particles is added through a filling aperture located in the lid. The table gyrates at 300 cycles per minute to cause abrasion of the specimens. The amount of abrasion is evaluated by measuring the loss of gloss or loss of weight in the specimens after a specified time period.

The Peters abrasion block is based on a block that has a weight of 2 kg and a size and contour suited to hand operation. Three 50 by 80-mm abrasive surfaces are provided. Each has a rubber base over which aluminum oxide abrasive paper is stretched. The block is drawn back and forth from edge to edge across the test surface while water is applied. This is continued until the coating begins to show wear through to the substrate. The number of back and forth cycles to reach this end point is taken as a measure of abrasion resistance.

Dynamic Mechanical and Tensile Properties

by Loren W. Hill[1]

DYNAMIC MECHANICAL AND TENSILE PROPERTIES are determined in all branches of materials science. There is a large body of published structure/property information that can be integrated with coatings research and development. By using structure/property information, coatings chemists can design and optimize chemical structures of the binder components of coatings. Purposeful and enlightened formulation with well-designed components makes it possible to obtain desirable coatings performance in many cases.

Determination of dynamic mechanical and tensile properties requires the use of free films. This requirement is a serious limitation because many, if not most, of the performance properties of coatings are influenced by coating-substrate interactions. Therefore, tests of coatings intact on their end-use substrates must be thoughtfully coupled with free film determinations. The practical utility of basic methods described in this section is greatly enhanced when results are interpreted in relation to results of adhesion, abrasion, hardness, flexibility, toughness, and internal stress tests as described elsewhere in the manual.

Dynamic mechanical analysis (DMA) and stress-strain analysis (SSA) of tensile properties are complementary methods in several ways. DMA involves very small strains, whereas SSA involves the maximum strain that the sample can withstand. Since the small strains used in DMA usually do not exceed the tensile strength or yield strength of the sample, the method is nondestructive. This feature facilitates property determination over a wide temperature range on a single sample, that is, DMA is often used as a temperature-scanning method. In contrast, SSA data are usually obtained at a single temperature, preferably on an instrument located in a controlled temperature and humidity room. Since the sample is broken in each test, it is very arduous to carry out SSA over a wide temperature range, and SSA is not amenable to temperature scanning.

DEFINITIONS

Tensile Versus Shear Tests

Two types of deformation of a block-shaped sample are depicted in Fig. 1. These deformations are used frequently in property determinations because they can be carried out reproducibly and treated by simple mathematics. In a tension test (Fig. 1*A*), the sample is pulled apart with straight line application of force, called "uniaxial extension." In a shear test (Fig. 1*B*), one face of the cube is held stationary and the sample is pushed sideways by application of force at the opposite face. Note that different symbols (ϵ epsilon or γ gamma) are used for strain in these two tests. A single symbol is used for stress (σ sigma), but subscripts indicate the type of test. In Fig. 1, F is force and A, B, and C are initial sample dimensions. The product $A \times B$ is the initial cross-sectional area.

It is evident in Fig. 1 that strain is defined quite differently in tension and shear tests. In a tension test, strain is the fractional increase in sample length. In a shear test, strain is the distance moved by the movable face divided by sample thickness, i.e., the distance between the stationary and movable faces. In both tests, stress is force divided by cross-sectional area, and modulus is stress divided by strain. Since strain is unitless, stress and modulus have the same units (force/area). It is evident in Fig. 1*A* that cross-sectional area will decrease as ΔC increases. If the initial cross-sectional area is used to calculate σ_t, the resulting E is called "engineering" modulus. If the change in cross-sectional area is incorporated in the calculation, the resulting E is called "true" modulus.

The relationship between tensile modulus and shear modulus is

$$E = 2(1 + \mu)G \tag{1}$$

where μ is Poisson's ratio [*1,2*]. For materials that do not undergo change in volume with strain, $\mu = 0.5$, and Eq 1 becomes $E = 3G$. Experimentally, μ is very close to 0.5 for rubbery materials and slightly less than 0.5 for many thermoplastic polymers [*1,2*].

Definitions of Dynamic Properties

In dynamic testing, an oscillating strain is applied, and the resulting oscillating stress is measured, or conversely an oscillating stress is applied, and the resulting oscillating strain is measured. Definitions and mathematical treatments do not depend on which of these modes of operation is used. Relationships between strain, stress, and time are sketched in Fig. 2 for tensile DMA with application of strain and measurement of stress. The maximum applied strain is ϵ_0. The maximum resulting stress is $\sigma_{t,0}$. Oscillation is depicted as a sine wave, but whether or not the driver of the instrument in use actually delivers a sine wave oscillation may depend on the particular instrument. The sample is held under sufficient

FIG. 1–Deformations of test samples: *A.* tensile, *B.* shear. The two types of deformation have different definitions and different symbols for strain, stress, and modulus.

tension so that it remains taut (not slack) even when the oscillating strain is at a minimum.

The sine waves for strain and stress have the same frequency, but for viscoelastic samples the waves are out of phase by an amount, δ, called the phase lag. Theoretically and experimentally, δ is zero for an ideal (Hookean) elastic solid. If an ideal (Newtonian) liquid could be tested in this way, δ would be 90°. For viscoelastic materials, δ lies between 0 and 90°, and the value of δ is a rather direct indication of viscoelastic character [*1–4*].

Definitions of dynamic properties depend on the concept of resolving the stress wave of Fig. 2 into two waves, one that is in phase with strain and one that is 90° out of phase with strain. The in-phase resolved plot represents elastic response, and the 90° out-of-phase resolved plot represents viscous response. In terms of modulus, the separated responses result in the following definitions

$$\text{Tensile Storage Modulus} = E' = \frac{\sigma_{t,0} \cos\delta}{\epsilon_0} \tag{2}$$

$$\text{Tensile Loss Modulus} = E'' = \frac{\sigma_{t,0} \sin\delta}{\epsilon_0} \tag{3}$$

$$\text{Loss Tangent} = \frac{E''}{E'} = \tan\delta \tag{4}$$

The term "storage" is associated with the elastic part of the response E' because mechanical energy input to elastic materials is "stored" in the sense of being completely recoverable. The term "loss" is associated with the viscous part of the response E'' because mechanical energy input to ideal liquids is totally lost through viscous heating. The ratio E''/E' is viscous response expressed relative to elastic response. This ratio reduces to $\sin\delta/\cos\delta$, which is $\tan\delta$. Thus, the name "loss tangent" is appropriate.

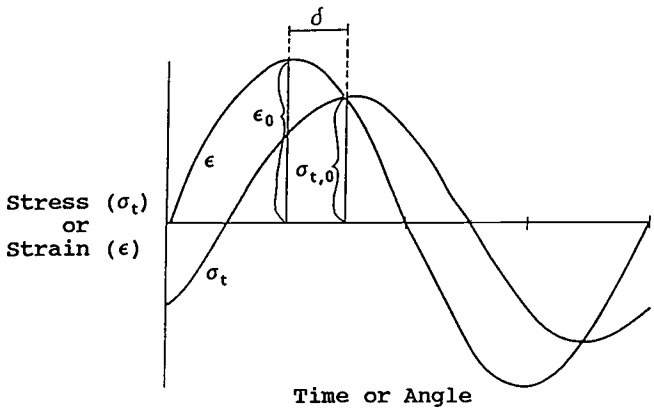

FIG. 2—Applied oscillating strain (ϵ) and resulting oscillating stress (σ_t) in a dynamic mechanical analysis experiment with tensile deformation. The phase lag (δ) and maximum values of strain (ϵ_0) and stress ($\sigma_{t,0}$) are indicated.

A check of limiting values of δ is consistent with assignment of elastic and viscous responses in Eqs 2 and 3. When $\delta = 0°$, $\cos\delta = 1.0$ and $\sin\delta = 0$. By Eq 3, E'' is zero and all of the response is elastic, i.e., E' from Eq 2. When $\delta = 90°$, $\cos\delta = 0$ and $\sin\delta = 1.0$. Now E' is zero by Eq 2 and all of the response is viscous, i.e., E' from Eq 3.

DMA relationships in Eqs 2 and 3 relate directly to characterization of samples that are solid or semi-solid. Other objectives of DMA include following viscosity and elasticity changes as the cure of thermoset coatings takes place and determining the melt-flow properties of powder coatings before the onset of cross-linking. When viscous response is the main interest, DMA is often carried out in shear.

The treatment for shear DMA is identical, but with selection of appropriate shear symbols from Fig. 1, the definitions are

$$\text{Shear Storage Modulus} = G' = \frac{\sigma_{s,0}\cos\delta}{\gamma_0} \tag{5}$$

$$\text{Shear Loss Modulus} = G'' = \frac{\sigma_{s,0}\sin\delta}{\gamma_0} \tag{6}$$

$$\text{Loss Tangent} = \frac{G''}{G'} = \tan\delta \tag{7}$$

Once the experimenters have values of $\sigma_{s,0}$, γ_0, and δ in hand, it is their choice whether to express results in terms of modulus values, Eqs 5 and 6, or in terms of "dynamic viscosity." For dynamic viscosity, the frequency of oscillation, ω in radians per second, is required, but this frequency is usually known. The frequency is required because viscosity is (shear stress)/(rate of shear strain). In a dynamic shear test, rate of shear strain is the product $\omega \times \gamma$. Definitions of dynamic viscosity are

$$\text{Dynamic Loss Viscosity} = \eta' = \frac{G''}{\omega} = \frac{\sigma_{s,0}\sin\delta}{\omega\gamma_0} \tag{8}$$

$$\text{Dynamic Storage Viscosity} = \eta'' = \frac{G'}{\omega} = \frac{\sigma_{s,0}\cos\delta}{\omega\gamma_0} \tag{9}$$

$$\text{Loss Tangent} = \frac{\eta'}{\eta''} = \tan\delta \tag{10}$$

In the Newtonian liquid limit ($\delta = 90°$), η'' is zero by Eq 9, and all of the response is viscous, η' from Eq 8. Furthermore in this limit, G' is zero by either Eq 9 or Eq 5, and the viscous response could alternatively be expressed in terms of G'' from Eq 6. Thus, in dynamic shear tests, modulus and viscosity determinations are one and the same experiment. Usually experimenters will choose Eqs 5 and 6 when the sample has a lot of elastic character and only a little viscous character, whereas the logical choice for mainly viscous materials having only a little elastic character will be Eqs 8 and 9. In principle, it would be valid to express tensile DMA results in terms of dynamic viscosities as well. This is not done very often, probably because viscosity is strongly associated with shearing experiments, not with tensile experiments. The close association of viscosity with shear is the basis for omitting the word "shear" at the left in Eqs 8 and 9.

The relationships between modulus values defined in Fig. 1 and the dynamic modulus values are [*1–4*]

$$E^2 = E'^2 + E''^2 \tag{11}$$

$$G^2 = G'^2 + G''^2 \tag{12}$$

Use of complex numbers and quantities such as $i = \sqrt{-1}$ has been avoided here. If readers would like definitions of such quantities as the "complex tensile storage modulus," E^*, they should consult Refs *1–4*. Complex notation may be convenient for mathematical derivations, but complex modulus values, with their imaginary parts, add little or nothing to the interpretation of structure/property relationships.

Definitions of Tensile Properties

The term "tensile properties" logically refers to all properties that can be determined in tests that involve tensile deformation as depicted in Fig. 1*A*. Common tests that involve tensile deformation include stress-strain tests, creep tests, and stress relaxation tests. Stress-strain tests are used much more frequently than the others. Therefore, the terms "tensile properties" and "stress-stain properties" are often used interchangeably. Creep and stress-relaxation tests are sometimes referred to as "transient tests" because responses, either elongation or stress, change with time and are determined as a function of time [*5*].

Terminology, definitions, and symbols for stress-strain tests have been taken from an earlier edition of the *Paint Testing Manual* [*6*] and from several ASTM standards:

D 2370	Test Method for Tensile Properties of Organic Coatings
D 638M	Test Method for Tensile Properties of Plastics (Metric)
D 882	Test Method for Tensile Properties of Thin Plastic Sheeting
D 412	Test Methods for Vulcanized Rubber and Thermoplastic Rubbers and Thermoplastic Elastomers—Tension
D 883	Terminology Relating to Plastics

In a stress-strain test, the sample is elongated at constant rate. The force, also called "load," required to maintain constant rate of elongation is determined. Force is converted to tensile stress (σ_t) by division by the initial cross-sectional area ($A \times B$ in Fig. 1*A*). Results are presented as a plot of stress (σ_t)

on the vertical axis versus strain (either ϵ or $100 \times \epsilon = \%$ elongation) on the horizontal axis. A hypothetical example is shown in Fig. 3 [5,6]. The tensile modulus (E) is the slope of the initial, linear portion of the plot (see Fig. 3). If the initial part of the plot is not linear, several calculations for estimating E have been suggested in ASTM D 638M. Use of the slope for E amplifies the simple definition of tensile modulus given in Fig. 1A. Other terms used for tensile modulus include "elastic modulus," "Young's modulus," and "stiffness."

The first point on the plot of Fig. 3 where the slope is zero is called the "yield point." Strain at the yield point is called "elongation at yield" (ϵ_Y). Stress at the yield point is called "yield strength" (σ_Y). Elongation is continued until the sample breaks. Strain at the break point is called "elongation at break" (ϵ_B). Stress at the break point is called "tensile strength" (σ_B) as shown in Fig. 3. However, in some cases (not shown) the stress is higher at the yield point than it is at the break point. In such cases, ASTM standards specify that the "tensile strength" be indicated as the higher value of stress and be designated as "tensile strength at yield." Practice is not uniform with regard to this latter "tensile strength" terminology.

Results of transient tests have not frequently been published for coatings. Such tests clarify viscoelastic character quite directly. Possibly unexpected field failures of coatings could be avoided in some cases if more attention were given to viscoelasticity. Only the most simple form of retardation and relaxation concepts are treated here.

In a tensile creep experiment, the sample is subjected to constant stress, σ_t, and elongation is determined as a function of time, $\epsilon(t)$. Analysis of dependence of elongation on time yields "retardation time," τ (tau). The simplest mechanical model that permits definition of τ is the Maxwell model as shown in Fig. 4. This model consists of a series connection of an ideal Hookean spring of modulus, E, and a dashpot that contains an ideal Newtonian liquid of viscosity, η. As indicated in Fig. 4, τ is the viscosity of the liquid in the dashpot

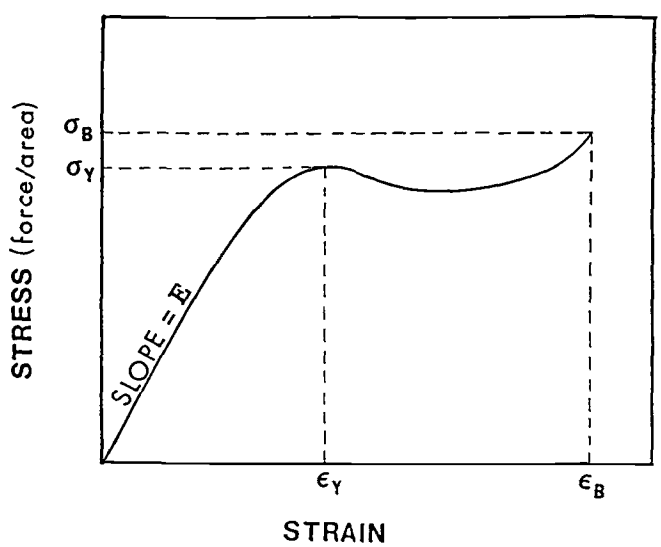

FIG. 3–A hypothetical stress-strain curve for a ductile film. Tensile properties are defined: tensile modulus (E), elongation at yield (ϵ_Y), elongation at break (ϵ_B), yield stress (σ_Y), and tensile strength (σ_B).

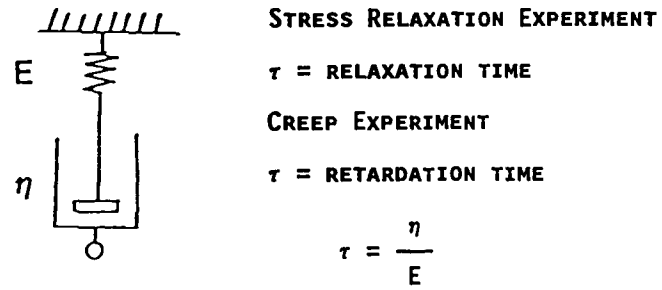

FIG. 4–A mechanical model consisting of a spring and a dashpot permits definition of relaxation time and retardation time.

divided by the modulus of the spring. Tau has units of time. Results of the creep experiment for the Maxwell model can be expressed as

$$\epsilon(t) = \epsilon(0) + \frac{\epsilon(0)}{\tau} t \tag{13}$$

When stress is first applied, the spring extends instantaneously by an amount $\epsilon(0)$. Then retarded further elongation takes place due to flow in the dashpot. It is evident in Eq 13 that the retarded elongation is linear with time. The value of τ can be obtained from the product (reciprocal of the slope) $\times$ (intercept) [4,5].

In a tensile stress relaxation experiment, the sample is elongated instantaneously by an amount ϵ, and thereafter ϵ is held constant. Stress is determined as function of time, $\sigma(t)$. Analysis of the dependence of stress on time yields "relaxation time," τ. For the Maxwell model, τ values are the same whether from creep or relaxation. For real materials, experimentation is required to determine whether or not retardation and relaxation values are equal. Results of the stress relaxation experiment for the Maxwell model can be expressed as

$$\sigma(t) = \sigma(0)e^{-t/\tau} \tag{14}$$

When the instantaneous elongation is applied, the time zero response is entirely in the spring. Then the dashpot extends with time relieving stress on the spring. It is evident from Eq 14 that the value of τ can be obtained as the time at which stress has been reduced to $1/e$ (0.368) of its initial value. Alternatively, one can obtain the value of τ from the negative of the reciprocal of the slope of a plot of $\ln \sigma(t)$ versus t [4,5].

To represent mechanical response of viscoelastic polymeric materials, it is usually necessary to use more elaborate mechanical models and to replace a single value of τ by "a spectrum of relaxation times" [1,2].

PREPARATION OF FREE FILM SAMPLES

Methods for preparation and cure of adherent films are described elsewhere in the manual and in ASTM Test Methods for Producing Films of Uniform Thickness of Paint, Varnish, and Related Products on Test Panels (D 823-87). Since dynamic mechanical and tensile property determinations require free films, ASTM Practice for Preparation of Free Films of Organic Coatings (D 4708-87), is also very useful. Details

concerning thickness measurements, which are required for calculation of cross-sectional area, are given in ASTM Test Method for Measurement of Dry-Film Thickness of Organic Coatings Using Micrometers (D 1005).

The most widely used method for free film preparation involves application on release substrates, i.e., low surface energy substrates. Four release substrates are described in ASTM D 4708-87. Low surface energy results in poor adhesion so that the coating can be stripped from the release substrate after it is cured. Surface tension differences between the coating and release substrate must be carefully balanced. If the surface tension of the liquid coating is higher than the critical surface tension of the release substrate, the coating will crawl inward from the edges to give nonuniform thickness. In extreme cases of crawling, the coating will break up into unconnected puddles. There are many types of release paper and many surface treating agents to convert glass or metal panels into low-energy surfaces. It is worthwhile to try several release surfaces to find the balance which will avoid crawling but will still permit separation. Tendency to crawl can be reduced by use of high-viscosity formulations. Viscosities for draw-down application (see ASTM D 823-87) can be quite high compared to those required for spray application.

The second most widely used method for preparation of free films involves amalgamation of tin by mercury. ASTM D 4708-87 describes use of 25-μm-thick dental tin foil. The foil is smoothed onto glass plates before application of the coating. In our laboratory we have used 7.6 by 15.2-cm (3 by 6-in.) tin-plated steel panels (Type DT panels, Q-Panel Co.) The tin plate on the panels amalgamates much more quickly than that on tin-plated food can stock. After the coating is cured, the panel is placed in a wide-mouth quart jar containing mercury to a depth of only 0.64 to 1.3 cm (1/4 to 1/2 in.). The jar is tightly capped during amalgamation. During a period of one and one half to two days, mercury creeps up the panel underneath the coating as tin is amalgamated. After the film is completely freed from the substrate, it can be lifted off and wiped to remove mercury. The amalgamation procedure is best carried out in a hood reserved for this purpose. The work surface of the dedicated hood can consist of a metal grid mounted 1.3-cm (1/2 in.) above a shallow tray that contains sulfur. Other safety precautions include careful attention to panel handling procedures and disposal procedures, frequent monitoring of air flow velocities, use of protective gloves, and mercury vapor monitoring devices. Danger of exposure to mercury vapor has resulted in prohibition of amalgamation methods in some coatings laboratories.

Thickness is an important consideration in preparation of samples for dynamic mechanical and tensile property tests. Usually tests are more reproducible if samples are thicker than normal coatings thicknesses. However, film formation seldom occurs in exactly the same way for thick films as for thin ones. Several reasons for dependence of cured film properties on thickness have been discussed [*5*]. In our laboratory, films of 1 mil (25 μm) and up have been analyzed routinely. It has not been possible to analyze or even handle very thin free films such as beverage can coatings which are approximately 3 to 5 μm thick.

Coatings and thin plastic film samples are usually prepared as rectangular strips, whereas thicker materials are prepared as dogbone-shaped samples. The narrowing in the middle of the dogbone tends to control where failure occurs in tension tests, but for thin samples this narrowing causes the cross-sectional area to be too small for many load measuring cells. The dogbone shape also provides more area for clamping which facilitates the balance between slip-free clamping and avoidance of rupture at the clamp.

There is extensive literature on the notch sensitivity of polymeric materials in stress-strain tests [*7*]. The challenge in preparation of high *Tg* coating samples is to avoid undesired notches, nicks, or cracks along the edges. Small edge cracks, which are very difficult to detect even with magnification, can cause premature failure in tension tests. Usually samples are die cut, and the sharpness and condition of cutting edges of the die affect uniformity of sample edges.

DETERMINATION OF DYNAMIC PROPERTIES

Description of Dynamic Mechanical Analysis (DMA)

One of the reasons for rapidly expanding use of DMA for coatings and other research is the availability of automated and computer-controlled instrumentation. Automated instruments and the suppliers of these instruments are listed in Table 1 [*4*]. A common feature of all these instruments is oscillatory deformation, an example of which is shown in Fig. 2. Variable features include: the type of deformation (tensile, shear, or poorly defined), free versus forced oscillation, frequency scan versus temperature scan versus either, sensitivity for thin film analysis, capability of transversing the entire range of property behavior (glassy to transition to rubbery) during a single temperature scan, breadth and rate of temperature scan, breadth and rate of frequency scan or range and number of frequency settings, versatility of sample holding devices, ruggedness versus flimsiness, amount of attention required once a run has been started, accuracy and versatility of the associated software for control during the run and data treatment and plotting after the run. In several cases, newer models permit determination of properties at several fre-

NOTE: In addition, several thermo-mechanical analysis instruments have an option of oscillatory loading of the TMA probe.

quencies during a single temperature scan. Although it is necessary to use a rather low temperature scan rate in multiple frequency runs, the amount of data obtained is remarkable. Chances of acquiring an instrument that will actually function well in the intended experiments are greatly increased by asking suppliers about these variable features.

The procedure for carrying out a DMA run on an automated instrument is rather simple, with details depending on the particular instrument. Usually the associated software includes a "run" program which prompts the operator to input sample data (e.g., thickness) and settings for the run such as initial and final temperatures, frequency of oscillation, heating rate, etc. After the input steps, there is usually a cooling period. The instrument takes over when the preset initial temperature is reached. Thereafter nothing is required of the operator until the run is finished. Usually initial and final temperatures are selected to span the glassy region, transition region, and rubbery plateau region. For direct tensile DMA, the run program usually contains a tensioning subroutine, which provides constant static tension sufficient to avoid slack in the sample in the glassy region and then decreasing static tension as the sample softens in the transition region. Modification of the tensioning sub-routine is often necessary. If tension is too high, films break in the glassy region or are pulled apart in the transition region. If tension is too low, slack results or the oscillatory stress falls below measurable values. Skilled operators soon develop several modified run programs with different tensioning parameters that are suitable for samples of various properties and dimensions.

Various support materials, such as glass braids and metal springs or shims, are used when the sample is a viscous liquid and the objective is to follow cure as the coating formulation is converted to a solid. Use of supports makes it difficult to obtain absolute values of E', but relative values are often sufficient for component optimization. The position of peaks in E'' or tanδ plots are usually not shifted when a support is used. When coating samples do not contain solvents, e.g., powder coatings and 100% active coatings, parallel plate, and cone and plate geometries can be used.

In some cases, DMA is treated as an adjunct to thermomechanical analysis (TMA). The TMA probe is driven up and down in an oscillatory manner as temperature is scanned. General indications of liquid-like character during transitions can be obtained, but quantitative DMA data are not often obtainable in this manner.

Interpretation of DMA Plots

DMA plots are shown in Fig. 5 for a clear film prepared from an acrylic polyol (ACR) and an etherified melamine formaldehyde (MF) cross-linker. Plots are labeled according to Eqs 2, 3, and 4. The storage modulus level at the left is typical of amorphous, unpigmented films in the glassy state. The 25°C data are of interest for comparison with modulus values obtained from the slope of stress-strain plots because SSA is usually carried out at 25°C. The value of E' (25°) from the computer printout corresponding to Fig. 5 is 1.38×10^{10} dynes/cm^2. The same value expressed in other units is 1.38×10^9 Pa or 2.00×10^5 psi (1 pascal = 1 newton/m^2 = 10 dynes/cm^2 = 1.45×10^{-4} pounds-force per square inch). The recommended SI unit is Pa. The value of E'' (25°) is 6.86×10^8 dynes/cm^2. Inserting E' and E'' (25°) values into Eq 11 and solving for tensile modulus, E, we obtain $E = 1.382 \times 10^{10}$. In this case $E = E'$ (25°) to a very close approximation, and the contribution of E'' (25°) to E is negligible. Hard, tough coatings often have tensile modulus values from SSA ranging from 1×10^{10} to 3×10^{10} dynes/cm^2 [*5,7,8*], in agreement with the DMA value. For a quantitative comparison of E from SSA and E from DMA via Eq *11*, the strain rate from SSA would have to be matched with the oscillating frequency from DMA.

The viscous response is not always negligible relative to elastic response, of course. The E'' contribution is highest at the temperature of the maximum in tan delta, 79°C in Fig. 5. Note that E' (79°) is 1.04×10^9 dynes/cm^2, and E'' (79°) is 5.15×10^8 dynes/cm^2. From Eq *11*, $E = 1.16 \times 10^9$ dynes/cm^2, and $E > E'$ (79°) for this case. If we actually carried out SSA at 79° and a strain rate corresponding to 11 Hz, we would expect to find $E = 1.16 \times 10^9$ dynes/cm^2. During the elongation in SSA it would not be evident that a significant fraction of the resistance was viscous in nature. However, after the sample broke or was released from the grips, retraction would be delayed (not instantaneous) and part of the deformation would be permanent.

The middle portion of the plots in Fig. 5 represents the transition region where E' drops sharply and both E'' and tanδ go through a maximum. The glass transition temperature, *Tg*, is usually taken as the temperature of the maximum in the tanδ plot, 79° in Fig. 5. Some users of DMA prefer to define the temperature of the maximum in the E'' as *Tg*, 55° in Fig. 5. The lower *Tg* value agrees more closely with that obtained from differential scanning calorimetry, but the higher value can be obtained with better reproducibility because the tanδ peak is sharper than the E'' peak. Regardless of the data point selected to express *Tg*, it is important to remember that *Tg* depends on rate of testing for viscoelastic materials.

The effects of changing rate of testing, i.e., frequency in DMA, are shown in Table 2. The 11 Hz data of Table 2 correspond to the run depicted in Fig. 5. A ten-fold increase in frequency results in a 7 to 9° increase in *Tg* with a slightly stronger dependence on frequency at the higher frequencies. In a recent review, Hartmann [*9*] noted that a 7°C *Tg* change per decade change in frequency is used as a "rule-of-thumb." Results of Table 2 are consistent with this generalization. The height of the tanδ peak is nearly independent of frequency, but the width increases with increasing frequency. Very similar dependence of height and width on frequency was observed for lightly cross-linked epoxy films [*9*]. Values of E' (min) increase slightly with increasing frequency (Table 2). The structural implications of E' (min) will be discussed in the next sub-section.

Height and width of tanδ peaks reflect structural homogeneity and cross-link density. Homogeneous, uncross-linked, noncrystalline polymeric materials of narrow molecular weight distribution usually have tanδ (max) values greater than one and sometimes greater than two. Such tanδ peaks are very narrow. A broader molecular weight distribution results in a wider peak and a lower value of tanδ (max). Introduction of cross-links invariably reduces tanδ (max) and usually increases peak width. For homogeneous cross-linked

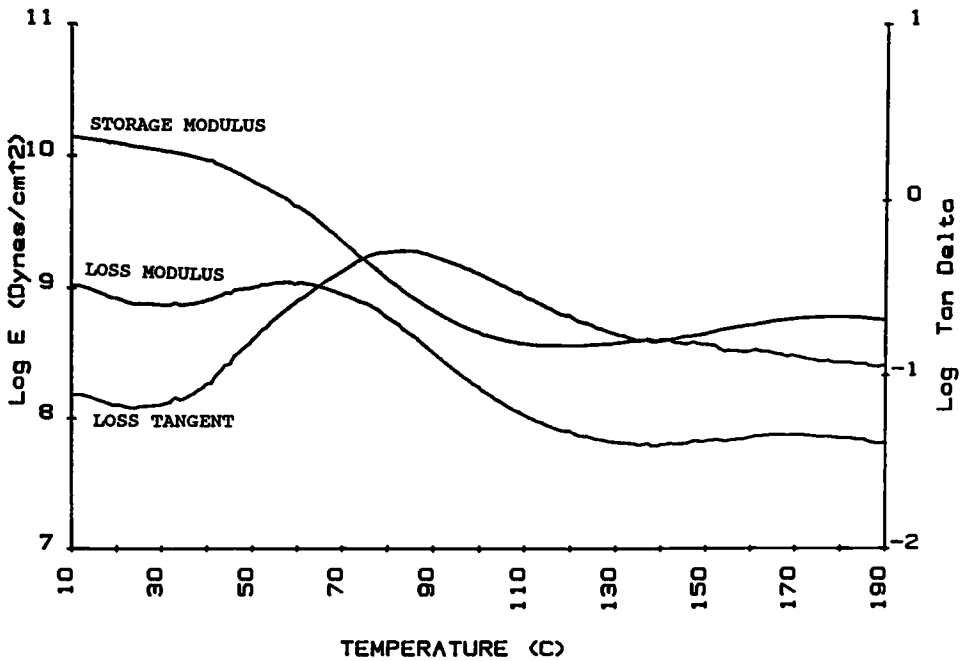

FIG. 5–DMA plots for a clearcoat prepared from an acrylic polyol (ACR) and an etherified melamine formaldehyde (MF) resin, ACR/MF 70/30. The film was cured before DMA for 30 min at 120°C with 0.5% para-toluenesulfonic acid. DMA was carried out at 11 Hz. See Table 2 for dynamic properties.

TABLE 2—Dynamic properties of acrylic/MF clearcoat.

Frequency, Hz	*Tg*, °C	Tanδ, max	*PW*,[a] Δ, °C	*E'*, (min), dynes/cm^2	Temperature of *E'* (min), °C
3.5	76	0.49	45	3.3×10^8	108
11.0	79	0.49	50	3.6×10^8	112
35.0	83	0.52	55	4.2×10^8	116
110.0	88	0.52	59	4.7×10^8	121

[a]*PW* is peak width at half height.

samples, peak width reflects the broadness of the distribution of lengths of chains between junction points in the network [*2,3*]. For sound and vibration damping, materials with both high and wide tanδ peaks would be desireable, but height and width cannot be adjusted independently [*9*]. High peaks tend to be narrow, and wide peaks tend to be low. These observations have resulted in speculation concerning a general comparability of peak areas of the glass transition. Eventually theoretical treatment of peak areas may prove to be useful for structure/property correlations.

Samples that undergo partial phase separation during molecular weight buildup and cross-linking often have very broad transitions [*4,9,10*]. Manson and Sperling [*10*] have described the use of interpenetrating polymer networks to limit and control the extent of phase separation. When *Tg* values of the separate domains are close to one another, a general broadening is observed. When *Tg* values of the separate domains are considerably different, tanδ plot shapes provide considerable structural information. Observation of two narrow peaks with low tanδ values between them indicates distinct phase separation with little mixing at domain boundaries. Observation to two broad and indistinct peaks with high tanδ values between them indicates diffuse domains with extended regions of varying composition at the boundaries [*4,10*]. Diffuse domains have also been created in multiblock uncross-linked polymers, and block design has resulted in controlled broadening of tanδ peaks [*11*].

The relationships between transition width and coating end-use performance have been presented for radiation-cured coatings [*12*], polyol/melamine thermoset coatings [*13,14*], gel coats [*14*], and can coatings [*14*]. Although the glass transition is emphasized in this section, many polymers are known to have multiple transitions. Low-temperature transitions are observed in DMA as tanδ or *E"* peaks that are quite small compared to the glass transition peaks. As discussed in the section entitled **Relationship to Other Mechanical Properties,** good impact resistance is often attributed to transitions that produce low-temperature loss peaks.

Interpretation of tanδ peak broadening in terms of structural nonuniformity requires considerable restraint because in some cases broadening is caused by physical or chemical changes that take place during the temperature scan. In some cases, DMA has its own uncertainty principle; the structural features that are under study are changing during the determination. Physical changes include loss of plasticizer or absorbed water and morphological changes

such as partial crystallization. Chemical changes include additional cross-linking of thermoset coatings during the scan and oxidative or thermal degradation. In general, if the temperature of processing the samples is well above the temperature of the tanδ peak under analysis, there is much less chance that properties are changing during the scan.

Determination of Cross-Link Density

For unpigmented, cross-linked coating films, the level of storage modulus, E', in the rubbery plateau region above Tg is an indication of cross-link density. A wide range of variation has been observed from approximately 4×10^7 dynes/cm^2 for lightly cross-linked films to approximately 2×10^9 dynes/cm^2 for very highly cross-linked films. Increases in E' values in the rubbery plateau have been attributed to increases in cross-link density for many types of studies: increasing cure temperature and cure time [*13,16–18*], increasing radiation dose in electron beam curing [*15*], increasing the stoichiometric balance in epoxy films [*2,19*] and in polyol/melamine films [*13,17,18*], increasing the functionality of the cross-linker in radiation cure films [*20*] and in powder coatings [*21,22*], and increasing the molecular weight of the main film former in acrylic clearcoats [*23*].

Quantitative aspects of the relationship between E' in the rubbery plateau and cross-link density have recently been clarified [*18*]. Cross-link density is defined as

$$\nu_e = \text{moles of elastically effective network chains per cubic centimeter of film} \quad (15)$$

Cross-link density can be calculated using Eq 16

$$\nu_e = \frac{G'}{RT} = \frac{E'}{3RT} \quad (16)$$

where the storage modulus values, G' or E', are obtained in the rubbery plateau, T is temperature in degrees K corresponding to the storage modulus value, and R is the gas constant (8.314×10^7 dynes/degrees K · mole in the cgs unit system). Inserting the 3.5 Hz data from Table 2 ($E' = 3.3 \times 10^8$ dynes/cm^2 and T = 108°C = 381°K) into Eq 16 gives $\nu_e = 3.47 \times 10^{-3}$ moles/cm^3. Since Eq 16 has no correction for frequency dependence of E', a more accurate value would be obtained if frequency were reduced until E' no longer depended on frequency. Extrapolation to zero frequency was used in cross-link density calculations for powder coatings [*21*]. For a polyurethane film of low Tg but relatively high cross-link density, E' plots were identical in the rubbery plateau at 11 and 110 Hz [*18*]; thus, no frequency extrapolation was necessary for this case.

Equation 16 has been called "the ideal network law" with an analogy implied to the ideal gas law [*18*]. In an ideal network, all chains are elastically effective. Conversion in the network forming reaction is complete, and there are no small loops or dangling ends. For ideal networks formed by functional group reactions of terminally functional (telechelic) starting materials, the value of ν_e can be calculated directly from Eq 15. The calculation requires only a balanced chemical equation and an experimental determination of cured film density. For example, consider a tetrafunctional coreactant B_4 (M_n = 3000) cured by a trifunctional cross-linker A_3 (M_n = 300)

$$4A_3 + 3B_4 \longrightarrow \text{Ideal Network (density} = 1.10\ \text{g/cm}^3)$$

The mass of the network formed by this reaction is 10 200 g (3 × 3000 + 4 × 300), and the volume is 10 200/1.10 = 9273 cm^3. This volume of cured film contains 24 mol of chain ends (4 × 3 + 3 × 4) coming into junction points in the network. By definition, a chain has two ends; therefore, there are 12 mol of elastically effective chains in 9273 cm^3 of ideal network film. From Eq 15, $\nu_e = 12/9273 = 1.29 \times 10^{-3}$ mol/cm^3.

Equation 17, attributed to Scanlon [*18,24*], formalizes this type of calculation

$$\nu_e = \frac{3}{2}C_3 + \frac{4}{2}C_4 + \frac{5}{2}C_5 + \cdots = \frac{1}{2}\sum_{f=3}^{\infty} fC_f \quad (17)$$

where C_f is the concentration of "f" functional reactant expressed in unusual units, i.e., moles of reactant per cubic centimeter of *final film*. Difunctional reactants contribute to volume but do not increase the number of moles of chains. Therefore, there is no C_2 term in Eq 17.

Ideal network calculations have been carried out for several types of coatings such as polyester polyol/melamine films [*17*], epoxy/diamine films [*19*], and powder coating films [*21,22*]. The ν_e values calculated from reactant structures agree remarkably well with experimental ν_e values from Eq 16.

Although ν_e is useful for network characterization, most coating chemists can more easily visualize a network based on the value of M_c

$$M_c = \text{weight of sample in grams that contains one mole of elastically effective chains} \quad (18)$$

If chain lengths in the network vary, one can place a bar over M_c and refer to this quantity as "number average molecular weight of effective network chains." Based on Eqs 15 and 18, the relationship between ν_e and M_c is

$$M_c = \frac{\rho}{\nu_e} \quad (19)$$

where ρ is film density in g/cm^3. For the $4A_3 + 3B_4$ example, $M_c = 1.10/1.29 \times 10^{-3} = 853$ g/mol. For the film of Table 2, the experimental density is 1.12 g/cm^3, and M_c is $1.12/3.47 \times 10^{-3} = 323$ g/mol. Of course, a high value of M_c corresponds to a loose network and a low value to a tight network.

Equation 16 can be considered empirical or the result of kinetic theory of rubber elasticity [*20,24-28*]. The theory was developed for networks that have very long chains between junction points. For long chains, conformations can be treated by statistical-mechanics concepts. The chains in networks of greatest interest for coatings are much too short for such treatments. For long chains between junction points, results of the theory are often expressed as [*20*]

$$\nu_e = \nu_c + \nu_p = \frac{G}{gRT} \quad (20)$$

where ν_e is sum of a chemical contribution, ν_c, and a physical contribution, ν_p. The physical contribution is attributed to chain entanglements [*28*] or physical constraints [*25–27*]. The factor, g, is related to junction point displacement under stress and is reported to depend on functionality [*20,25*]. If the reader chooses to use rubber elasticity theory, Eq 16 is

obtained from Eq 20 with $g = 1.0$, $G = G'$, and $\nu_p = 0$ (relative to ν_c).

A new theory is needed that results in Eq 16 by consideration of entropy of conformations of short chains. This approach would avoid applying long chain theory to material having short chains.

Relationship to Other Mechanical Properties

Knowledge of dynamic properties is useful for optimizing the chemical structure of coatings components. When the binder is a copolymer, monomer ratios can be altered to control *Tg*. In thermosets, increasing the functionality of the cross-linker is expected to cause an increase in cross-link density. DMA is a very direct method for determining whether purposeful structural changes have actually had the desired effects.

In addition to general structure/property uses of DMA, progress is being made in establishing relationships between dynamic properties and the results of paint test methods for hardness, flexibility, impact resistance, and solvent resistance. DMA has some inherent limitations in the establishment of these property/property relationships. The oscillatory deformation, e.g., ϵ_0 in Fig. 2, is very small. If the paint performance property depends critically on large deformations, a property/property correlation should not be expected. Results of paint performance tests usually depend to some extent on interactions between coating and substrate. When dependence on coating-substrate interactions is dominant, a free film method such as DMA should not be expected to correlate with results of paint tests.

DMA has helped elucidate the causes of reversals in rank order of hardness among films when different tests are used [*5,29*]. As described elsewhere in the manual, hardness is determined by penetration, pendulum, and scratch test methods. The most important property for influencing hardness is *Tg*. However, even for a series of films that have the same *Tg*, considerable differences are sometimes observed in hardness test results. We have observed that penetration hardness depends more directly on the E' (25°) value than on *Tg*. Films of the same *Tg* can have quite different values of E' (25°). Pendulum hardness depends more directly on E'' values than on E' values. This result is expected because damping of the swings of a pendulum depends on conversion of mechanical energy into heat through viscous effects in the coating. As noted earlier, E'' is a measure of viscous response. Films which have nearly the same E' (25°) values and the same penetration hardness can have quite different E'' (25°) values and quite different values of pendulum hardness. The back and forth rolling motion of a Sward Rocker is also damped by viscous effects, and therefore depends strongly on E'' values. In this case, there is also a contribution from sliding friction. Usually pendulum hardness is determined at a single temperature, but Sato [*29*] describes studies of damping time as a function of temperature. Plots of the reciprocal of damping time versus temperature have exactly the same shape as the tanδ plot for the same films. Both glassy and rubbery materials have low tanδ values as shown in Fig. 5. If a pendulum hardness test is carried out at room temperature on a material that is in its rubbery region at room temperature, a careless interpreter of results is likely to conclude that rubber is very hard. This example illustrates that DMA can be used to understand the results of paint tests more fully.

Among the many scratch tests that have been devised, the most widely used is pencil hardness. Although pencil hardness results are quite reproducible when carried out by one skilled in the art, these results sometimes do not correlate with either penetration or pendulum hardness results. Furthermore, there is no known dynamic property that correlates well with pencil hardness. The plowing action involved in pencil hardness failures may involve large localized deformations. A relation to stress-strain analysis, which involves large deformations, is more likely.

Flexibility of coatings is often measured by mandrel bend tests and falling weight impact tests (see a previous chapter in this book). In thermoplastic polymer studies, good flexibility and impact resistance are often associated with low temperature peaks in E'' and tanδ plots [*30*]. Rubber-toughened epoxy coatings clearly show the low temperature peak attributable to the rubber phase [*31*]. Polyester/melamine films have much better mandrel bend performance than do acrylic/melamine films of similar *Tg* and cross-link density. DMA scans beginning at −100°C show a weak tanδ peak at −70°C for the PE/MF films, but no such peak is observed for the ACR/MF films [*18*]. In some cases [*12,13*], extreme broadening of the peak in the E'' plot has been associated with improvements in flexibility of coatings.

Pigments often increase the toughness of coatings without broadening the transition or introducing low-temperature loss peaks [*15*]. The main effect of increasing pigment volume content (PVC = 0 to 55%) on DMA plots is to increase E' values moderately in the glassy region and strongly in the rubbery plateau [*15*]. Values of *Tg* often increase by about 5 to 10°C at PVC = 0.4 relative to the corresponding clear coatings [*15*].

Solvent resistance as measured in methyl ethyl ketone double rub tests is related to E' values in the rubbery plateau, i.e., to cross-link density [*5,13*]. MEK resistance also depends on the solubility parameter of the coating. Although the double rub test is widely used to determine the degree of cure of thermoset coatings, the only ASTM method adopted relates to zinc-rich primers (D 4752-87). Relationships between the number of double rubs and E' (min) values are quite reproducible within a coating type but not from type to type. For example, with acrylic clearcoats, 200 double rubs are obtained when E' (min) = 2×10^8 dynes/cm^2 [*13*]. Films of this type having 50 to 100 double rubs typically have E' (min) values in the range of 5×10^7 to 1 to 10^8 dynes/cm^2. In contrast, polyester polyol powder coatings, cured with several types of cross-linkers, yielded 200+ double rubs despite having E' (min) values as low as 5×10^7 dynes/cm^2 [*22*]. The lack of generality in the relationship of MEK resistance to E' (min) for various coatings types is believed to result in part from differences in solvent-polymer interactions. There may also be a weak dependence of MEK resistance on *Tg* as well as a strong dependence on E' (min).

DETERMINATION OF TENSILE PROPERTIES

Description of Stress-Strain Analysis (SSA)

Instrumentation for SSA is described in detail in the ASTM test methods listed in the section of this chapter entitled Definitions of Tensile Properties. In most cases, specific instruments are not identified, apparently to avoid commercial implications, but it is generally known than Instron® instruments (Instron Engineering Corp.) are widely used. For organic coatings the most suitable test method is usually ASTM D 2370. However, other tension test methods contain additional useful information. ASTM D 638M is useful for selection of metric units and units consistent with SI recommendations. ASTM D 882 has rather extensive data on statistical treatments for plastic sheeting, but the statistical methods could be beneficially applied to coatings films. For certain types of coatings, such as flexible primers or coatings for plastic substrates, rubbery behavior is expected, and ASTM D 412 provides useful information such as data treatment when a crack moves slowly across the sample as opposed to the more usual instantaneous failure mode. Often stress-strain curves do not start out with constant slope as shown in Fig. 3, but instead have an initial curvature caused by takeup of slack. The initial curved portion is called a "toe," and toe compensation is described in ASTM D 638M and in ASTM D 882. Some stress-strain curves have no linear (i.e., no Hookean) region from which to calculate the slope for modulus values. In such instances the "toe corrected" origin and another point on the curve are joined by a straight line. The slope of the line is reported as the "secant modulus." The elongation percentage at the second point selected is always reported along with the value of secant modulus. Graphical illustrations of secant modulus determinations are given in ASTM D 638M and in ASTM D 882. Among the various test methods, D 638M contains the most complete list of definitions and symbols.

Determination of "tensile energy to break" is described in ASTM D 882. The area under the stress-strain curve, e.g., see Fig. 3, is divided by sample volume to obtain this quantity, which has also been called "work-to-break" or "toughness" [5]. Recommended units are megajoules per cubic meter. ASTM D 882 describes how an integrated chart paper area (distance^2) can be converted to energy/volume by using the ordinate setting (force/distance of chart paper), the abscissa setting (distance of elongation/distance of chart paper), and the sample dimensions. Now that computers are used to control operation and to treat data for SSA [32], numerical integration is nearly instantaneous, and tensile energy to break is likely to be reported more often. This SSA property may prove to be useful for correlations with paint test results.

Interpretation of Stress-Strain Curves

Schematic stress-strain curves for various types of polymeric materials are shown in Fig. 6 [2]. This extremely wide range of property variation is represented in coatings of various types. Scales on the graphs give an order-of-magnitude indication of property values. Brittle materials (6*A*) have high

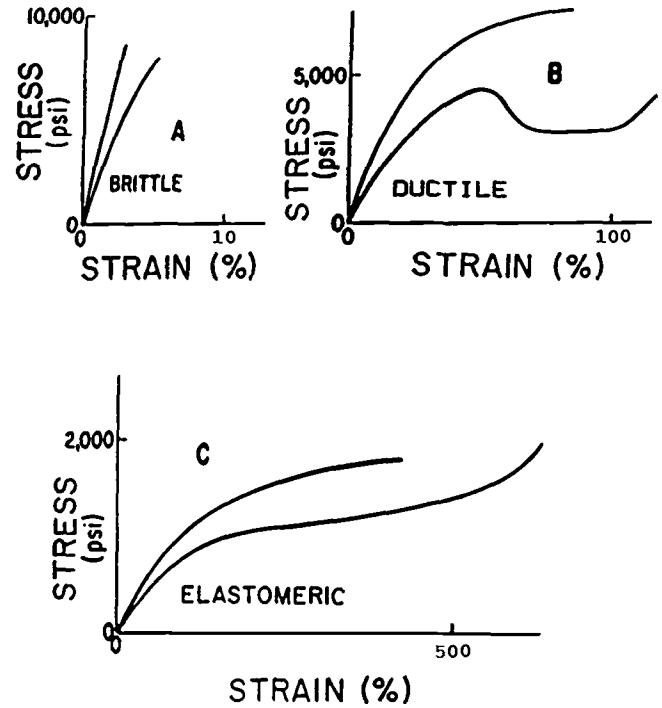

FIG. 6–General kinds of stress-strain curves for various types of coatings. Scales indicate order-of-magnitude values.

modulus values (initial slope), tensile strengths up to about 8000 psi (5.5×10^7 Pa = 5.5×10^8 dynes/cm^2), and elongations below 10%. Ductile materials (6*B*) usually have lower initial slopes, tensile strengths in the 4000 to 6000 psi range, and elongations of about 100%. The upper plot in 6*B* corresponds to yielding with uniform sample deformation between the grips. The lower plot in 6*B* corresponds to a ductile sample that necks down at the yield point, and further elongation (~40% to 110% in Fig. 6) occurs with increase in length of the necked part of the sample. Elastomeric (rubbery) samples (6*C*) have much lower initial slopes than brittle materials, tensile strengths of about 2000 psi, and elongations of the order of 400 to 500%. The upward curvature near the end of the lower plot in Part C is attributed to strain-induced crystallization [2].

Materials represented in 6*A* and 6*B* of Fig. 6 have *Tg* values above the test temperature. Therefore, modulus values depend on secondary interactions of polymer chain segments and partial crystallinity, if any exists. The elastomeric material (6*C*) has *Tg* well below the test temperature. Therefore, modulus values depend in part on cross-link density, chain entanglements, or both.

Stress-strain curves are carried out at a constant rate of strain and results depend on strain rate selected. In general, a higher rate results in higher modulus. The two curves in 6*A* could represent the same material strained at different rates. In fact a large increase in strain rate could cause the plots of 6*B* to be converted to the plots of 6*A*. Dependence on strain rate is evidence of viscoelasticity. Strain rate dependence in SSA, therefore, has the same origin as dependence on oscillatory frequency in DMA (see Table 2).

A recent study of silicone-epoxy resins cross-linked with amines of various functionality [*32*] illustrates the extreme range of stress-strain properties exhibited by coating films. Tensile strength ranged from 31 to 4418 psi. Percent elongation ranged from 7 to 177%. Unfortunately, neither modulus values nor tensile energy to break were reported. Property variations were attributed to differences in degree of entanglement and to partial phase separation. In a network-forming thermoset system, it would be impossible to get a tensile strength as low as 31 psi unless incompatibility had prevented occurrence of the network-forming reaction.

Examples of all types of behavior shown in Fig. 6 are represented in a single figure for coatings used on naval aircraft [*33*] (see Fig. 4, Ref *33*). One plot shows results for a polysulfide sealant that has a tensile strength of about 250 psi and an elongation >130%. Results for a flexible polyurethane primer are a tensile strength of 3500 psi, a yield strength of 3200 psi, an elongation at break of 90%, and an elongation at yield of 40%. The plot shows that a polyurethane topcoat yields and breaks at about the same point: 4000 psi and 22% elongation. The plot for an epoxy primer shows brittle behavior (no yield point), a tensile strength of 2300 psi, and an elongation at break of 7%. The authors [*33*] report that replacing the epoxy primer by the flexible polyurethane primer eliminated the need for the sealant coat.

SSA has been used extensively to characterize cationic UV-cured cycloaliphatic epoxy/polyol coatings [*34-36*]. The mechanism of introduction of polyol is a chain transfer step [*34*], which permits use of a wide range of epoxy:polyol ratio without need for stoichiometric balance. Selection of flexible polyols with this wide formulating latitude permits preparation of cross-linked films with an extremely wide range of mechanical properties. Numerous stress-strain curves have been presented for this type of system with oligomeric propylene oxide polyols [*35*] and with oligomeric caprolactone polyols [*36*]. Examples of stress-strain curves for a cycloaliphatic diepoxide (CYRACURE® UVR-6110, Union Carbide) and a propylene oxide triol (*MW* = 702) are shown in Fig. 7 [*35*]. The corresponding tensile properties are given in Table 3. Films from Compositions 1 through 4 all give brittle failure (compare Fig. 6*A*) and only moderate changes in tensile properties (Table 3) despite a large change in composition. At Composition 5 (70/30 epoxy:polyol, see Table 3) a yield point is first noted, and thereafter very large property changes occur despite relatively small changes in composition. Compositions in the 4 to 6 range (see Table 3) are reported to give excellent post formability, as required for coatings on beverage can ends, while maintaining adequate hardness and solvent resistance [*34-36*].

Relationship to Other Mechanical Properties

Stress-strain analysis (SSA) is used in a general way to assess suitability of a binder for various coating end uses. Most coating chemists associate modulus with coating hardness and percentage elongation at break with coating flexibility. Quantitative correlations of these properties are not published very often, however. The lack of published correlations may result from the fact, noted above, that paint tests of adherent coatings depend on coating-substrate interactions, whereas SSA is carried out on free films. ASTM Test Method for Elongation of Attached Organic Coatings with Conical Mandrel Apparatus (D 522-88) describes how to calculate percent elongation from the crack length in a conical mandrel bend test. Comparison of elongation of adherent coatings by the conical mandrel method and elongation of the same coating as a free film from SSA would certainly be of interest, but such comparisons were not found in the literature.

The logic of associating yield behavior in SSA with post formability of coil coated metal was noted in 1977 [*37*]. In 1987, Koleske [*35,36*] confirmed that compositions that exhibited a yield point performed well in the demanding post-forming operations carried out on beverage can ends.

Evans and Fogel [*38*] provided convincing evidence that gloss retention during abrasion of floor coatings is related to the area under stress-strain curves. This area, divided by sample volume, is called "work-to-break" or "toughness" as noted in the subsection of this chapter entitled **Definitions of Tensile Properties.** The authors provide a clear example of the need to match strain rates when attempting to correlate SSA results with paint test results.

Failure of attempts to correlate pencil hardness with penetration hardness, e.g., Tukon Hardness, probably result because the former has a strong requirement for toughness, whereas the latter is more dependent on the modulus value at room temperature (see chapter subsection entitled **Relationship to Other Mechanical Properties**).

DMA is much more generally applicable to determination of cross-link density (see chapter subsection entitled **Determination of Cross-Link Density**) than is SSA. If the *Tg* of a coating binder is well below the temperature at which

[d]1% secant modulus. (The modulus range expressed in pascals is 2.68×10^9, No. 1, to 1.79×10^8, No. 8.)

SSA is carried out, then the modulus from the initial slope of the stress-strain curve is a rubbery plateau modulus and Eq 16 is valid at least in principle. In practice, curvature in stress-strain curves and permanent deformation usually result in inappropriate modulus values. An innovative approach to avoiding the permanent deformation problem consists of reversing the extension mode of SSA so that a retraction plot is also obtained. Hergenrother [*39*] has applied this tensile retraction method for determination of cross-link density of elastomeric polyurethanes.

CONCLUSIONS

A wide range of automated and computer-controlled instruments is available for determination of dynamic mechanical and tensile properties. Careful review of variable features is necessary to insure suitability for property determinations on coating samples of normal thickness. Determination of basic physical properties makes it possible to integrate structure/property knowledge from many polymer fields with coatings research and development. Free film coating data are much more useful when thoughtfully interpreted in relation to results from tests carried out with films intact on their end-use substrates. This review includes many examples that illustrate the benefits of combining DMA or SSA data with results from well controlled and documented tests as provided by the ASTM. The goal of much of the discussion provided here is better understanding of hardness, flexibility, post-formability, solvent resistance, and abrasion resistance.

DMA and SSA are often complementary because strains imposed on test samples are very different. SSA provides information on yield behavior and failure at high strains. DMA provides low strain properties and reveals the viscoelastic nature of coatings very directly and quantitatively.

For unpigmented thermoset coatings, values of storage modulus, E', in the rubbery plateau can be used to calculate cross-link density (XLD). Determination of XLD usually makes it possible to confirm or deny that purposeful reformulation or changes in resin structure have had the desired effects.

Flexibility and Toughness*

by Mark P. Morse[1]

DEFINITIONS

TO PERFORM PROPERLY IN USE, a coating must possess the proper amount of flexibility and toughness to withstand cracking when subjected to stresses produced by shrinking or swelling, forming, mechanical abuse, and weathering. Flexibility is the ability of a material to be bent or flexed without cracking or undergoing other failure. Toughness is the strength and resilience of a material; it is the material's ability to withstand great strain imposed in a short time period without tearing, breaking, or rupture.

INTERPRETATION

The flexibility of a coating applied to a substrate depends not only on its distensibility, but also on the coating thickness and on the adhesion between coating and substrate. Good adhesion tends to give better apparent flexibility than does poor adhesion. The toughness of a coating is dependent on its hardness, stiffness, resiliency, distensibility, and the existence of an energy dissipation mechanism that operates at temperatures far below room temperature and is discernable by dynamic mechanical measurements made over a broad temperature or frequency range.

Generally, the bend and impact tests used to evaluate flexibility and toughness are much more severe than actual service conditions. This is because the tests are usually performed on relatively fresh, unaged coating films. Since coating films tend to lose flexibility during use due to volatilization of free plasticizing components and chemical changes such as degradation, cross-linking, and the like, these severe tests that exceed normal expectations are useful in predicting long-term serviceability [*1*].

BASIC PROPERTIES AFFECTING COATING PERFORMANCE

Both flexibility and toughness depend on very basic properties: the viscoelastic behavior of the coating and its physical transitions and relaxations. The following is a discussion of these properties taken from a paper by Skrovanek and Schoff [*2*].

Coatings, as the polymers from which they are prepared, are viscoelastic in nature, that is, they behave both as viscous liquids and as elastic solids. The coatings have elastic recovery and yet will flow with time when placed under a stress. In general, viscoelastic behavior and mechanical properties are markedly affected when a coating enters the glass transition, softening point, or other relaxation. To be certain that the properties of a coating will fulfill the needs of its intended use, the viscoelastic behavior of the coating should be measured, controlled, and designed to meet the particular end use.

The softening point of a coating can be used as an index of flexibility. The softening point is between the temperature where the coating changes from being hard and glassy and the temperature where it is leathery or rubbery. For example, if a coating has a softening temperature region near the temperature of the forming operation, the coating is less susceptible to failure by cracking or a similar mechanism than if the softening region was above the forming temperature. Measurement of energy storage (related to elasticity) and energy loss (related to viscous losses) as a function of temperature is a means of predicting impact resistance.

Impact resistance of a paint film can be considered as energy dissipation by vibration or rotation of various molecular segments so that at no time will sufficient energy be focused to cause fracture. Since the impact tests performed on paint films often produce deformations beyond the elastic limit of the films, flow within the films must take place or fracture will occur [*3*].

To obtain good impact resistance, the paint film must consist of a polymer that has a sufficiently high molecular weight to have strong intermolecular entanglement (and therefore, high tensile strength), but sufficiently low viscosity (by choice of proper molecular constituents and limiting molecular weight) that flow and accompanying energy dissipation will take place.

Polymer viscosity increases as molecular weight increases so that polymers with very high molecular weights will have greater flexibility than those polymers with intermediate or low molecular weights. At the same time, molecular weights below the critical molecular weight for entanglement lead to very low tensile strengths and the mechanical behavior observed is brittleness. It has been found that modulus is the dominant factor in the relationship between the tensile properties of a coating and its impact resistance [*4*].

In addition to dynamic mechanical behavior, the relaxation behavior as measured by dissipation or damping of coatings has been determined by application of dynamic electrical tests [*5*]. In a dielectric relaxation test, a periodic electrical

*This chpater is an abridged and modified version of the chapter entitled "Flexibility," written by Garmond G. Schurr, found in the previous edition of this manual.

Copyright© 1995 by ASTM International

potential is applied to the sample coating situated between a pair of electrodes. The dielectric constant and dissipation factor are measured as a function of frequency and temperature.

TECHNIQUES FOR MEASURING BASIC VISCOELASTIC PROPERTIES

Thermal Mechanical Analyzer (TMA)

This instrument employs transducers to sense the position of a vertical rod that rests on the surface of a coating sample. The instrument is usually equipped with a furnace and program planner so that heating, cooling, and isothermal temperature operations can be employed.

With its use, softening points and glass transitions can be determined from plots of coating indentation as a function of temperature. Also, changes in stresses within a coating at a constant temperature (creep) can be determined from plots of indentation versus time [*2*].

Dynamic Mechanical Thermal Analyzer (DMTA)

This instrument produces vibrations in a coating film over a wide frequency range and/or temperature range. It can scan a wide range of sample temperatures at different rates. The resulting deformations from the sinusoidally applied stresses are analyzed to compute values related to energy storage and energy loss [*2*].

EXTERNAL FACTORS AFFECTING FLEXIBILITY AND TOUGHNESS

Flexibility and toughness are not constant characteristics of a specific coating. A number of external factors affect these properties.

Humidity

Water is a good plasticizer for almost all paint films. A change in relative humidity of as little as 2% can be detected in flexibility measurements. Some paint films, such as those based on latexes, imbibe moisture very rapidly, whereas others reach equilibrium with the atmosphere very slowly. It is imperative that tests be conducted in an atmosphere of controlled relative humidity and that the specimens are conditioned in that atmosphere for a day or more before the tests are performed. Generally, flexibility and toughness tests are carried out at a relative humidity of 50 ± 5%. The 10% tolerance is needed because of the difficulty in more accurately controlling relative humidity in most laboratories. If the environment cannot be controlled at this recommended level, then the relative humidity should be measured and reported along with the mechanical properties.

Temperature

The flexibility and toughness of coatings are dependent on temperature. This is particularly true of thermoplastic coatings, but it also is a factor for thermoset coatings. These coatings have a definite second order transition temperature known as the glass transition temperature, T_g. Coatings at a temperature below T_g are hard and brittle with poor flexibility and impact resistance unless there is another relaxation at low temperatures as exists in polycarbonates that have a high T_g of about 160°C (at 1 Hz) and yet have excellent impact resistance because of a relaxation that occurs at about −90°C (at 1 Hz). If coatings do not have this type loss mechanism, at temperatures just above T_g they are flexible, and at temperatures substantially above T_g they tend to develop viscous rather than elastic properties. There is a tendency for all thermoplastic coatings to have identical flexibility properties if these properties are measured at the same temperature relative to T_g, for example, at 10°C above T_g [*1,6*].

Flexibility and toughness measurements are usually made at a temperature of 25 ± 1°C after the coatings are equilibrated at that temperature. However, there are many instances when test are performed at lower temperatures as might be encountered in cold climates.

Strain Rate

Strain rate is the rate at which a coating specimen is elongated and is usually expressed in percent per minute, in./in./min or cm/cm/min. This is the rate of extension relative to specimen size. That is, if a specimen 10 cm long is elongated at rate of 1 cm/min, it is the same as a specimen 1 cm long being elongated at a rate of 0.1 cm/min (1 mm/min). In both cases, the strain rate is 10% per minute.

Strain rate has a great influence on the flexibility and toughness of a coating. In general, the effect of increasing the strain rate is similar to decreasing the coating temperature, that is, as the strain rate is increased, flexibility and toughness decrease.

There can be critical strain rates where flexibility has sharp changes which are very similar to the effects produced at the glass transition temperature [*7*]. This means that the strain rate used in a test must be closely controlled. In some tests, such as bend test, this is difficult to do. This also means that tests performed at a low strain rate (cupping test) are likely to produce different flexibility ratings than those produced by a high strain rate (conical mandrel test) [*1,7*].

FLEXIBILITY AND TOUGHNESS MEASUREMENTS

Mandrel Bend Tests

Both conical and cylindrical mandrels are often used for evaluating the flexibility of coatings. Even though it is difficult to control the strain rate in these manually operated tests, they can provide very useful flexibility ratings.

Conical Mandrel Tests

A conical mandrel test consists of manually bending a coated metal panel over a cone. As described in ASTM Test Method for Elongation of Attached Organic Coatings with Conical Mandrel Apparatus (D 522), a conical mandrel tester consists of a metal cone, a rotating panel bending arm, and panel clamps. These items are all mounted on a metal base as

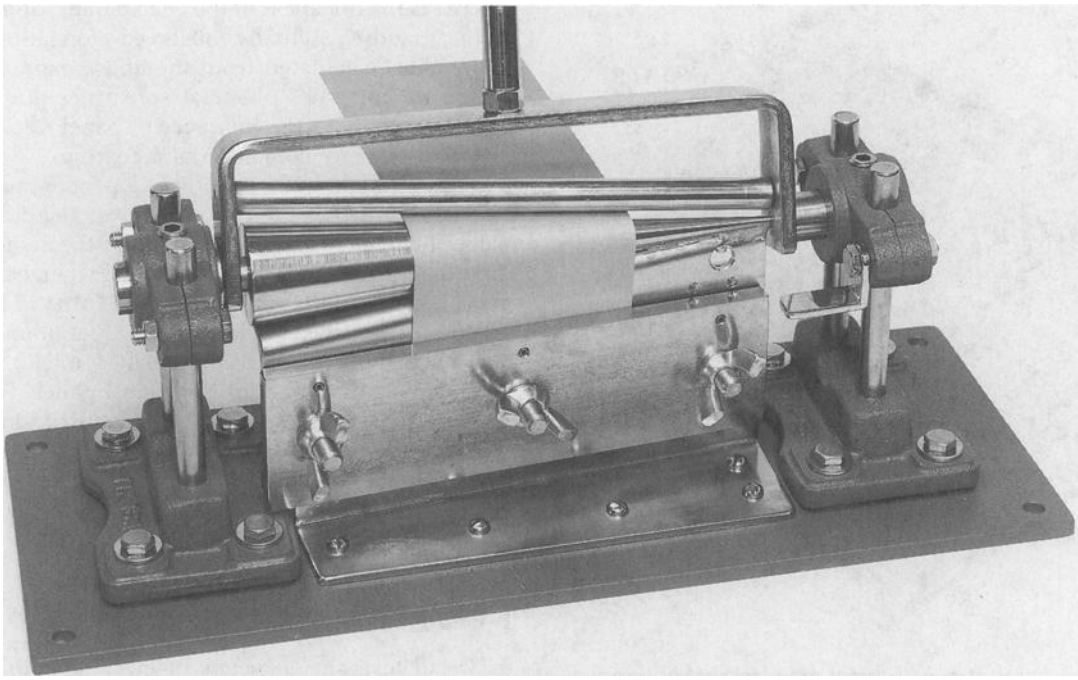

FIG. 1–Bending a specimen over a conical mandrel (courtesy of Gardner Laboratory) [*1*].

illustrated in Fig. 1. The cone is smooth steel 8 in. (203 mm) in length with a diameter of ⅛ in. (3 mm) at one end and a diameter of 1.5 in. (38 mm) at the other end.

When a coating is applied on a 1/32-in. (0.8 mm)-thick cold-rolled steel panel, as specified in ASTM D 522, a bend over the mandrel produces an elongation of 3% at the large end of the cone and of 30% at the small end of the cone. The coated panel is bent 135° around the cone in approximately 1 s to obtain a crack resistance rating under simulated abuse conditions. In some instances, longer bend times have been found to be useful. For example, if the percent elongation of the coating at the point of cracking is to be determined, the method specifies a bend time of 15 s.

Since variations in temperature and humidity can affect mandrel bend tests, it is imperative that the coated panels be conditioned at a standard temperature and relative humidity before performing the test, which is conducted under the same conditions.

The crack resistance value of a coating is obtained by measuring the distance from the furthest end of the crack to the small end of the mandrel. This distance is converted to cone diameter by means of a plot given in ASTM D 522. The mandrel diameter at which cracking occurs is taken as the crack resistance value.

If the elongation of the coating at the onset of cracking is to be reported, a bend time of 15 s is used and the diameter at which the onset of cracking occurred is converted to percent elongation from a plot given in ASTM Test Methods for Mandrel Bend Test of Attached Organic Coatings (D 522).

Cylindrical Mandrel Bend Tests

When executing cylindrical mandrel flexibility tests, a coated panel is bent manually over one or more cylindrical rods or surfaces of different diameters. ASTM D 522 states that the testing device should include mandrels with 1-in. (25 mm), ¾-in. (19 mm), ½-in. (12.7 mm), ⅜-in. (9.5 mm), ¼-in. (6.4 mm), and ⅛-in. (3.2 mm) diameters. Examples of cylindrical mandrel testers are given in Figs. 2 and 3.

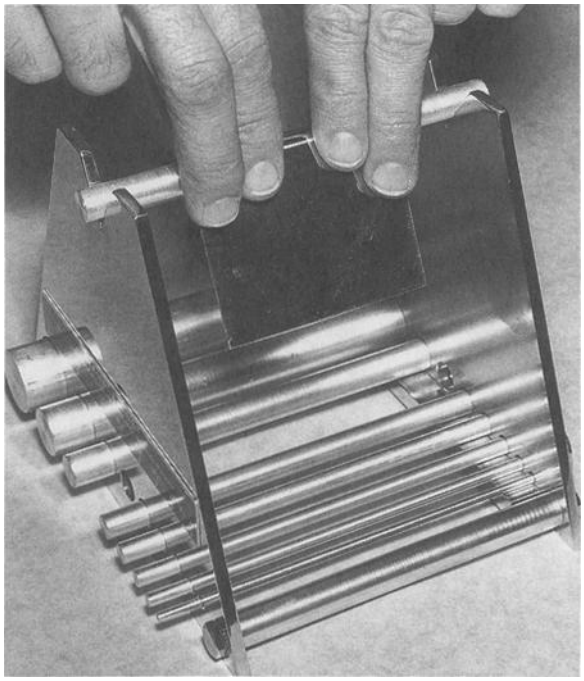

FIG. 2–Bending a specimen over a cylindrical mandrel (courtesy of Gardner Laboratory) [*1*].

The panel should be bent over a mandrel with the uncoated side of the panel in contact with the mandrel surface. The panel should be bent approximately 180° around the mandrel at a uniform velocity in a time of 1 s. If cracking has not occurred, the procedure is repeated using successively

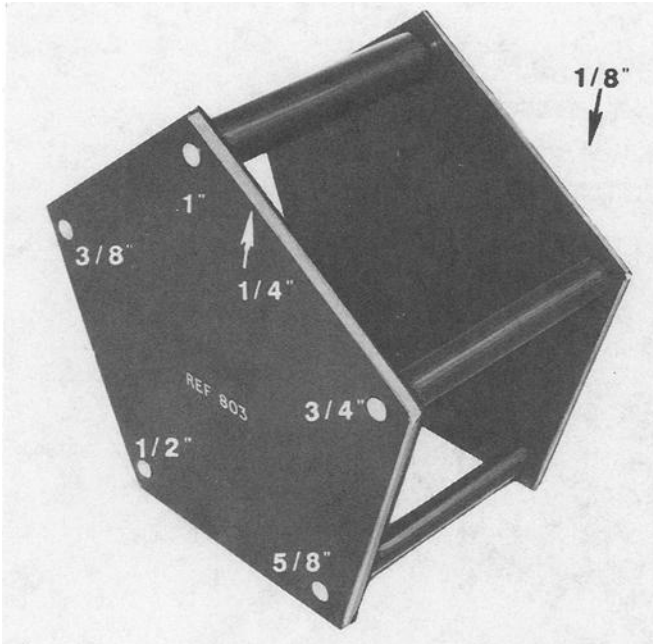

FIG. 3–An illustration of a cylindrical mandrel test apparatus.

smaller and smaller diameter mandrels until cracking is apparent. The cracking-resistance value of a coated panel is the minimum diameter at which cracking does not appear.

This testing procedure can be applied as a "pass/fail" test by determining whether cracking is produced by bending over a specified mandrel diameter.

A table for converting mandrel diameter to percent elongation is given in ASTM D 522. The relationship between diameter of a mandrel and the elongation of a coating has been derived by Schuh and Theuerer [*8*] to be:

$$\text{Percent Elongation} = 100(t/(2r + t)) \qquad (1)$$

where t is the thickness of the coated panel and r is the radius of the mandrel. Actually, observed elongations are greater than values calculated from the above expression and vary with different types of metal substrates. Table 1 contains information about the influence of panel thickness and type metal on percent elongation of a coating.

Crack resistance of a coating is dependent on its thickness, that is, the thicker the film, the lower the crack resistance. Values of crack resistance obtained by the mandrel bend tests should be corrected for film thickness when comparisons are made between different coatings. ASTM D 522 contains corrections to be added to elongation values obtained with coatings having thickness greater than 1 mil (0.03 mm) when applied to ⅛-in. (0.8-mm)-thick steel panels (Table 1).

Conical mandrel bend test procedures similar to those given in ASTM D 522 are found in ISO Method 6860 and BS 3900. Cylindrical mandrel bend test procedures similar to those given in ASTM D 522 are found in ISO 1519, DIN 35 152, and BS 3900 E1.

T-Bend Tests

T-bend tests are a means of evaluating the flexibility of coated strip metal that is to be formed during a fabrication process (Fig. 4). Multiple 180° bends of the coated metal are made, and the amount of cracking produced at each bend is visually determined. Ratings are classified as 0T, 1T, 2T, 3T, and so on. The 0T (pronounced zero T) bend consists of making a 180° bend with the paint on the outside of the bend and pressing the bend flat so there is no space between the metal surfaces. This operation is repeated successively to produce a 1T (pronounced one T), 2T, 3T, etc. bends (Fig. 5). These successive bends result in two, three, etc. thickness of the metal around the first bend. It should be apparent that the greater the number of thicknesses around which the coated metal is bent, the less severe the test. The DiAcro Brake Form machine is suitable for this test.

TABLE 1—Factors affecting elongation measurements of coated panels by mandrel bend tests.

	Mandrel Diameter, in.					
Panel Thickness	1	¾	½	⅜	¼	⅛
CORRECTIONS TO BE ADDED FOR THICKNESS OF PANEL SUBSTRATE						
1/64 in. Correction, %	1.5	2.0	3.0	4.0	5.9	11.1
1/32 in. Correction, %	3.0	4.0	5.0	7.7	11.1	20.0

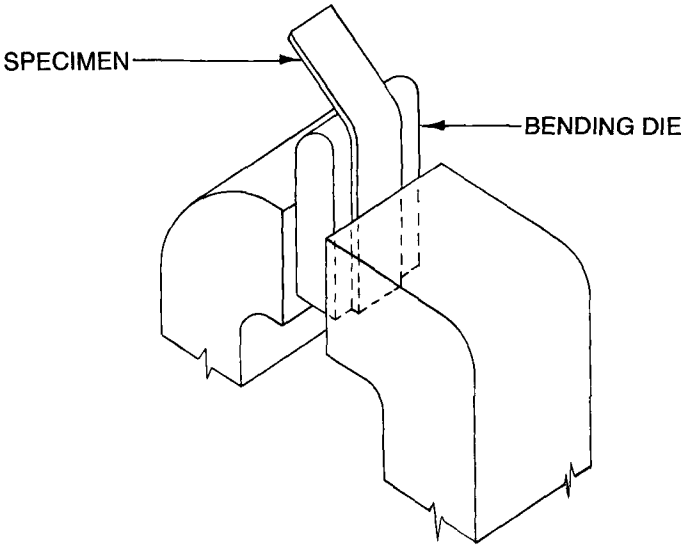

FIG. 4–T-Bend test using a die around which the specimen is bent (ASTM D 4145: Test Method for Coating Flexibility of Prepainted Sheet).

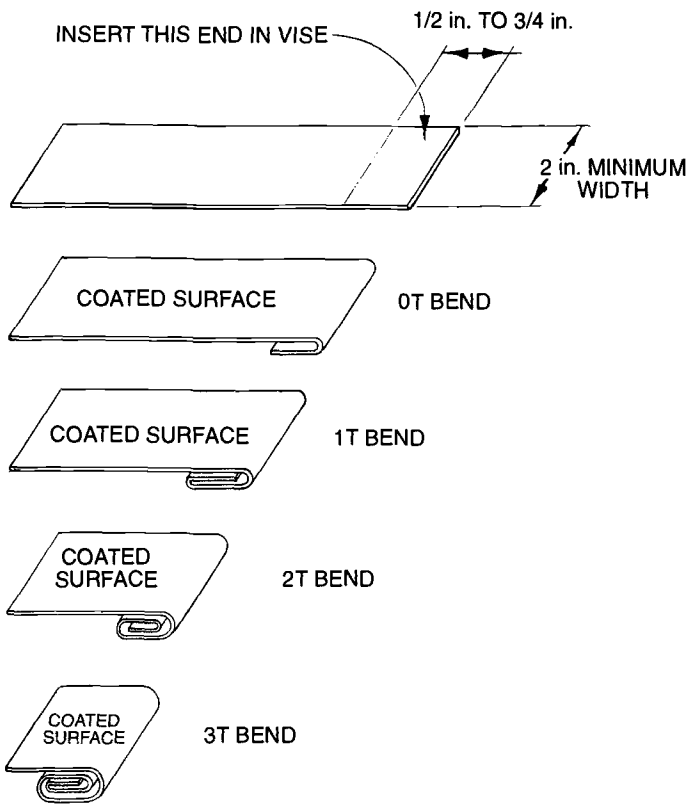

FIG. 5–T-Bend test in which the coated specimen is bent around itself (ASTM D 4145: Test Method for Coating Flexibility of Prepainted Sheet).

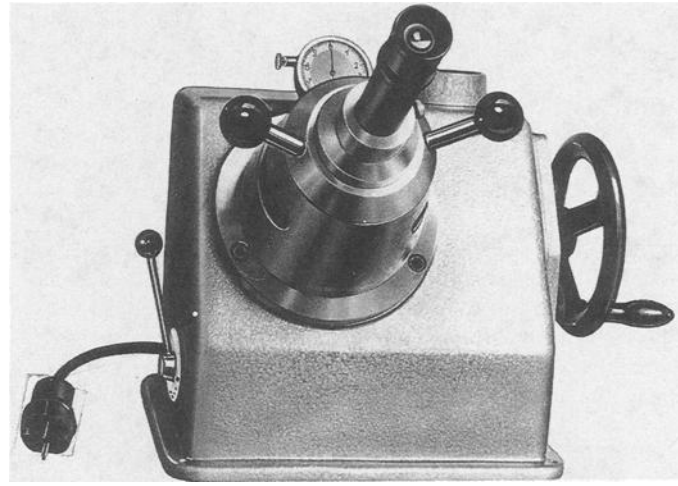
Test results are reported as passing the smallest T-bend on which cracks are observed. In some cases, cracking can be detected by removal of a pressure-sensitive tape placed on the bend edges and observing the degree of removed coating particles. ASTM Test Method for Coating Flexibility of Prepainted Sheet (D 4145) describes this test procedure.



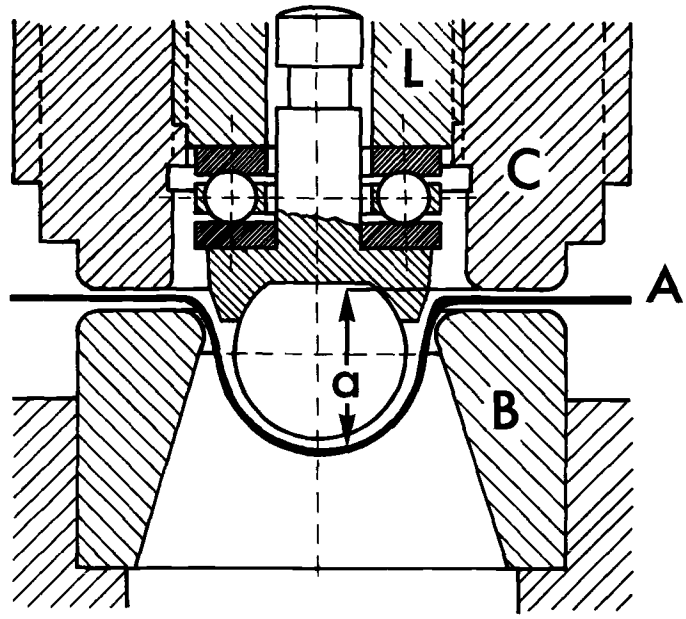


FIG. 6–Erichsen Cupping Tester (early model).

Cupping Tests

A relatively slow rate of forming test can be conducted with a cupping tester that pushes a punch into the unpainted side of a coated panel until the increasing deformation produces cracks in the coating. Test procedures are given in ISO TC 35, BS 3900 E4, NFT 30-019, SIS 18 41 77, DIN 50 101, and DIN 50 102. There are six models of Erichsen Cupping Testers; they provide different test conditions to simulate different forming operations. Two of these models are shown in Figs. 6 and 7. BYK-Gardner Cupping Testers are also suitable for conducting these test procedures (Fig. 8). The BYK-Gardner devices use a spherical punch and provide a range of cupping speeds. The maximum cupping depth is approximately 18 mm (0.7 in.). The cupping action is stopped when cracking in the coating is visually detected. The depth of cupping at that point is indicated on a digital display and is considered to be the flexibility rating. The cupping tester can be equipped with a stereo microscope for observing the onset of cracking.

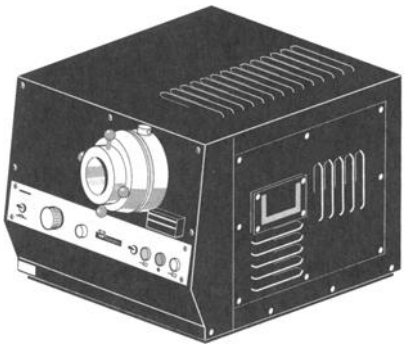

FIG. 8–BYK-Gardner Cupping Tester.

Forming Tests

In many industrial operations, metal is coated flat and then formed into various shapes by drawing the coated metal. This can be simulated directly or by elongating a coated metal sheet. A testing machine that has provided useful formability evaluations is the Erichsen Stamping Testing Machine (Fig. 7). It provides deformations in a few seconds by application of high pressure to a stamping tool. The stamped coated metal is examined for cracking as a "pass/fail" test.

Any tension testing instrument capable of rapidly elongating a metal strip can be used for determining drawability. A coated metal strip would be elongated at a high rate of strain until cracking occurs. The elongation would be measured with an extensiometer [*1*]. Drawability would be reported as the percent elongation obtained just before cracking is observed. Since elongation is rate dependent, the rate of elongation used should be reported.

ASTM Test Method for Formability of Attached Organic Coatings with Impact-Wedge Bend Apparatus (D 3281) describes a procedure for determining the formability of coated metal strips using an impact wedge bend apparatus termed the Coverall Bend Tester (Fig. 9). At the start of the test, the coated panel is bent 170 to 180° over a ⅛-in. (3.2 mm) cylindrical mandrel attached to an impact platform. The platform is adjusted to provide a taper of 0 to ⅛-in. This allows the platform to create a wedge that provides stress angles between 170 and 180°. The end of the coated panel with the 180° stress angle is defined as having 0T bend. The height of the impacter is adjusted until the load to produce a 0T bend is determined. The distance of the cracking produced in the coating by the impact is measured from the edge of the most severe bend outward to the edge of the least severe bend. The amount of film removed from the coating is indicative of its lack of formability.

ASTM Test Method for Formability of Zinc-Rich Primer/Chromate Complex Coatings on Steel (D 4146) also provides a procedure for determining the formability of coated strip metal. An outline of a testing machine that can produce a sufficiently high pressure for pressing a 1⅝-in. (41-mm)-diameter indenter ball into the coated metal is provided. The rate of forming can be adjusted over a range of 0.2 to 1.0 in./min (4.8 to 25 mm/min). A dial gage monitors the movement of the indenting ball. Adhesive tape is applied over the dome formed in the metal, and the tape is rapidly removed. The amount of coating removed is given a rating by comparing it with a set of photographic standards.

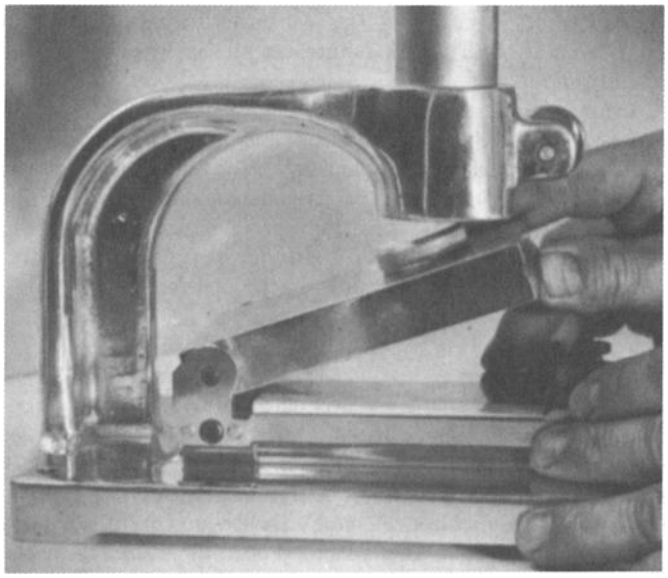

FIG. 9—Coverall bend test. After specimen is bent over a ⅛-in. mandrel, the bent portion is shaped into a wedge when a more severe test is needed (ASTM D 3281: Test Method for Formability of Attached Organic Coatings with Impact-Wedge Bend Apparatus).

Impact Resistance Tests

The most commonly used impact testers drop a weight onto an indenter resting on the surface of a coated panel that is resting on a platform (Fig. 10). A die in an opening in the platform allows the panel to be pushed down by the indenter to form a dimple in the panel. The weight is dropped through a guiding tube whose height is marked in increments.

There are a number of possible combinations of weights, indenter sizes, die sizes, and weight heights that can be used in performing impact tests. The tests can be performed by impacting either the coating directly (coating facing upward) or indirectly (coating facing downward).

Cracking observed on or around the impact-produced dimple is considered failure, and the force to produce the cracking is given in inch-pounds (killigrams-meters), that is, weight times height. The test can be performed either to determine the inch-pounds required to produce cracking or to determine whether a coating passes or fails at a specified inch-pound value. ASTM Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact) (D 2794) describes such a test procedure and offers three procedures for determining the degree of cracking produced in an impact deformation: (a) visual inspection with a magnifier, (b) visual inspection after application of an acidified copper sulfate solution, and (c) use of a pin hole detector.

The General Electric Impact Flexibility Tool is used for simultaneously making several indentations of different sizes. From these indentations, conclusions can be made regarding crack resistance and the amount of draw that a coating applied to sheet metal can tolerate. This tester consists of a steel cylinder that has knobs (segments of spheres) of different radii machined on each end. The cylinder is dropped onto a coated panel that is supported coating side down by a rubber pad. The height of drop is adjusted so that the boundary of the cylinder is just discernible. This procedure assures that each knob is used to its limit. Eight knobs cover a range of 0.5 to 60% elongation. See Federal Test Method Standard 141C, Method 6226.

ASTM Test Method for Impact Resistance of Pipeline Coatings (Falling Weight Test) (G 14) describes a test procedure for determining the impact resistance of pipe coatings. A fixed weight of 3.0 lb (1.36 kg) and having a ⅝-in. nose diameter is dropped through a guide tube onto a coated pipe specimen. The height of the weight is adjusted until the minimum height at which cracking appears is attained. A pin hold detector is used to determine the presence of cracks in the impacted pipe. An equation is given for calculating the impact resistance from the weight and its height of drop required to just produce cracking.

A different type of impact tester was developed and is being used at the Bell Laboratories of AT&T (Fig. 11). A coated panel is subjected to repeated glancing blows by a case-hardened steel ball at the end of a short arm that is pivoted to another arm connected to a rotating shaft. During the test, the coated panel is mounted on a platform that moves so that successive blows do not strike the same spot. The energy level of the blows may be held constant, as in a "pass/fail" test, or it

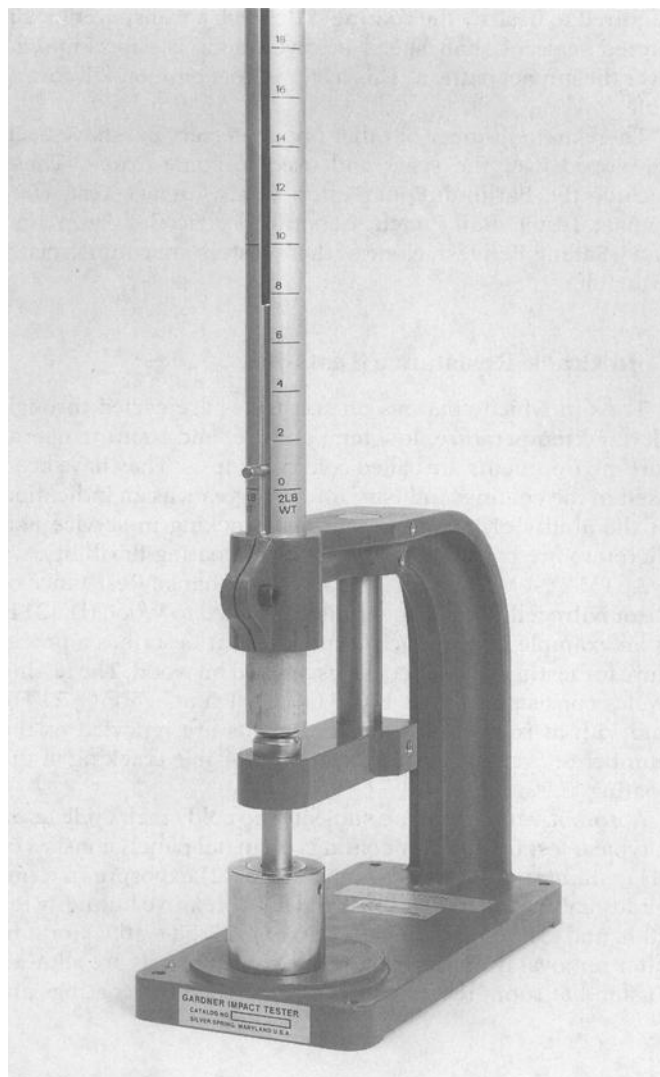

FIG. 10—Gardner impact tester, a falling weight impact tester.

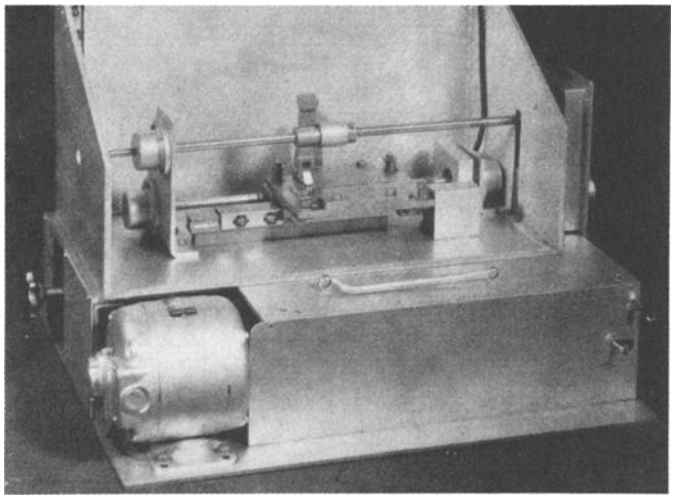

FIG. 11—Bell Laboratories impact tester and specimen. Ball on end of the rotating arm repeatedly strikes specimen, which is moving from left to right (courtesy of Bell Laboratories) [*1*].

can be adjusted by changing the speed of the rotating shaft to determine the onset of cracking. If the hammer energy level required to destroy the coating is desired, a transparent, calibrated scale of shaft speed in revolutions is superimposed over the impact pattern. This tester is not commercially available.

There are a number of other impact testers that have been developed over the years and used to some extent. These include the Parlin-duPont Tester, Camp Impact Test, Hart Impact Tester, Ball Punch, General Electric Ball Drop, and Navy Falling Ball test. None of these testers are commercially available.

Cold Crack Resistance Tests

Tests in which coatings on substrates are cycled through elevated temperature, low temperature, and room temperature environments are called cold crack tests. They have been used in the coatings industry for many years as an indication of the ability of a coating to resist cracking in service and therefore are considered to be tests of coating flexibility.

ASTM Test Method for Temperature-Change Resistance of Clear Nitrocellulose Lacquer Films Applied to Wood (D 1211) is an example of such a cold crack test. It describes a procedure for testing lacquer coatings applied on wood. The testing cycles consists of 1 h at 120°F (49°C), 1 h at −5°F (−21°C), and ½ h at room temperature. Results are reported as the number of cycles required to produce visible cracking in the coating.

Automotive coatings are subjected to cold crack cycle tests. A typical test for exterior coatings on metal panels consists of (1) equilibration at room temperature, (2) exposure in a humidity cabinet at 100°F (38°C) and 100% relative humidity for 20 h, and (3) exposure in a freezer at −22°F (−30°C) for 4 h. After removal from the freezer, the coated panels are allowed to stand at room temperature for 2 h. Then the coatings are visually rated for cracking. In some cases, an exposure of 2 h in an oven at 150°F (65°C) is introduced into the above cycle conditions.

A rapid cold crack test that has been developed is based on the use of cooled air entering a transparent, insulated box. Cold air that has been cooled at a rapid controlled rate is introduced into the box, and the coatings are observed for cracking. The coatings are then rated by determining the temperature decrease from room temperature that is required to produce visual cracks in the coatings [*4*].

Effects of Aging and Weathering

The ultimate measure of satisfactory flexibility and toughness of a coating applied to a substrate is performance under service conditions. Most flexibility and toughness tests are performed on relatively fresh-coated panels, that is, tests are usually performed after the panels have been conditioned in a specified atmosphere for a specified period between 24 h and seven days. The results obtained are applicable to service conditions if these are concerned with post forming or service indoors without a degrading atmosphere, since most coatings do not change appreciably in their physical service properties under such conditions. However, if the service conditions include exposure to weathering, this factor can cause appreciable changes to occur in the coatings properties.

The effects of moisture, temperature changes, and exposure to sunlight (ultraviolet wave lengths) encountered in outdoor exposure generally reduce the flexibility and toughness of organic coatings. Therefore, it often is desirable to conduct tests for flexibility and toughness after periods of weathering to determine how a coating will perform under actual weather conditions [*1*].

Hardness

by Paul R. Guévin, Jr.[1]

PHYSICAL CONCEPTS OF HARDNESS TESTING

HARDNESS IS A TERM HAVING a different meaning to different people. It is resistance to penetration to a metallurgist, resistance to wear to a lubrication engineer, a measure of flow stress to a design engineer, resistance to scratching to a mineralogist, and resistance to cutting to a machinist. While these actions appear to differ greatly in character, they are all related to the plastic flow stress of the material, i.e., Young's Modulus, Y [*1*]. K. Sato wrote an overview paper on the hardness of coating films [*2*] which merits mentioning and reviewing.

Hardness is not a fundamental property of materials but a composite one dependent on the elastic moduli, elastic limit, the hardening produced by "working" a metal, etc. Empirical relationships are used to determine other properties from the easily measured hardness, but all such schemes are of doubtful or limited validity.

Hardness testing can be a very useful tool for studying modern materials, but it is plagued by well-known experimental difficulties. Reasons for the unusual behavior of hardness data at very low loads are explored by Monte Carlo simulation, which will be discussed later. These simulations bear remarkable resemblance to the results of actual hardness experiments. The limit of hardness as load or indentation depth tends to zero, which is shown to depend on experimental error rather than upon intrinsic material properties. The large scatter of hardness data at very low loads is ensured by the accepted definition of hardness. A new definition of hardness is suggested which eliminates much of this scatter and possesses a limit as indentation depth approaches zero. Some simple calculations are used to show the utility of this new approach to hardness testing.

Over the years, many methods and devices have been employed to measure the hardness of organic finishes. P. C. Wheeler, chairman of a technical committee within the Dallas Paint and Varnish Production Club, as it was called then, reported [*3*] the results of a survey of findings concerning how coating hardness is measured. Following this survey, the first meeting of what is now called ASTM Task Group D01.23.14, Hardness, Mar and Abrasion Resistance, was held in June 1947. The Hardness Group of Subcommittee XVIII, as they were called at the time, of Committee D-1 was organized in Atlantic City to provide an opportunity for expression of opinions by those present concerning their understandings of concepts that were connoted by hardness as applied to organic coating films.

The consensus was that the subject of hardness is very complex. Several of the characteristics of an organic film are simultaneously judgmentally weighed in order of relative importance to obtain the usual expression of hardness judgment. The same physical characteristics of films were employed, and the weighing importance of the various characteristics chosen is not carried out in the same manner; choices are operator dependent and are based on experience with results in practical use of the material.

At the time of this first meeting in 1947, the purpose of the group was to (1) study the subject of hardness and attempt to define some of the physical properties or attributes of an organic coating which affect hardness, (2) limit the study to the development of procedures for measuring the attributes of film hardness, and (3) further evaluate limitations to smooth films of organic coatings as they are normally applied on a substrate. Switzer [*4*] conducted a survey to determine which methods were being used by the coatings industry to measure hardness. They found that some form of scratching or abrasion was used 84% of the time, pendulum or damping hardness (also referred to as entropy hardness) 56% of the time, and indentation hardness 20% of the time. The percentages total more than 100% because some companies surveyed use more than one procedure to evaluate hardness. In 1991, ASTM Task Group D01.23.14 conducted a similar survey. The study showed pencil hardness to be the most commonly used test method with the Sward-type rocker method the next most widely used [*5*]. The modern trend in industries as a whole has been towards an increasing use of indentation methods.

Scratch Hardness

Scratch hardness is the oldest form of hardness measurement and was probably first developed by mineralogists. Back in 1822, F. Mohs [*6*] evaluated comparative scratch hardness of many materials. Assuming the liquid state to be equivalent to "zero" hardness, he arranged solid materials into ten hardness groups, rating them as follows: talc, 1; gypsum, 2; calcite, 3; fluorite, 4; apatite, 5; orthoclase, 6; quartz, 7; topaz, 8; corundum, 9; diamond, 10. As the system was set up, any material of a given Mohs hardness number could scratch any other material with a lower Mohs hardness, and about 99% of all known materials have hardness ranging from Mohs 1 to 9. However, the Mohs scale, though conve-

nient to apply, is essentially qualitative in nature. The wide variety of hardness test procedures that have been used may be described by the following sections.

As user demands for improved resistance to scratch and hardness increased for applications such as automotive finishes, high-performance coatings were developed and became more widely used. As the primary objective was to improve the surface hardness rather than resistance to deformation of the coating, scratch resistance tests were examined [7]. The coatings industry developed, adapted, or adopted various instruments and test methods, which are described below.

Bierbaum Microcharacter—This instrument, designed by C. H. Bierbaum [*8-12*], has a polished prismatic diamond cube (diamond pyramid) held in an elastic support as a scratching tool. It is a rather elaborate device consisting of a microscope, stage, and diamond tool on a balanced arm. The sharp point is the corner of a cube, one edge of which acts as a leading edge, being inclined to the horizontal surface of the specimen at 35.25°. The lubricated specimen is slowly moved under the point, and the standard load is 3 g. The scratch width w in micrometre is measured under a microscope according to recommendations made by the inventor, and several readings are averaged to give:

$$\text{Bierbaum Microhardness} = \frac{10^4}{w^2} \qquad (1)$$

Bierbaum scratch hardness is the ratio of the load on the diamond, in kilograms, to the square of the scratch width (w), in millimetres. It was marketed in the United States by the American Optical Company primarily for testing the hardness of metals. It had been used on plastics [*13*] but never gained general acceptance for use on organic finishes.

In 1958, ASTM Committee D-20 on Plastics adopted D 1526-58T, Tentative Method of Test for Bierbaum Scratch Hardness of Plastic Materials. Their published [*14*] statement said:

> This method fills a need for a test to determine the relative resistance of a plastic surface to defacement by a sharp abrasive particle as occurs in tableware, optical elements, and similar applications.

When the Bierbaum Microcharacter Hardness Tester wasn't useful any more for ASTM purposes, it was withdrawn in 1964.

Clemen Scratch Hardness Tester—The current instrument, shown in Fig. 1, is marketed by Erichsen GMBH & Co. This device is available in two versions: hand-operated and motor driven. Both determine the scratch resistance of protective surface coatings, such as paint and lacquer finishes, plastic coatings, etc. It consists of a sliding test panel carrier mounted on a base frame. A scratching tool is fixed at the end and a sliding weight in the middle of a counterpoised lever that is supported by two pillars. Operated by means of a dropping and lifting mechanism, the scratching stylus or needle is moved along the test surface during the working stroke, but is lifted for the return traverse.

The weight-loaded blade or ball-shaped carbide tool is applied with a defined force (0 to 20 N) to the specimen, which is moved with constant speed. The scratch hardness is measured by the force necessary to cut through the coating to the substrate. It is operated manually or uses a motorized drive. Suitable scratching tools are: the Clemen scratching stylus, a chisel-shaped tool with a tungsten carbide edge, or a scratching needle according to Danske Elværkers Forening (DEF) 1053, Method 14, which is an inexpensive, ball-shaped, hardened-steel tool easily replaced when worn.

Dantuma Scratch Tester—This device was developed in 1940 by H. Dantuma in the physical laboratory of Sikkens (now Akzo-Sikkens) [*15,16*]. It employs a novel means of increasing the load during travel of the scratching tool across

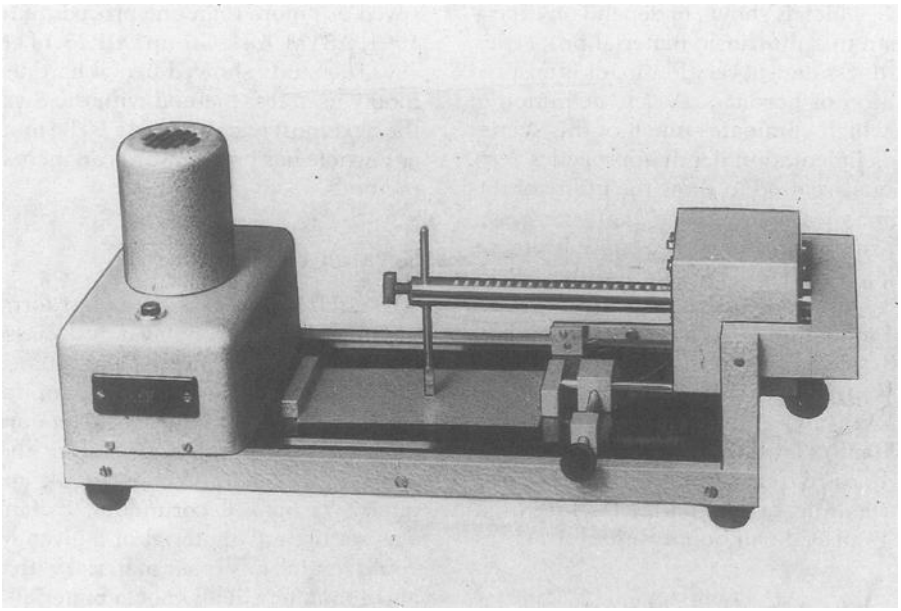

FIG. 1–Clemen Scratch Hardness Tester. (Courtesy of Erichsen GMBH & Co.)

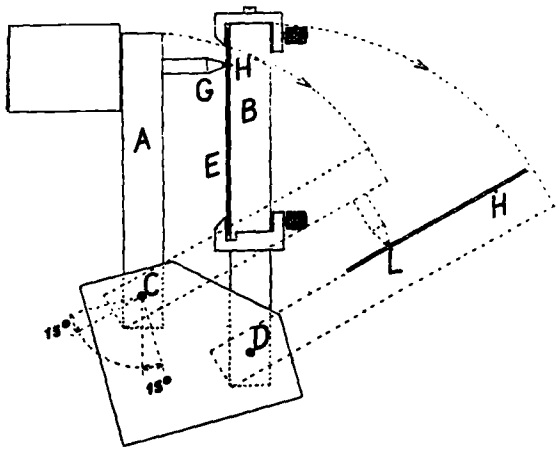

FIG. 2–Dantuma Scratch Tester. (Figure from previous edition of this manual.)

the film. Referring to Fig. 2, as Arm B, with Tool G resting on Panel H, is lowered, Arm A follows. The scratching tool travels from H to L, a distance of 5 cm. The load varies from 0 to 5000 g. Operation may be by hand crank or motor. Four types of hardened-steel scratching tools are provided: a ball 1 mm in diameter, a simulated finger nail, and two wedges. The Dantuma Scratch Tester was never produced for distribution.

du Pont Scratch Testing Machine—This type of instrument was once used at the du Pont lacquer plant at Parlin, New Jersey, for determining the hardness of lacquers and their resistance to scratching. It was one of the first to electrically signal the end point of the test. It is shown in Fig. 3.

The device consists of a wooden base on which is mounted: (1) a fulcrum holding a graduated level equipped with weights and a needle point, (2) a transformer, (3) a 6-V lamp, and (4) a metal plate. These parts are connected in series, the transformer being used to step down ordinary light voltage to that of the small lamp. The metal panel, coated with lacquer, is placed coated side up on the metal plate under the needle. The weight is adjusted, and the panel is drawn along the plate in the direction of the long axis of the instrument. This operation is repeated, each time using an increased weight, until the needle penetrates the film. When this happens, the electric circuit is closed, and the lamp lights.

Erichsen Hardness Tester—The Erichsen Company [*17*] markets a pocket-size hardness tester, Model 318, shown in Fig. 4, that somewhat resembles a mechanical pencil in appearance. It has three tungsten carbide hemispheres or ball points 0.5 mm (Opel), 0.75 mm (Bosch), and 1.0 mm (to relate to International Standardization Organization [ISO] 1518) in diameter that are spring loaded. Holding the instrument upright and placing its point on the test surface, one draws a 5 to 10-mm-long line at a rate of approximately 10 mm/s. The stylus should produce a scratch that is just visible. By locking the slider each time, one can control the applied pressure, which is marked in newtons. Thus, one can gradually approach the correct setting. Three scales are engraved into the pencil for the three pressure ranges: 1.0 to 3 N (accuracy 0.1 N), 2.0 to 10 N (accuracy 0.5 N), and 3.0 to 20 N (accuracy 1.0 N). The hardness is defined as the minimum load or force, in g, on the ball point, that leaves a mark in the surface just visible to the unaided eye [*18*].

Graham-Linton Hardness Tester—This device, illustrated in Fig. 5, might also be considered an adhesion tester. As shown in the figure, it is essentially a small, circular blade upon which pressure is exerted by a coil spring. A scale, graduated in 100-g increments from 0 to 2000 g, indicates the load on the blade.

Hoffman Scratch Tester—The Hoffman Tester is one of the "old line" instruments in the paint industry and comes as close as any instrument to date of being "the paint chemist's educated knife." Figure 6 shows the original instrument that was developed and patented [*19*]. There is a low carriage with a weighted level on one end. The scratching tool is a sharp-edged, hardened-steel cylinder with its axis at an angle of 45° to the plane of the film. This cylinder is attached to the lever arm, and the load is varied by varying the position of the weight on the lever. This instrument has been used for adhesion and mar resistance tests. A General Electric Company test method [*20*] and a federal test method [*21*] specify how the instrument is to be used. Figure 7 shows the refined instrument. The edge of the hardened-steel tool is positioned at 45° with respect to the test surface and can be loaded at any value between 0 and 250 g or 0 and 2500 g. The Hoffman Tester, when used in the lower range of up to 250 g loading, has been used for determining scratch resistance of a surface coating. It has had its greatest application, however, in the high range, up to 2500 g, for cutting completely through the coating to the support surface for measuring such properties such as degree of cure and adhesion.

In use, the desired loading is set on the cutter dial, and the lower edge of the instrument is held against the test surface to

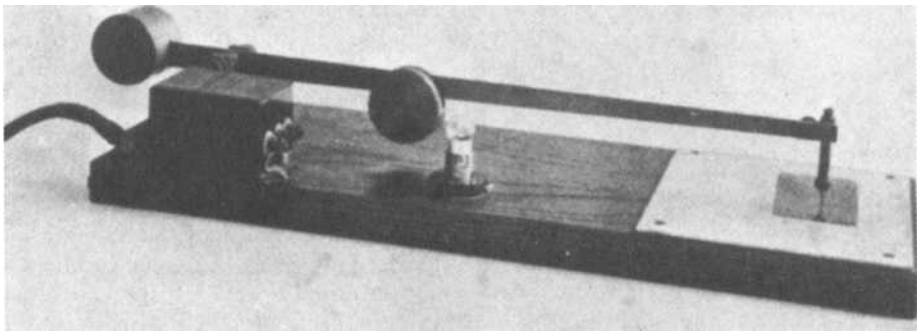

FIG. 3–du Pont Scratch Testing Machine.

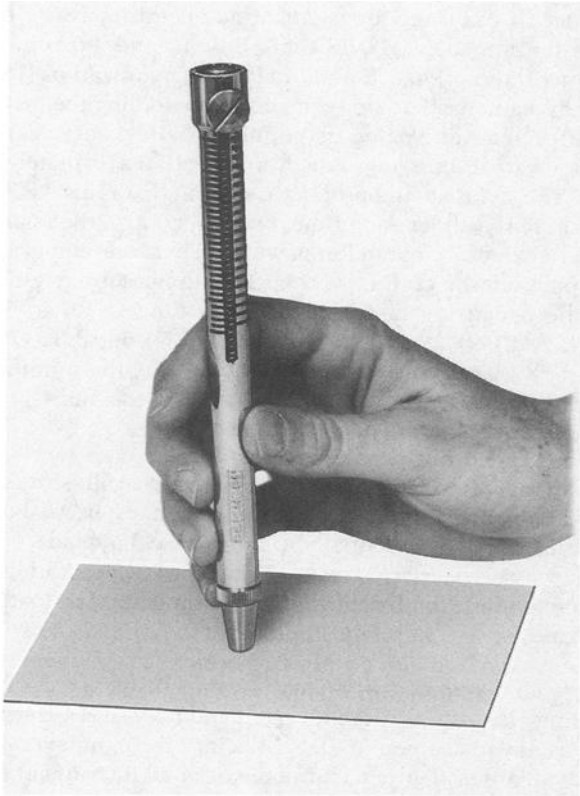

FIG. 4–Erichsen Model 318 Hardness Tester. (Courtesy of Erichsen GMBH & Co.)

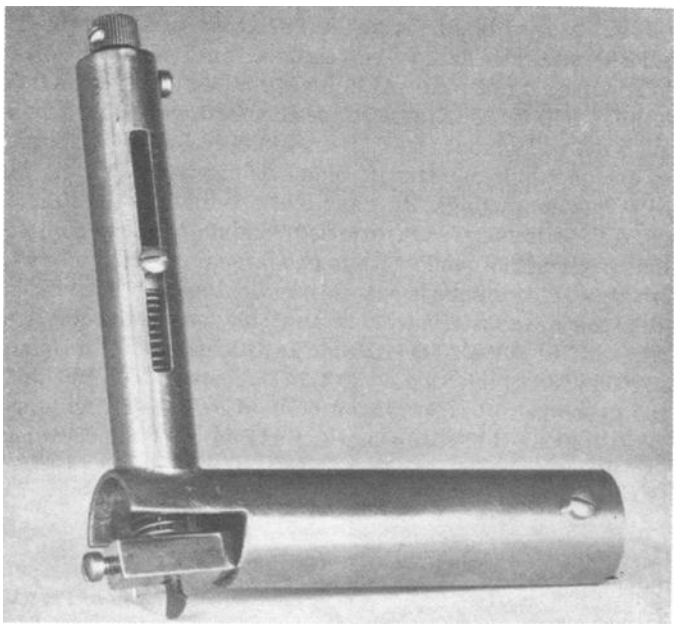

FIG. 5–Graham-Linton Hardness Tester.

ensure uniform contact. While held in this position, the instrument is drawn in a direction away from the cutter. The nature of the mark left by the cutter, if any, is observed, and the test may then be repeated at a different cutter loading.

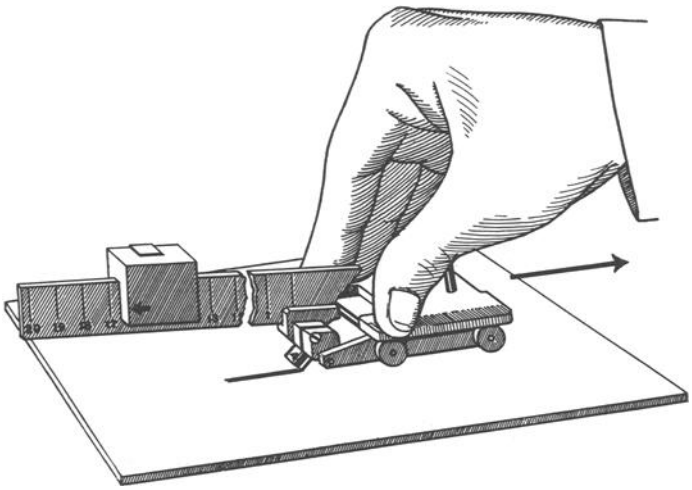

FIG. 6–Original Hoffman Scratch Tester.

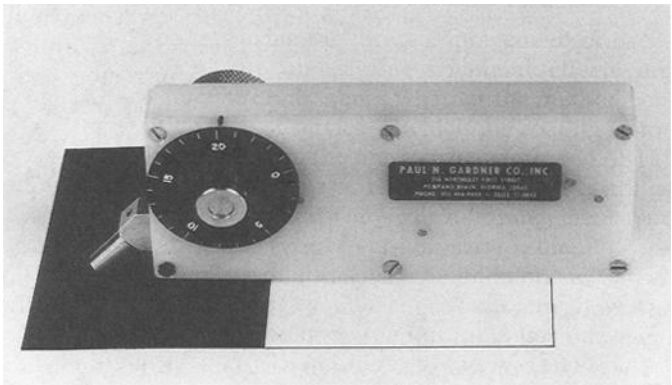

FIG. 7–Current Hoffman Scratch Tester. (Courtesy of The Paul N. Gardner Company, Inc.)

Inspector's Dur-O-Test Pocket Size Hardness Tester—The Inspector's Dur-O-Test Pocket Size Hardness Tester, shown in Fig. 8, is a simple pocket instrument used to evaluate the vulnerability (scratch hardness) of surfaces such as coatings, varnishes, plastic coverings, etc. Especially valuable for quick "on line" tests in plants, paint shops, building sites, etc., it determines the force required to scratch or scar a surface with a defined spherical tool. It consists of an engraving needle with spherical tip of tungsten-carbide of 0.75-mm (0.03-in.) diameter. The spring tension of the tip can be altered and set with a fixing device. The instrument has three interchangeable springs. The limitation is an inability to test elastic coatings.

In the operation, the scratch needle extends slightly out of the jacket. A line is drawn on the surface to be tested in 1 s while maintaining sufficient pressure to keep the needle against the rod stop. If the tension is high, the surface will be clearly marked. If low, there will be no mark. The correct tension will result in a barely visible mark.

Laurie-Baily Hardness Tester—This apparatus [*22*], shown in Fig. 9, was among the first to be developed for films and was invented by A. P. Laurie and F. G. Baily of Heriot-Watt College, Edinburgh. The apparatus consists essentially of a hardened, blunt steel point upon which pressure is exerted by

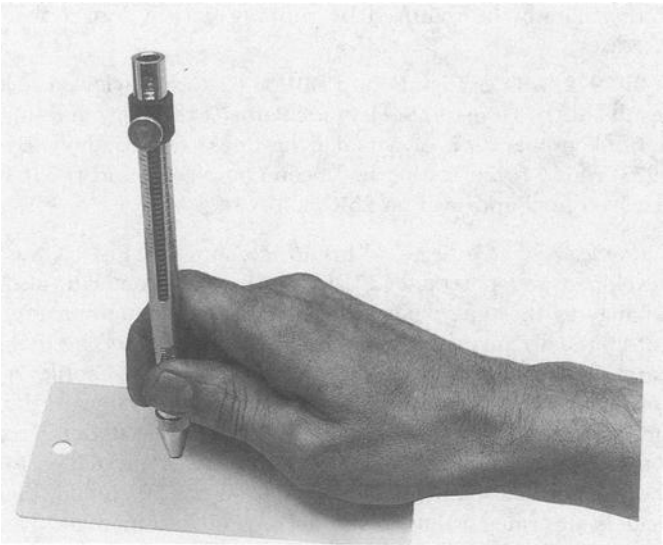

FIG. 8–Inspector's Dur-O-Test Pocket Size Hardness Tester. (Courtesy of The Paul N. Gardner Company, Inc.)

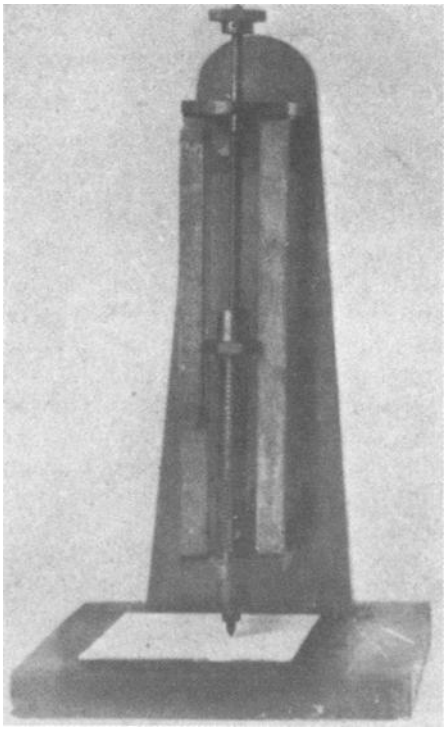

FIG. 9–Laurie-Bailey Hardness Tester.

a vertical coil spring. The spring tension is controlled by an adjusting screw and can vary from 0 to 2000 g. The finish to be tested is placed under the point and slowly moved horizontally by hand as the pressure is increased until a scratch is made. Then the scale readings are recorded.

Parker-Siddle Scratch Tester—This tester is a very simple form of the Schopper type in which the load on a needle is increased as the scratch is made. The point of the needle is a hemisphere 0.2 mm in diameter. The panel carrier is moved by hand, the speed recommended by Parker and Siddle being 30 cm/min. Appreciably greater speeds give inconsistent results.

Pencil Hardness Tester—Rating the hardness of an organic finish according to the hardness of a lead (graphite) pencil that will just scratch it was described by Wilkinson [*23*]. Gardner [*24*] studied the method using pencils sharpened to different shapes: sharp cones, rounded cones, and chisels. He found the principal source of error lay in the character of the point because it was difficult to reproduce points. Other sources of error were the pressure on the pencil and the angle at which the pencil was held while it was moved over the organic finish. Gardner built a device to hold eight pencils at one time at an angle of 45° to the panel, but found that it was impossible to align all pencils uniformly. Modern production has overcome this problem, and several companies offer a pencil hardness gage composed of eight mechanical drawing lead holders (pencils) permanently mounted in a circular array on a plastic cylinder. A small metal tube through the center of the cylinder provides storage for spare leads and a guide for positioning pencils for a test.

ASTM Test Method for Film Hardness Test (D 3363) is practical for laboratory use, for use on a production line, or in the field to assess quantitatively the rigidity or firmness (elastic modulus) of organic coatings applied to rigid substrates such as metal or plastic. Hardness values may define requirements for particular coating applications or may be used to evaluate state of cure or aging of a coating.

In this test, pencil leads of increasing hardness values are forced against a coated surface in a precisely defined manner until one lead mars (marks) the surface. Surface hardness is defined by the hardest pencil grade which fails to mar the organic coating surface.

Today, pencils are available in about 14 different grades of hardness, ranging from the softest, 6B, to the hardest, 6H, although hardnesses greater than 6H have been available. Pencil leads are blends of graphite, clay, and binders. They range in hardness from softest to hardest as follows: 6B, 5B, 4B, 3B, 2B, B, HB, F, H, 2H, 3H, 4H, 5H, and 6H. Over the years certain features of the method have been standardized. They are:

1. The lead is "squared" against fine abrasive paper (as opposed to a sharp, fine point).
2. The pencil is held at an angle of 45° to the surface of the test panel.

Variations in the method have occurred with respect to how the test is actually carried out. Smith [*25*] made a study in 1956 and used the following method:

1. Strip the wood from the lead for a distance of approximately ¼ in. (6 mm) using care not to nick the lead. Square the exposed lead by a gentle rotary motion against No. 400 carbide abrasive paper.
2. Hold the pencil in a writing position, that is, at approximately 45° and push forward against the film. Use pressure short of breaking the lead. By turning the pencil after a test, a new edge is available for use, and three or four trials may be made with one dressing of the lead.
3. Clean the marks with a soap or "artgum" eraser. Any marring of the surface, visible at an oblique angle in strong

light, indicates that the pencil is harder than the film. The hardness is expressed as the grade of the next softer pencil.

In developing this method, Smith determined the pencil hardness of 14 different organic finishes that varied widely in hardness. Five different brands of pencils were used, and the results are shown in Table 1. The results indicated that there were variations in hardness between different brands of pencils and that it was necessary to use only one brand to obtain reproducibility.

Smith also compared the Knoop hardness and Sward rocker hardness versus pencil hardness of the 14 organic finishes. These results, also in Table 1, showed that pencil hardness rated the various organic finishes in the same order of hardness as the two other more elaborate methods. This is interesting because, according to Smith, three widely different mechanisms were involved. They are:

Sward rocker = deformation *within* the elastic limit.
Knoop hardness = deformation *beyond* the elastic limit.
Pencil = deformation beyond the elastic limit and tearing away of material.

Smith's work provided a broad foundation for the pencil hardness test, and many features of his method are used today. It was the exact manner in which the pencil was applied to the test that was never adopted.

Those test methods which have been adopted and are used almost universally were outlined by the Houston Society for Coatings Technology [*26*] in 1966. The Houston Society described two basic methods, which were:

1. *The Disbonding Method* in which the pencil, at an angle of 45°, is pushed into the organic finish. The organic finish is considered to have failed when a pencil removes chips, flakes, scales, or shears the finish from the substrate without breaking the lead of the pencil. This method has also been an adhesion test.
2. *The Indentation Method* consists of using the pencil as an indentation instrument by drawing the point (at an angle of 45°) across the film to produce a continuous indentation. The Houston Society developed a special carriage to hold the pencil and apply a load of 200 g to it while the carriage was being drawn across the test panel. The organic finish is considered to have failed when the pencil leaves an indentation in the film (visible under a ×15 magnifying glass) that cannot be removed by rubbing with a soft rubber eraser.

In 1972, ASTM Task Group D01.53.02 Cure reviewed the results of the Houston Society for Paint Technology and undertook preparation of a pencil hardness test method. By 1973, round-robin testing had been completed, and D 3363 received final approval on 25 Oct. 1974.

Rondeau Scratch Tester—This device, shown in Fig. 10, was developed and patented [*27*] by Herbert F. Rondeau, also belongs to the type where the load on the scratching tool automatically increases as the test is being made. The tool, parabolic in shape, is mounted on the free end of a cantilever spring, one end being moveable in a slot in the frame. At the start of a test, the tool rests on the test surface under zero load. The finish end of the slot is 0.100 in. (2.5 mm) nearer to the test surface than it is at the start. At the finish end, the load is the rated value of the spring. At intermediate distances, the load is proportional to the distance. Three springs are provided, giving loads of 300, 600, and 1200 g at the finish end.

Scheppard-Schmitt Scratch Dynamometer—The principle of this device was employed by Eastman Kodak's S. E. Scheppard and J. J. Schmitt [*28*] in the development of a new scratch hardness instrument. The scratching tool is a hardened steel, 45° tetrahedron.

Measurement of scratch resistance is expressed as the threshold load producing a scratch or by a curve expressing the relation between the load and size (width) of the scratch.

Schopper Hardness Tester—This device [*29*], shown in Fig. 11, was one of the first to provide for automatically increasing the load on the scratching tool while the scratch is being made. Arms extending upward from the panel carrier end in slots above the beam carrying the scratching tool. A roller resting on the beam is guided by the slots. As the panel carrier is drawn along, the roller travels with it, thereby increasing the load on the scratching tool. Provision is made for automatically lifting the load from the specimen at the end of each trip and also for a sidewise displacement of the specimen to provide a new path for repeat tests. The interpretation of results is the same as with other types of scratching devices, that is, according to the character of the mark under a partic-

ular load or tool, or the load at which a particular tool makes a mark.

Sheen Scratch Tester—This instrument determines the scratch resistance (i.e., scratch hardness) of paint coatings and is designed to meet the requirements of the British Standards (BS) Method of Test for Paints (BS3900: Part E2). Its usefulness, however, extends beyond the rigid limits for operating conditions set by this authority as the test provides data outside the specification. Performance is related to many factors that include the hardness of the coating with other physical properties such as adhesion, lubricity, resilience, etc., as well as the influence of coating thickness and curing conditions. It is a quantitative indication of the extent to which serious damage is resisted when a loaded needle is raked across a relatively smooth, flat surface.

The instrument is shown in Fig. 12. The needle arm is counterpoised and rigid to prevent whip or chatter at the ball point. Weights totaling 2000 g and providing increments of 100 g from 100 g are supplied and additional weights are available. A total load of 6 kg can be used for very hard coatings. A 2000-g weight (or two) is useful for baked coatings. The 1-mm tungsten carbide-tipped needles are held in a chuck and can readily be removed for inspection and replacement.

Sikkens Scratch Hardness Tester—Sikkens Scratch Hardness Tester, Model 601, is marketed by Erichsen Company [*30*] and conforms to ISO 1518, BS 3900: E2 and Stichting Nederlands Normalisatie-Instituut (NEN) 5336. This device simulates a scratching or scouring action and creates stresses under controlled conditions that enable quantitative evaluation of the ability of coatings to withstand repeated horizontal and vertical abrasions. There are three scratching tools: a 1-mm cutting carbide sphere, a Clemen designed scratch cutting tool, and a VW designed scratch cutting tool; two speeds: 35 and 1 mm/s, and two load ranges: 0 to 20 and 0 to 90 N.

The test is performed by selecting a load which is applied to the cutter and can remain either constant in value or automatically increased at a linear rate. The weighted cutter is brought into contact with the coated surface at a constant speed, and it penetrates the coating when a critical force is attained. The force required to be applied to the tool to penetrate the coating and just touch the substrate is the measure at the scratch hardness. Testing using the automatically increased force shortens the test and quickly evaluates the scratch resistance at the coating.

Simmons Scratch Tester—This coating hardness measuring instrument [*31*] is another tester of the increasing load type and is suitable only for films on metal. When the stylus breaks through the film, a relay stops the machine. Hardness is reported as the weight necessary to penetrate the film.

Steel Wool Scratch Tester—The Panelgraphic Rotary Steel Wool Scratch Tester (Fig. 13) is constructed so scratch resistance may be measured using loads of 13 and 24 lb/in.^{2} (0.9 and 1.7 kg/cm^2) on the steel wool pad attached to a square testing foot of 1.25 in.^{2} (8.065 cm^2). The 0000 steel wool on the testing foot is then rotated for five revolutions, after which the sample is visually inspected for scratches in the coating and rated. The test then may be repeated in other locations to determine uniformity of the coating. This instrument is being removed from production and will not be available for purchase.

While this test may be acceptable for materials that are homogeneous or essentially homogeneous, when attempting to measure the scratch resistance of relatively thin coatings, other complicating factors arise. The measured scratch resistance of the coating is dependent upon factors independent of the coating itself, including the coating thickness and the substrate over which the coating is applied. Stated another way, scratch resistance is not an intrinsic property of a coating, and it may mean different things depending on how the property is measured. When attempting to measure only the resistance of a material to surface scratching, the concept of "mar resistance" comes into play.

Teledyne Taber Shear/Scratch Tester—Shear and scratch tests are significant because rigorous controls are exercised over these parameters affecting materials' resistance to shear and scratch. The unique Model 502 Teledyne Taber Shear/Scratch Tester [*32*] features three cutting tools: the S-20 tungsten carbide tool for shear testing and 139-55 and 139-58 diamond tools for scratch testing. The instrument is shown in Fig. 14. A tool is fixed to the underside of a beam pivoted on ball bearings. Riders provide for adjusting the load on the tool between 0 and 1000 g.

The test films for this tester are prepared on panels containing a hole in the middle for locating on a turntable. In making a test, the panel is rotated counterclockwise. Three tools are provided: "thumb-nail" contour shear tool (S-20) lapped to a

25-mm radius with a 30° clearance, a diamond cut to the shape (diamond pyramid) of a corner of a cube, and a diamond cut to the shape of a cone.

Wolff-Wilborn Scratch-Hardness Tester—This test apparatus, shown in Fig. 15, is another pencil method that belongs to the group of scratch-hardness testing instruments that is a simple and quick method for testing the surface hardness of coatings with regard to stresses inflicted by scratching with sharp edges or other rough surfaces. The speed of measuring even permits testing during the production, e.g., coil coating. The test instrument, Model 291, enables the test to be carried out in accordance with Wolff-Wilborn and ensures that the specified force and angle remain constant throughout. This

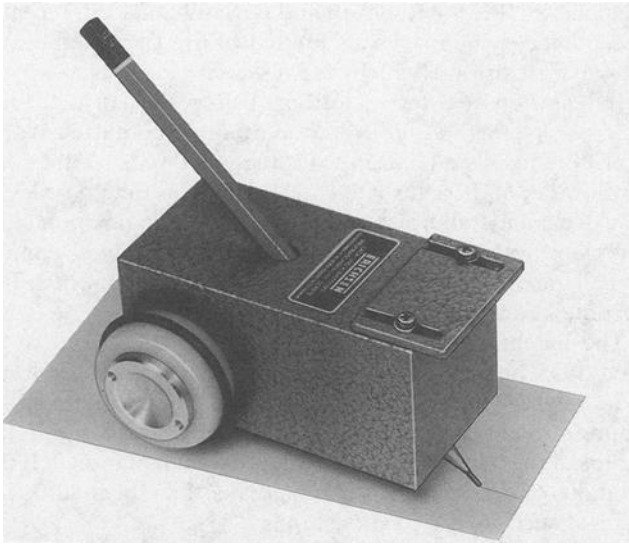

FIG. 15–Wolff-Wilborn Scratch Hardness Tester. (Courtesy of Erichsen GMBH & Co.)

instrument is specified in MIL C 27227, which has been discontinued as a specification.

In the test, pencils of various grades of hardness are moved over the painted surface at an angle of 45° to the horizontal with a 7.5-N (735-dyne) force. The softest pencil hardness that produces injury to the film is the Wolff-Wilborn hardness of the coating.

Universal Hardness and Adhesion Test Instrument—This Erichsen Model 413 hardness tester, shown in Fig. 16, will allow an operator to determine Clemen Scratch Hardness, Micro Scratch Hardness (mar resistance), and the Buchholz Indentation Hardness test Deutsches Institut für Normung e. V. (DIN 53 153) [*33*]. Like its name implies, it is a universal hardness tester.

Indentation Hardness

Microhardness testing has proved to be very popular in many industries because of its simplicity and nondestructive nature. It has been particularly successful for quality control work where it can be used as an indicator of surface durability and, in some cases, of strength. Static indentation hardness tests are "nondestructive" physical tests that employ either a ball, cone, or pyramid that is forced into a surface. The load per unit area of impression is taken as the measure of hardness. The testers use indentors classified by the following names: Brinell, Rockwell, Vickers, and Knoop. A sketch of these indenters is shown in Fig. 17.

The hardness of a material can be defined as a measure of its resistance to indentation. Basically, an indentation hardness test can be classified into two categories [*34*]:

1. Those based on a measure of the residual deformation after the indenter was removed.
2. Those based on the load-indentation characteristics.

Indention hardness values have been reported in a number of different ways, such as: depth of the indentation, the width of the indent, the load necessary to produce a specific depth or length of indent, the load divided by the projected, planar area of indent, etc. The load divided by the projected, planar area of indent is really an expression of pressure and has become the widely accepted method of reporting indentation hardness.

Consider the force on an annulus of radius x and the width dS. The load L is distributed over the contact area as a pressure P. The area of the annulus lying on the curved surface of the indentation is $2\pi x dS$, and the force on it is $P2\pi x dS$ and can be resolved into two component vectors, dH and dV. By conditions of symmetry, the horizontal component dH is an-

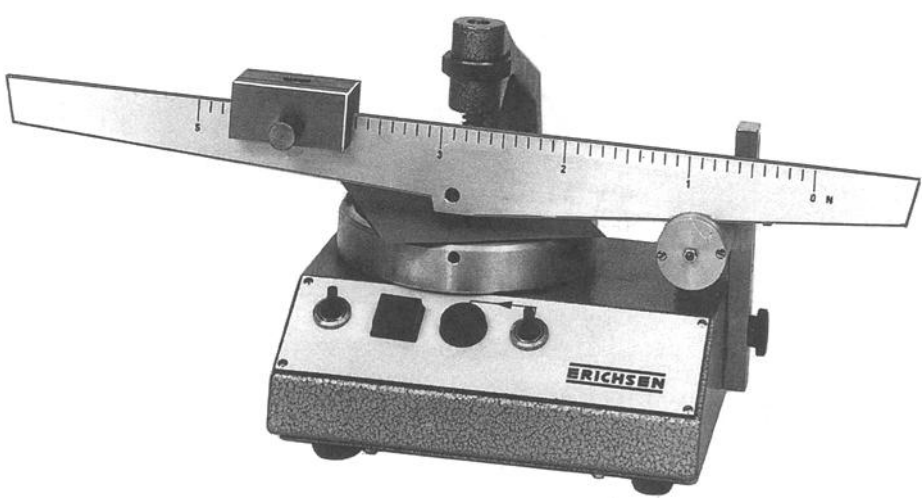

FIG. 16–Universal Hardness and Adhesion Test Instrument. (Courtesy of Erichsen GMBH & Co.)

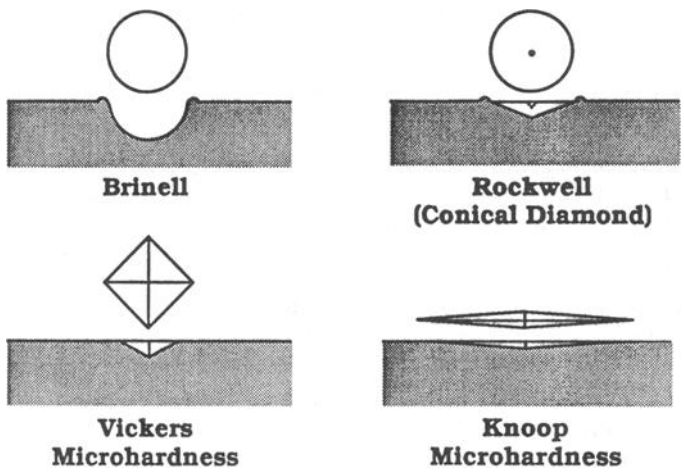

FIG. 17–Hardness indenters' geometries and indentation shapes. (Courtesy of Wilson Instruments, Inc.)

nihilated by an equal and opposite dH on the opposite side of the annulus. The vertical component dV is therefore $P2\pi x dS$ and

$$L = P\pi\frac{d^2}{4} \tag{2}$$

$$P = \frac{4L}{\pi d^2} = \frac{L}{A_p} \tag{3}$$

where P is the mean pressure and A_p is the projected, planar area of indent. Therefore, the mean pressure on the surface of the indenter is equal to the ratio of the load L to A_p.

The indentation hardness tests are performed by pressing an indenter of prescribed geometry against the test surface. The load is controlled at some constant value, and the duration of the indentation process is usually specified for a viscoelastic material. The size of the indentation may be measured with a microscope after the removal of the load. An alternate procedure is to measure the depth of indentation after a given time interval. The latter procedure is preferred for viscoelastic bodies. The hardness number is generally calculated by dividing the load by the area of the indentation. The hardness values obtained are independent of the specimen thickness if the indentation depth is less than one tenth the sample thickness.

Since coating films are very thin, the indentation apparatus must be capable of measuring precisely very small indentations. Because it is difficult to set the zero position, a small preload may be applied before the application of the main load. A number of different instruments, described later, have been devised for making indentation hardness measurements on organic coatings.

The beginning of the twentieth century marked a milestone in the history of hardness testing. In 1900, Dr. J. Brinell, chief engineer at Fagersta Iron Works in Sweden, presented a paper to the Swedish Society of Technologists in which he described his ball test. In the same year, he showed his hardness tester at the Paris Exposition. Following the Brinell innovation was the development of the scleroscope (1906) [*35*]. The 136° diamond pyramid hardness indenter, commonly referred to as the Vickers indenter, was introduced in England in 1925 by R. Smith and G. Sandland [*36*]. Its early acceptance by industry was limited to the largest laboratories, and its use was chiefly for research purposes.

Indentation hardness testing using the Brinell and Scleroscope methods grew in importance, and during World War I practically all hardness testing was done on either one or the other of these instruments. During this time, Stanley P. Rockwell, a metallurgist in a large ball-bearing manufacturing plant, was particularly concerned with hardness control of ball races. As a result, he invented the tester which has become known as the Rockwell Hardness Tester.

The indentation hardness of a material is related to its modulus. The theory of the indentation hardness of an elastic material test has been derived for a spherical indenter. Young's modulus E is related to the indenting force F, the radius of the indenter r, and the depth of indentation h. If the modulus of the indenter is much greater than the modulus of the test surface, the relationship is

$$E = (3/4)(1 - \nu^2)r^{-1/2}h^{-2/3}F \tag{4}$$

where ν is Poisson's ratio (lateral contraction versus longitudinal extension). In the case of viscoelastic materials, a similar relationship holds, but the variation with indenter radius and penetration are somewhat modified. Mercurio [*37*] has discussed the relationship of Tukon hardness to modulus.

The theory of indentation hardness tests on homogeneous materials has received much interest in the last few decades. D. Tabor has been working intensely in this area. In his recent paper [*38*] he said

> The hardness of a solid is usually understood to mean its resistance to local deformation. The simplest method of quantifying it is to press a hard indenter of specific geometry into the body, divide the load by the area of the indention formed, and express the answer in units of kilograms per square millimeters or pascals (1 kg mm^{-2} $\simeq 10^7$ Pa). . . . For elastic solids such as rubber, the indentation pressure is a direct measure of the elastic properties of the material.

Another example of this type study is that of Lebouvier et al. [*39*].

W. W. Walker [*40*] evaluated the Knoop hardness of three organic coatings using a Model LR Tukon Microhardness Tester in accordance with ASTM Test Methods for Indentation Hardness of Organic Coatings (D 1474) except he calibrated the instrument at 100 g load and ran the tests at 200 g load. In addition, he tested the pencil hardness of the same coatings in accordance with ASTM Test Method D 3363. Comparative data are shown in Table 2.

W. W. Walker concluded that a useful correlation existed between the 200-g Knoop indentation hardness and pencil

TABLE 2—Comparison of pencil and Knoop hardness of selected coatings.

hardness of thick paint films but that further work needs to be done.

Krautkrämer Branson conducted a similar test using their MicroDur Portable Hardness Tester fitted with a Vickers indenter. The preliminary results, shown in Fig. 18, represent an evaluation of eight organic coatings. The results are promising. However, additional work is needed.

Bell Telephone Laboratories Indenting Rheometer—The BTL Indenting Rheometer, shown in Fig. 19, was designed and developed by Eugene M. Corcoran of the Bell Telephone Laboratories specifically for use as an indenting rheometer, sensitive enough for use with organic coatings but with sufficient load-deflection capacity to make it useful for relatively thick materials such as molded plastics and casting resins.

To achieve this, two separate head assemblies were required. Basically the rheometer consists of a specimen stage or platform, indenter-LVDT transducer head assembly, weights, transducer amplifier indicator, and a 10-in. (25.4 cm) strip chart recorder. In normal use, the specimen or test panel is clamped on the platform, and the instrument is zeroed in with the indent or tip just touching the specimen. This is done by using the knurled rings on the heads and the platform ring (the rings on the sensitive head have 80 threads per inch or 80 threads/25.4 mm) to obtain a coarse adjustment follow by a fine adjustment on the transducer amplifier-indicator. A load (weight) is applied to the weight tray (by means of an overhead pulley), and the depth of indentation is recorded as a function of time. After a specified period of time, the load is removed and the recovery is recorded.

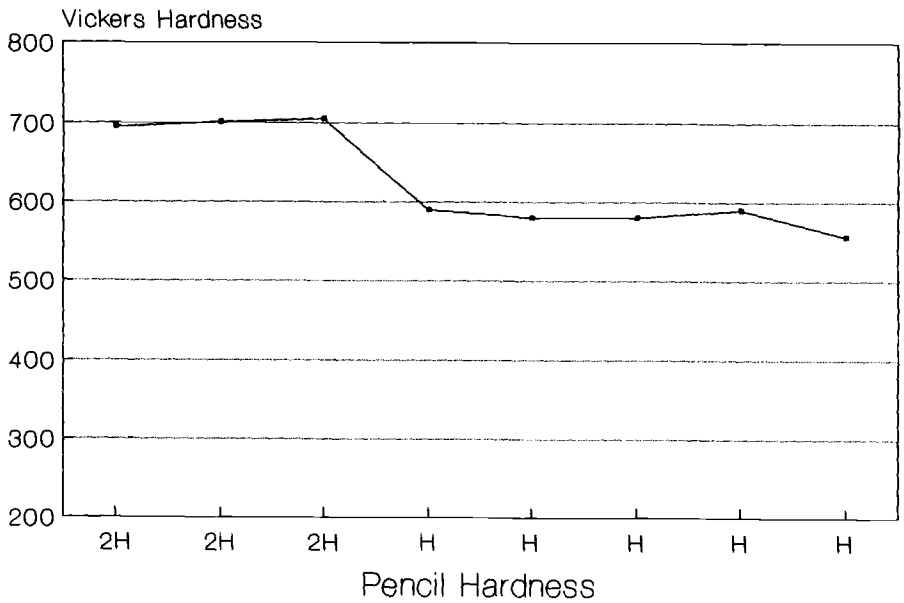

FIG. 18–Comparison of Vickers hardness versus pencil hardness.

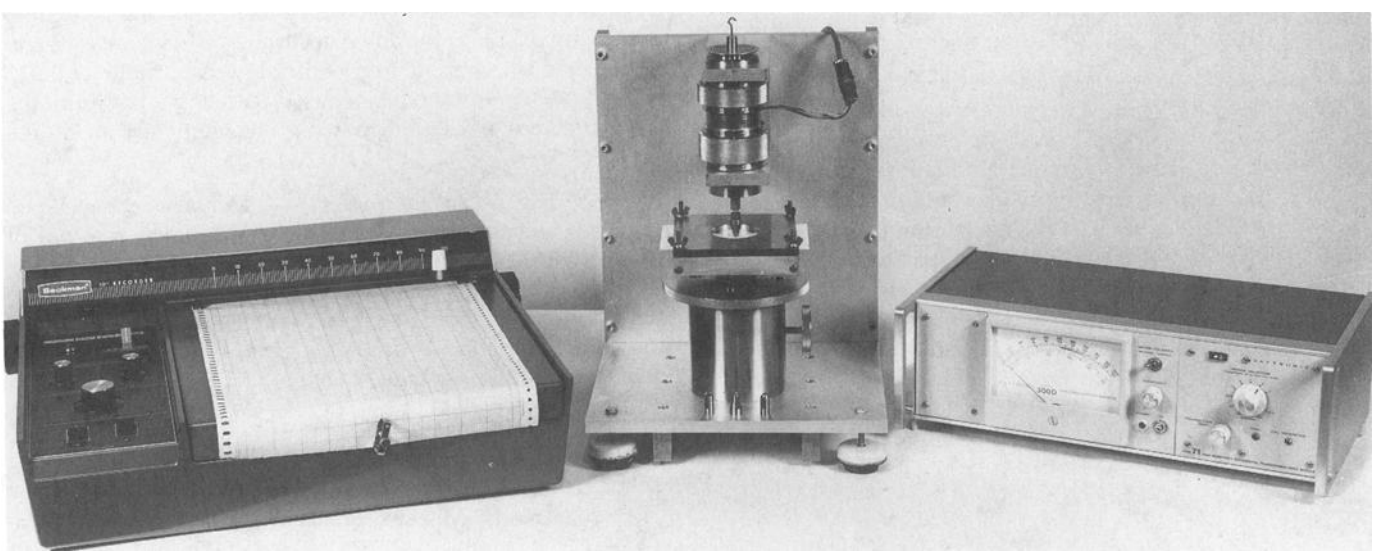

FIG. 19–Bell Telephone Laboratories Indenting Rheometer.

Brinell Indentation Hardness Tester—In 1900, J. A. Brinell published the results of his tests that involved pressing steel balls into materials [*41*]. The Brinell test is based on the following formula

$$H = \frac{P}{\frac{\pi D}{2}(D - \sqrt{D^2 - d^2}} \quad (5)$$

The relationship between the hardness H and the diameter of the depression d has been worked out on a form for a given size steel ball whose diameter is D.

Buchholz Indention Hardness Tester—This device, shown in Fig. 20, is made by the Erichsen Company [*42*] and has been standardized in Germany [*33*]. It is a simple, portable instrument and, like the Knoop, measures the length of the recovered indent impression after the load has been removed. In fact, the resultant impression, though much larger, is quite similar in appearance to the Knoop impression.

A diagram of the Buchholz Indention Hardness Tester in use is shown in Fig. 21. Basically a weighted (500-g) wheel, with an included angle of 60° from center to each edge (total angle of 120°), is placed on a coated test panel. The test panel is marked "5" in the diagram, and the coating is marked "4." The wheel is removed, and the length of the impression made by the indenter, marked "3" in the diagram, that remains is measured by means of a small, ×20 microscope, marked "2" in the diagram, and an attached light source, marked "1" in the diagram. To facilitate measurement, the impression is illuminated from the side, thereby creating a shadow in that side of the impression. The impression may be measured to within 0.05 mm (compared to 0.001 mm for the Knoop).

CDIC Hardness Penetrometer—Still another variation applied to artists' colors is the CDIC (the old Cincinnati-Dayton-Indianapolis-Columbus Paint and Varnish Production Club) Hardness Penetrometer [*43*]. A diagram of it is shown in Fig. 22. By this device, a ½-in. chisel is caused to penetrate the film that has been applied to metal. Chisel and metal are wired in series with an electric bulb, which lights up when the chisel contacts the panel. The instrument was never commercialized.

Fischerscope® Microhardness Tester[2]—The Fischerscope® H100V, shown in Fig. 23, is a dynamic microhardness tester which can be used on a variety of materials, including coatings, to measure hardness under load. It works with very small test loads up to 256 mN. Determination of hardness based on the plastic and elastic deformation of a material is the direct result of measurements under load. Hardness measurement is expressed in N/mm^2, corresponding to the quotient of load P over area of impression A (whereby A can be derived directly from the depth of indentation). This definition of hardness is physically meaningful by providing a measurement of hardness to an uncertainty of ±1%. This requires exact measurement of load and indentation depth, which is possible with a Fischerscope® H100V Microhardness Tester.

[2]Available from Fischer Technology, Inc., 750 Marshall Phelps Rd., Windsor, CT 06095.

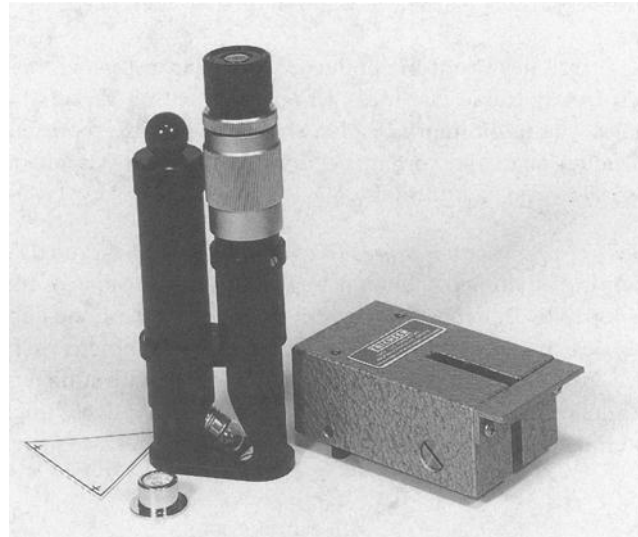

FIG. 20–Buchholz Indention Hardness Tester. (Courtesy of Erichsen GMBH & Co.)

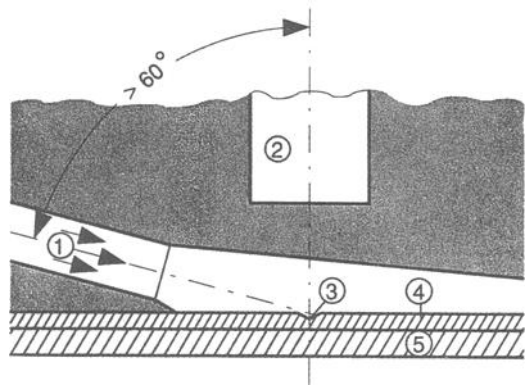

FIG. 21–Buchholz Indention Hardness Tester in use. (Courtesy of Erichsen GMBH & Co.)

Using a Fischerscope® H100V Microhardness Tester, W. W. Weiler developed a dynamic, nondestructive test method to measure the microhardness of surface layers, coatings, and homogeneous materials in the ultra-low load range of 0.025 to 1 N [*44*]. The method was based on using a conventional Vickers indenter coupled to a displacement measuring device.

General Electric Indention Tester[3]—This device, developed by C. Dantsizen, consists of a dial micrometer, the foot of which terminates in a metal sphere 0.20 in. (5 mm) in diameter, and with means for applying a load. The depth of indentation is read on the dial. The General Electric Indention Tester was not widely used within the General Electric Co. nor did it gain industry acceptance.

ICI Pneumatic Microindenter—This commercially available device,[4] shown in Fig. 24, was developed by Monk and

[3]Christian Dantsizen, personal communication to G. C. Sward, 1938.

[4]Available from Research Equipment (London), Ltd., 64 Wellington Road, Hampton Hill, Middlesex, England.

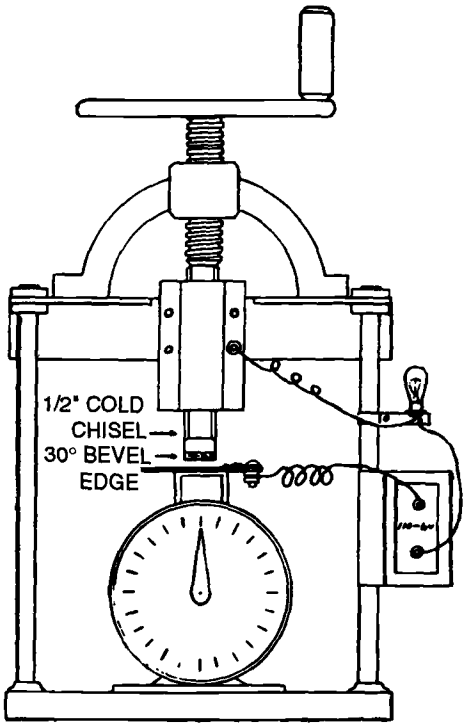

FIG. 22–CDIC Hardness Penetrometer.

Wright [*45*]. As the name implies, it is a pneumatic type (air pressure) instrument that measures and records the depth of indentation or penetration of a ball-ended needle under the application of a constant load and the recovery subsequent to removal of the load. The needles have steel or sapphire ends and vary from 0.0025 to 0.063 in. (1.6 mm) in radius. A preload of 0.1 g must be applied. A 5-in. (12.7-cm), pneumatically operated, strip-chart recorder provides curves of the indentation and recovery thereof. An indenter movement of 6 μm causes a full-scale deflection on the recorder. A calibration knob is divided into 0.5-μm divisions, thereby giving an accuracy of about 0.2 μm (0.008 mil).

However, the chart can be read to within 0.1 μm (0.004 mil). The specimen stage or table is a Frigister unit which can raise or lower the specimen temperature. Disadvantages are that it is not a sturdy instrument and must be handled with some care. The panel or specimen must be small enough to fit on the rather small Frigister stage. Also, the use of relatively sharp indenters (referred to by the authors as needles) means that, in many cases, the organic coating will be cut or penetrated, yielding spurious results.

The load limit appears to be less than 100 g, and the design does not appear to be conducive to the use of commercially made Knoop or Vickers pyramid indenters. Finally, results obtained using the Frigister to heat or cool the specimen can be misleading. If the indenter is at room temperature, then the specimen temperature where the indenter contacts will not be the same as the temperature of the Frigister. However, the ICI pneumatic microindentation apparatus was still the first commercially available instrument that appears to have the sensitivity necessary to be seriously considered as an indenting rheometer suitable for use with organic coatings. Monk and Wright gave some results obtained from the use of the apparatus and went further than Gardner et al. [*46*] in the interpretation and meaning of the curves. Included in the data were curves showing how an alkyd finish changed properties as a function of temperature and accelerated weathering.

Knoop Indenter—At the National Bureau of Standards (now known as the National Institute of Standards and Technology), Frederick Knoop and his associates [*47*] developed a diamond-based pyramid indentation tool as an improvement over the Vickers indenter. This indenter gave well-defined indentations and reproducibility of results when testing glass and crystals of the Mohs scale, and dental plastics and enamels.

The Knoop indenter, illustrated in Fig. 25, is a pyramidal diamond with included longitudinal angles of 172° 30′ and an included traverse angle of 130° 0′. It produces a diamond-shaped (rhomb) indentation having long and short diagonals of an approximate ratio of 7 to 1. The depth of indentation is about 1/30th of its length. In essence, the Knoop indenter is a shallow double wedge. The Knoop indenter is subsequently mounted in a machine which applies a load, without impact, at a constant rate and has a microscope equipped with a filar eyepiece for measuring the size of the indentation within ± 1%. Although the Knoop indentation hardness method was developed originally for measuring the hardness of metals, shortly thereafter Lysaght [*48*] suggested its use for organic coatings. Gusman [*49*] reported on its use for organic coatings. The instrument was specified in ASTM D 1474, adopted in 1957.

In its use for organic coatings, a load of 25 g is applied for 18 s, after which time the indenter is removed from the coating, and the length of the long diagonal of the impression remaining in the coating is measured as quickly as possible. This dimension is then used to obtain the Knoop Hardness Number (KHN), which is the ratio of the load, in kg/mm^2, to the projected planar area.

$$KHN = \frac{L}{A_p} = \frac{L}{lC_p} \tag{6}$$

where

L = load in kilograms applied to the indenter,
A_p = projected area of indention in mm^2,
l = measured length of the long diagonal of the indentation in mm, and
C_P = indentor constant relating l to A_p, usually 7.028×10^{-10}.

Most writers refer to l and A_p as the unrecovered length and area, but as we shall see later, this is not true. Elastic recovery of the indentation impression takes place the instant the indentor is removed, and substantial viscoelastic recovery takes place before a measurement can be made.

The real difference between the Pfund and Knoop methods is that with the Pfund, the hardness measurement is made when the indenter is under load, while with the Knoop the measurement is made of the indentation impression remaining after both the load and indenter have been removed. This remaining Knoop impression is smaller than the original made while under the loaded indentor because all of the elastic and substantially all of the viscoelastic (creep) recovery occur in the indentation impression once the load is

removed. This will be explained and actually shown in the subsection on theory.

Therefore, the operation of the Pfund and Knoop methods rests on two entirely different principles. Each measurement represents a completely and substantially different point on a viscoelastic creep-creep recovery curve for any given material or organic coating (see Fig. 26). Yet, the amazing part is that, quite coincidentally, the numerical results can be quite similar. This similarity in numerical results (PHN ≈ KHN) with organic coatings probably could never have been achieved deliberately. How fortunate for the paint industry that the equivalence exists.

Of the two test methods, the Modified Pfund and the Tukon gage with the Knoop indenter, the former is a dynamic hard-

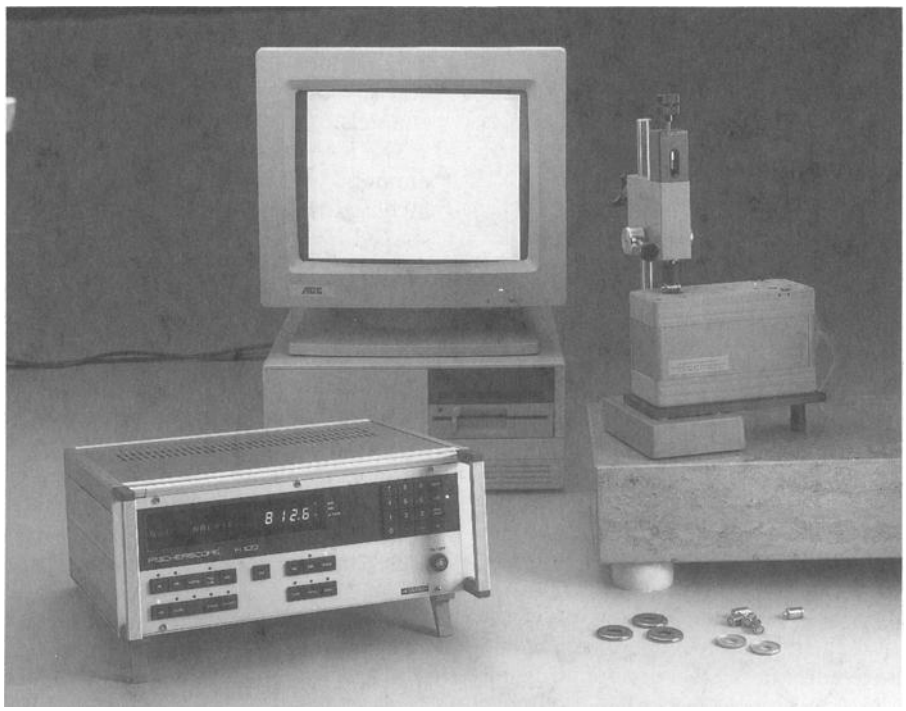

FIG. 23–Fischerscope® H100V Microhardness Tester. (Courtesy Fischer Technology, Inc.)

FIG. 25–Diagram of Knoop Diamond Indenter.

ness test and the latter is a static hardness test. Those in the automotive industry know how difficult it can be to obtain repeatable Knoop hardness numbers on metallic finishes. Secondly, with some types of finishes, the ends of the long diagonal of the Knoop impression recover, yielding rounded ends. In others, the organic finish sometimes recovers in such a manner as to partially close the indent near the ends of the long diagonal. However, the main reason for this preference is that the Pfund measures the indent under load. That is when the coating is resisting the indentation.

Pfund Hardness Tester—After numerous, unsuccessful attempts to grade the hardness of varnishes by means of the scratch test in which graded pencils, crystals, etc. were used, A. H. Pfund, an associate professor of physics from Johns Hopkins University, Baltimore, MD, modified the Brinell Indention Test [*50*]. In this method the measurements are made on the organic coating while the loaded indentor is in contact with the coating. At first a 1/16-in.-diameter steel ball was forced under load into the varnish, and the diameter of the resultant circular impression was measured under the microscope. This was soon changed to a quartz cylinder terminating in a hemisphere 1/4-in. (6 mm) in diameter. The results are expressed as the load on the indentor, in grams, necessary to achieve a specified diameter of indent. The device, shown in Fig. 27, consists of a counterbalanced brass beam containing the Indenter C. Illuminating light is reflected into the indenter by the clear Glass G and reflected back up to the Microscope 0, where the planar diameter of indent is measured by means of a filar eyepiece (shown in the upper right hand corner of Fig. 27). The results are expressed as the load on the indentor, in grams, necessary to achieve a specified diameter of indent. Table 3 shows typical results at an indent of 3 divisions (each division is approximately 0.1 mm). Additional data can be found in the work by Pfund, and Schuh and Theuerer [*51,52*].

In making a hardness determination, instead of attempting to find the exact load necessary to produce the specified diameter of indent, it was preferable to apply loads producing diameters both greater and less than the value sought and then interpolate to the specified diameter. However, this method is not precise because the relationship between load and diameter is not linear. Although this method of always achieving the same indent results in geometrically similar indents in all cases, this theoretical consideration of geometrically similar indents is significant only when the material being measured is thick enough for the hardness measurement to be uninfluenced by the thickness of the material. Such is not the case here. The theoretical consideration of geometrically similar indents will be discussed in the subsection on theory.

As this method was rather tedious and time consuming, the instrument and method were modified in the early 1950s by the Bell Telephone Laboratories. The modified Pfund and test method were incorporated into ASTM D 1474 [*53*]. The Modified Pfund device is shown in Fig. 28. The instrument devel-

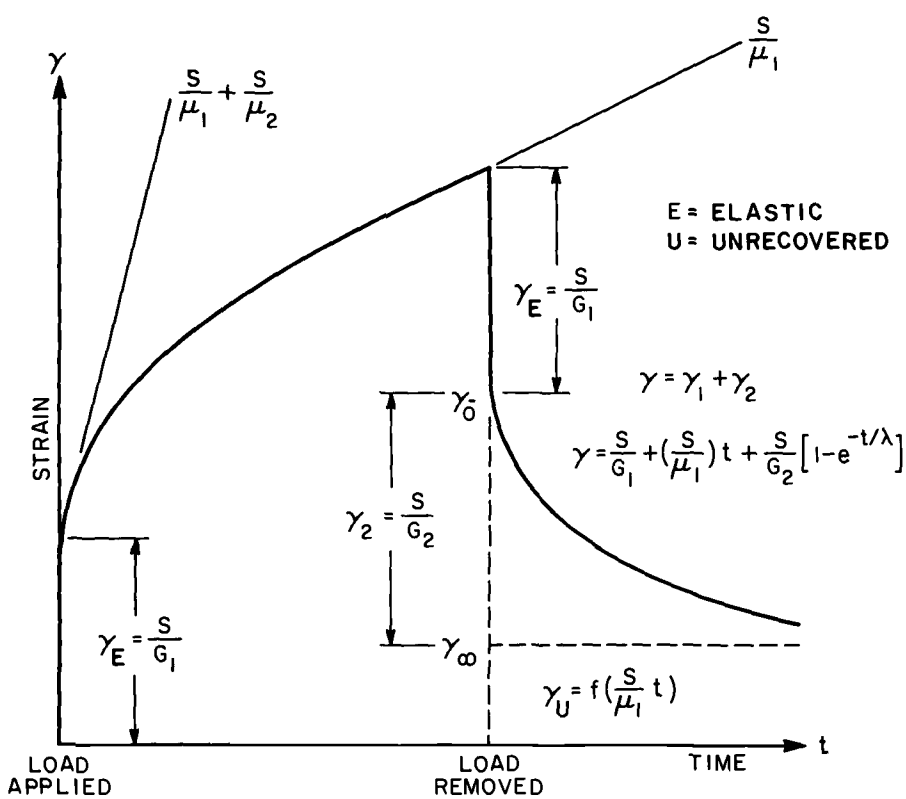

FIG. 26–Creep and creep recovery curves of viscoelastic material.

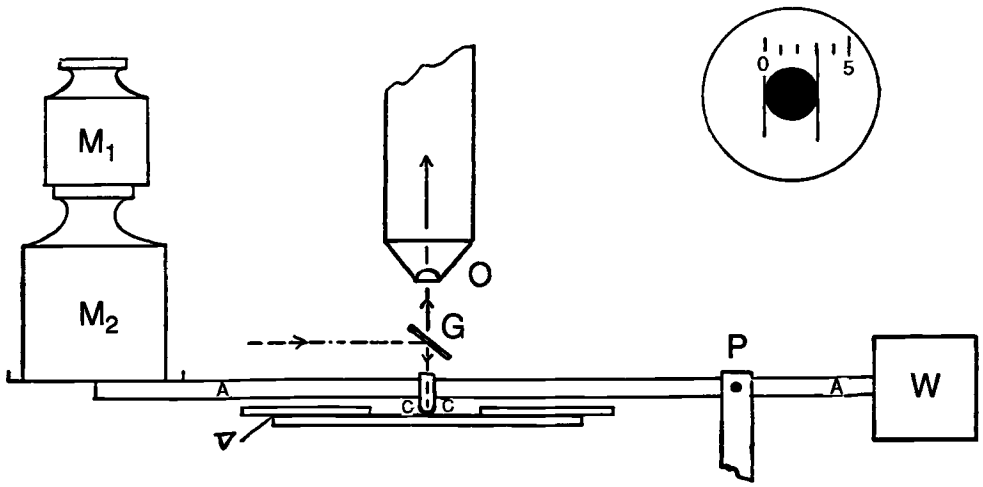

FIG. 27–Diagram of Pfund Hardness Indenter.

oped at the Bell Telephone Laboratories and initially adopted by the ASTM as Method D 1474 is shown in Fig. 29.

The indenter is a transparent, colorless synthetic quartz or sapphire hemisphere whose spherical radius is 0.125-in. (¼-in.) (6 mm) diameter with a maximum spherical eccentricity of 0.002 in. (0.05 mm). The indenter is mounted in a holder weighing 1000 g so that the indenter is always under a load of 1000 g when making measurements. Hence, we see that in this method the load is kept constant and the resultant diameter of indent is recorded. This is exactly opposite to the original Pfund method.

In operation, the test panel is brought into contact with the loaded indenter, and after 60 s (while still under load) the diameter of the circular impression is measured by means of a filar micrometer mounted in the eyepiece of the microscope. Each filar division represents 0.1 mm, and the diameter of the impression is converted into a Pfund hardness number (PHN), expressed in kg/mm^2 units, as follows

$$PHN = \frac{L}{A} = \frac{L}{\frac{\pi d^2}{4}} = \frac{1.27}{d^2} \tag{7}$$

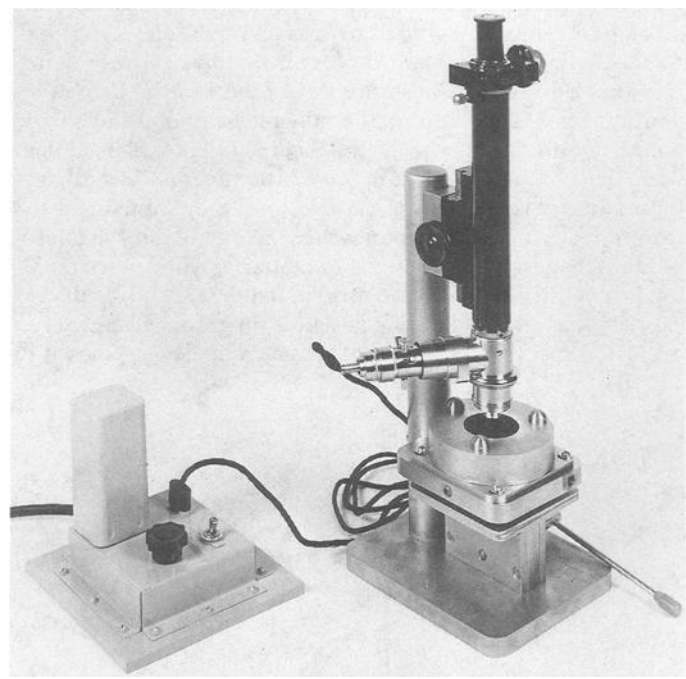

FIG. 28–BTL designed modified Pfund Hardness Gage.

TABLE 3—Pfund hardness.

Coating[a]	Thickness, mil	Hardness at Three Divisions

where

L = load in kilograms (1 kg) applied to the indenter,
A = planar or projected area of indention in square millimeters, and
d = diameter of the indentation in millimeters.

Therefore, the PHN is the load, in kilograms, divided by the planar or projected area of indentation.

The planar or projected area of indent deserves some explanation and was covered in detail in the introduction. Figure 30 illustrates what is meant by this for the case of a spherical indentor where the hardness measurement is made while the hemisphere is under load and in contact with the coating. Initially the hardness or PHN was reported as 10d. The reason for changing it to the load divided by the planar area of indentation was to make the reported PHN results have the same units of measurement as the Knoop hardness number

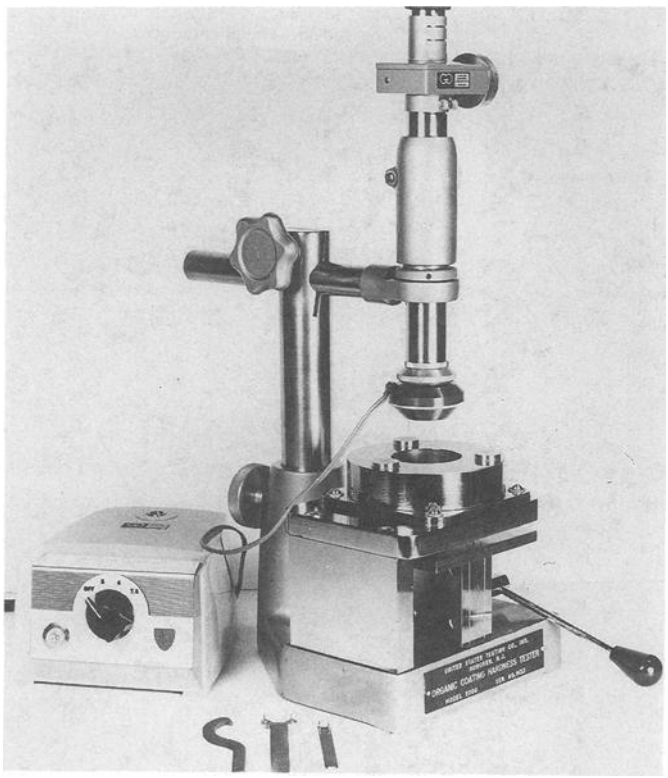

FIG. 29–Commercial modified Pfund Hardness Gage.

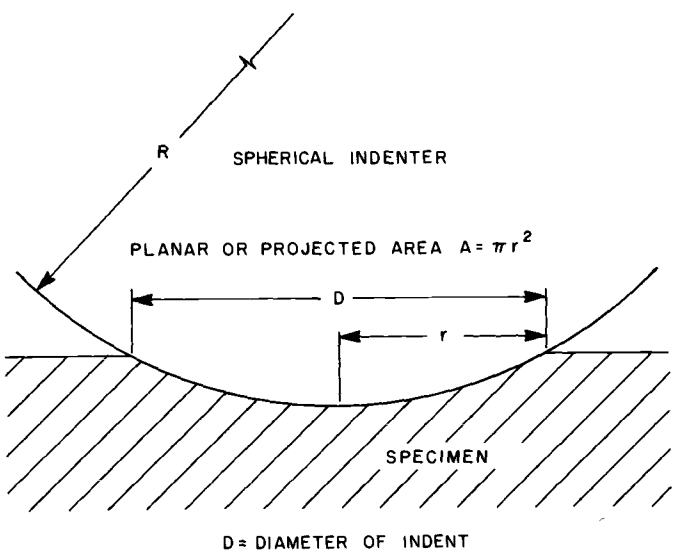

FIG. 30–Planar area of contact of the Pfund Indenter.

(KHN) also in ASTM Method D 1474. Surprisingly, the PHN and KHN values come very close numerically.

Rockwell Hardness Tester—Indentation hardness tests have been used as a means of checking the uniformity of the mechanical properties of metals since the 19th Century. The Rockwell Hardness Tester began as a hard steel conical indenter having a hemispherical tip of 0.50 mm in diameter. It was first used by Hugueny (1865) during his patent studies of hardness [*54*]. The machine was improved when Wilson in 1926 produced his polished spheroconical diamond indenter where the cone had an included angle of 120° and the tangential spherical tip of 0.40 mm in diameter.

Wilson®/Tukon® Hardness Tester[5]—Vincent E. Lysaght of Wilson Mechanical Instrument Co. took the work of the late Frederick Knoop and applied the technique to the testing of nonmetallic materials ranging from plastics to diamonds [*48*] using their Tukon Hardness Tester.

The Wilson®/Tukon® Microhardness Tester offers a variety of possibilities as a tool in research and development, materials testing, and quality control program. Some coating manufacturers use the Sward Hardness Tester to get approximate hardness values but rely on this tester to qualify a coating. It can be fitted with either a Vickers or a Knoop indenter. A comparison of these two indenters is shown in Fig. 31. A Knoop indenter is typically used to measure the hardness of coatings, whereas the Vickers indenter is used for hardness testing of harder materials such as metals.

This instrument, with the precision of x-y stage, makes it possible to locate indentions with great accuracy. The instrument has undergone many refinements such as having a computer controlled X-Y Auto Traversing Stage System and a software program for running statistical process analyses. One of their latest instruments is shown in Fig. 32.

Wallace Microhardness Tester H-7[6]—The Wallace Microindention Tester [*55*], like the Wilson®/Tukon® Hardness Tester, can also employ a Vickers diamond pyramid indentor and uses a capacitive form of measurement to determine the depth of indention under load. Figure 33 shows the Wallace tester. This instrument measures the depth of penetration of an indentor into a material under a known load, the depth of penetration being a function of that indicated on a dial gage.

Basically, the instrument consists of an indentor, supported by leaf springs, attached to a parallel plate capacitor which forms one half of a capacitance balance circuit. When no load is applied, the indentor "floats" in a "null" position, electronically balanced by the second half of the capacitance balance circuit. This "null point" (i.e., the point of electrical balance) is indicated by a zero reading on the center zero meter located in the base of the instrument.

The test panel is supported on a table that is raised or lowered by means of an accurately made wedge. The dial micrometer gage follows and indicates the lateral movement of the wedge which is, in turn, converted to vertical movement of the table. Primary loads of usually less than 1 g and secondary loads between 1 and 300 g are placed on the weight platform, which, in turn, is attached to the indenter.

In operation, the instrument is first set to a zero position, and a test panel is placed on the specimen table or stage. The panel is raised to the indenter. The primary load is applied to the indentor, and the system is once again zeroed. The secondary load is applied for the predetermined time during which the panel is raised to maintain the indenter in its zeroed position. At the end of the predetermined time, the reading on the gage is taken and the corresponding depth of indentation is obtained by dividing the gage reading by the wedge ratio (20 to 1 or 40 to 1). The Wallace Microhardness Tester was

[5]Available from Wilson Instruments, 6 Emma Street, Bingham, NY 13905.

used in a cooperative investigation by the Manchester Section of the Oil and Colour Chemists' Association [*56*] and is commercially available. According to Fink-Jensen [*57*], it is possible to obtain an accuracy of 0.3 to 0.5 μm or about 0.01 to 0.02 mil.

Indentation Hardness Miscellaneous

Imprint Resistance—Organic coatings for chairs, desks, and other furniture often appear hard, but when subjected to continuous pressure they may creep, yield, or flow enough to be permanently and seriously damaged. Print resistance is a measure of this phenomenon. The print resistance of an organic coating should be related to its glass transition temperature, *Tg*. Andrew Mercurio discussed this viscoelastic

behavior of polymers at length in his article [37]. Expressed mathematically

$$B = \frac{P}{\frac{\Delta V}{V}} \tag{8}$$

$$E = \frac{F/A}{\Delta l/l} \tag{9}$$

$$G = \frac{F/A}{\theta} \tag{10}$$

where B is the bulk modulus expressed in terms of the applied pressure, P, the initial volume, V, and the decrease in volume, ΔV. In tension, we obtain Young's modulus, E, given in terms of the applied force, F, per unit of original cross-sectional area, A, the original length, l, and the change in length, Δl. The shear modulus, G, is also expressed in terms of the applied force per unit original cross-sectional area and the angle of deformation, θ. In each case the numerator is termed the stress and the denominator is defined as the strain. Only two of these moduli represent independent properties of the isotropic material in question since the moduli are related through the Poisson ratio, ν.

$$E = 2(1 + \nu)G \tag{11}$$

$$B = \frac{E}{3(1 - 2\nu)} \tag{12}$$

This simple, basic method was adopted by the Federal Government (Federal Test Method Standard No. 141, Method 6211, Print Test). However, in 1980, the federal government canceled this test method in favor of an ASTM test method (D 2091: Test Method for Print Resistance of Lacquers). Another ASTM test method is Test Method D 1640: Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature. Print resistance may be evaluated by the load required to make an impression within a given time, the time required under a given load, or by comparing the imprint under identical loads and duration of test. The temperature may also be varied. This test is sometimes used as a drying time test.

Twisting Cork Tester—This device [58], shown in Fig. 34, was an attempt to simulate a thumb being pressed on a film and then twisted. It consists of a cork at the lower end of a vertical rod upon which may be placed varying weights. By means of an arm in the rod, the cork can be turned or twisted through any desired angle.

The average reader may consider that perhaps this device belongs in the section on drying time. However, it was developed for measuring the hardness of oils and oil mixtures, which can be soft enough to defy the use of more conventional methods.

Pendulum-Rocker (Damping) Hardness

A few pendulum hardness tests are in use by the coating industry. The Sward Rocker Hardness Test is widely used in the United States; The König Pendulum Test is commonly used in Germany and Europe; and the Persoz Pendulum Test

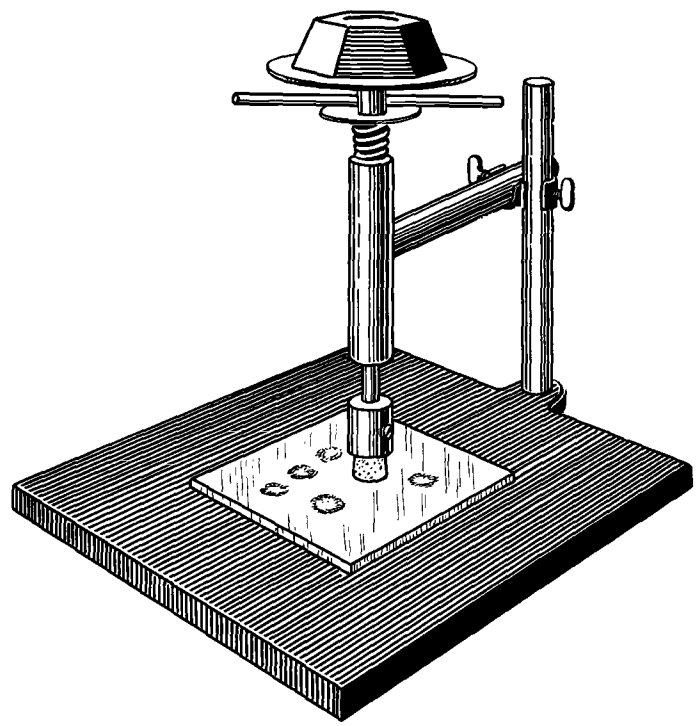

FIG. 34–Twisting cork hardness tester.

is employed for coating hardness testing in France and Europe. The specific apparatus employed in these methods is different, but, in principle, the tests are the same. These tests are described below.

The pendulum hardness tests are closely related to the Sward Rocker Hardness Test. The hardness pendulum rests on the test surface and pivots on two hardened steel balls. The time required for the pendulum to decay from some initial amplitude to some final amplitude is a measure of the hardness of the coating film.

The theory of the pendulum or rocker hardness testing was derived by Persoz [59]. Pierce et al. [60] made a detailed experimental investigation of the Sward Rocker Hardness Test. The observed mechanics of the Sward Rocker were found to be in complete agreement with the Persoz analysis. The Sward hardness of a coating was found to be influenced by temperature, humidity, film thickness, substrate hardness, and air pressure. Coefficient of rolling friction values were recovered from the values of Sward hardness and the physical parameters of the rocker. The coefficients of rolling friction are related to the shear modulus and loss tangent of the coating. The analysis shows that if the physical parameters of different rockers or hardness pendulums are known, it is possible to relate the hardness values obtained on different instruments.

Pendulum or damping is the least understood hardness test method. A pendulum supported on the specimen by a ball or cylinder was applied to hardness testing by Le Rolland [61] and can be used to measure strain hardenability. Similarly, the Herbert Pendulum Tester [62] employed the strain-hardenability principle to measure hardness. The Herbert Pendulum Tester consists of a 4-kg arched casting which is supported on the horizontal plane surface of the specimen by a 1-mm-diameter ball. The ball can be either hard steel or

diamond. In a pendulum hardness test, an inverted compound pendulum is supported on a hard steel ball which rests on the metal under examination. The hardness is measured by the damping produced as the pendulum swings from side to side. When applied to polished plate glass, the pendulum oscillates so that ten single swings requires 100 s. If the device is then placed on a specimen of lead, the time hardness (for ten swings) is only 2 to 4 s, and other metals give intermediate values. This device does not apply to measuring coating hardness, but those described below use this pendulum principle.

König Pendulum—The König pendulum hardness tester [*63*] is currently manufactured in England by Sheen, Ltd. and in Germany by Erichsen GMBH & Co. The one shown in Fig. 35 is manufactured by Sheen, Ltd. It uses the damping properties of organic surfaces (e.g., paints, coatings, plastic materials, films of all kinds, and paper) to determine the hardness. The measurements are so sensitive that the drying process of layers of paint can be followed from the start of the drying to complete hardening. It has been standardized in the United States and Germany. It is in accordance with ASTM D 4366: Test Method for Hardness of Organic Coatings by Pendulum Damping Tests, DIN 53 157, ISO 1522, Association Suisse de Normalisation (SNV) 37 112, and National Federation of Textiles (NFT) 30 016 for pendulum hardness test instruments.

In its operation, the oscillations of a standard pendulum supported on the test surface by balls are dampened more strongly on softer surfaces. The degree of dampening is measured by the time in seconds taken for the amplitude of the pendulum to diminish from the initial to the final value. It is described in the ISO Recommendation 1522 as follows:

> The pendulum rests on two stainless steel balls, 5 ± 0.005 mm diameter, of hardness HRC 63 ± 3, 30 ± 0.2 mm apart, and is counterpoised (to adjust the natural frequency of oscillation) by means of a weight sliding on a vertical rod attached to a cross bar. The period of oscillation should be 1.4 ± 0.2 s on a polished plate glass panel; the time for damping from a 6° displacement to a 3° displacement, on the same substrate, should be 250 ± 10 s. The total weight of the pendulum should be 200 ± 0.2 g.

Persoz Pendulum—Persoz designed the pendulum hardness tester [*59*] shown in Fig. 35. It is manufactured in Germany by Erichsen GMBH & Co. It was a result of Persoz's mathematical analysis and experimental studies. It is written up in the ISO Recommendation 1522 as follows:

> The pendulum rests on two stainless steel balls, 8 ± 0.005 mm diameter, of hardness HRC 59 ± 1, 50 ± 1 mm apart. A counterpoise is not provided. The period of oscillation should be 1 ± 0.001 s on a polished plate glass panel and the time for damping from a 12° displacement to a 4° displacement on the same substrate should be at least 420 s. The total weight of the pendulum should be 500 ± 0.1 g, and its center of gravity at rest should be 60 ± 0.1 mm below the plane of the fulcrum, the pointer tip being 400 ± 0.2 mm below the plane of the fulcrum.

The Persoz pendulum is prone to skidding on surfaces having a low coefficient of friction. However, compared to the König pendulum, the Persoz pendulum is particularly useful with relatively soft organic coatings. This is a result of longer damping time of the Persoz pendulum (about two times that of the König), which makes it more sensitive to small differences between soft organic finishes where the damping times are relatively short. The Persoz pendulum has been standardized: United States, ASTM D 4366; France, NTF 30 016.

A comparison of similarities and differences between the König and the Persoz pendulum hardness instruments is shown in Table 4. BYK-Gardner, Inc. distributed a graph which compares König hardness values with Persoz hardness values. This graph is shown in Fig. 36. The source of the data is reputed to be from Volkswagen Co.

Rolling Ball Hardness Tester—Dr. Howard Moore devised a rolling ball tester at the Navy Yard Laboratories in Philadelphia. A description of it appears in the 11th edition of *Gardner/Sward Physical and Chemical Examination of Paints, Varnishes, Lacquers, and Colors,* 1950. The device was used to evaluate the drying times of coatings and measured the time required for a small steel ball to roll a fixed distance over the coating. Using this principle, a new instrument for testing hardness properties using the rolling ball concept. It is shown in Fig. 37 and is marketed by the Paul N. Gardner Co. under the name Gardco Rolling Ball Hardness Tester. The instrument utilizes a 1.5-in. (38 mm) diameter steel ball confined in a raceway about 6 in. (15 cm) long, all mounted on a platform which may be accurately tilted by an electrical solenoid. Mounted at each end of the raceway is an electrical sensor for detecting the presence of the ball. The raceway assembly tilts to an equal and opposite incline whenever the ball is detected at the low end of the raceway. An electrically actuated timer is connected to register the number of seconds required for the

ball to complete a set number of complete cycles of the ball in the raceway. Specimens up to 12 in.^{2} (77.4 cm^2) and up to ½ in. (12.7 mm) thick are accommodated, and the new tester should find application in evaluating coated sheet metal, woven products, coated wood, floor coverings, paper, and leather.

Sward Rocker Hardness Tester—George Gilbert Sward was awarded a patent [*64*] for his coating hardness tester that was developed when he was associated with the National Paint, Varnish, and Lacquer Association [*65*]. This is shown in Fig. 38. It is perhaps the best known and most widely studied instrument for measuring the hardness of organic coatings. ASTM Committee D-20 on Plastics wrote a standard using the Sward hardness tester, D 2134. Committee D-20 turned over the responsibility of D 2134 to Committee D-1 in 1991. They are in the process of rewriting D 2134 and will be developing data for the Precision and Bias statement since many coatings companies use the instrument on a daily basis.

As to its operation and use, the following is from the 12th edition of this manual [*66*]:

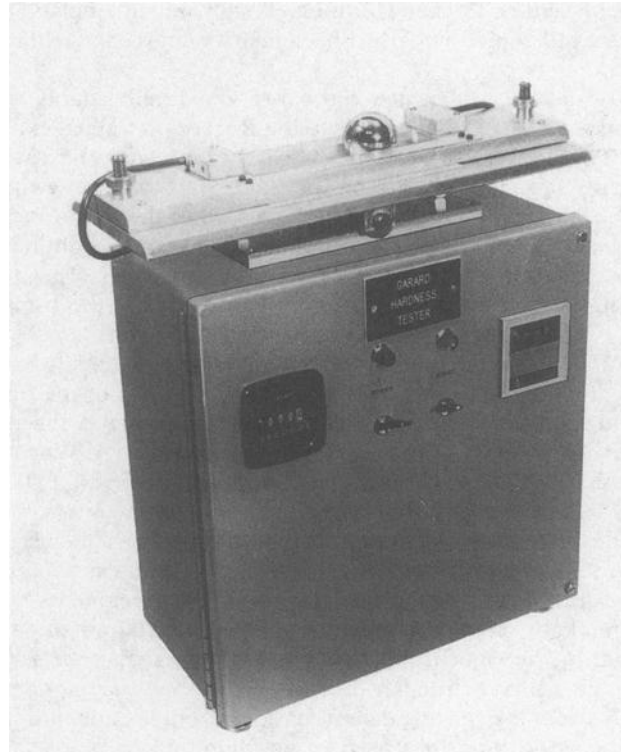

FIG. 37–Rolling Ball Hardness Tester. (Courtesy of The Paul N. Gardner Company, Inc.)

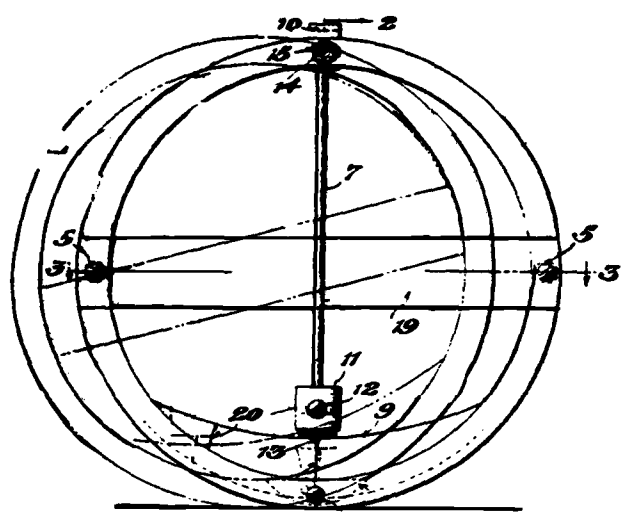

FIG. 38–George Sward's Original Rocker Hardness Tester. (From the patent.)

The Rocker operates on the same principle as does the Swinging Beam and other pendulums. However, it is self-contained and requires no separate scale. Some models also have their own circular level. It consists of two flat, 4-in. chromium-plated, bronze rings, spaced 1 in. (25.4 mm) apart. Amplitudes of oscillations are indicated by two tube-style levels in the lower half. The level at the left is for marking the start of a test; the one on the right for marking the end.

At the present time, Sward-type rocker hardness instruments are manufactured in Germany by Erichsen as the

Sward-Zeidler Rocker Hardness Tester and in England by Sheen Ltd. A picture of the Sheen instrument is shown in Fig. 39.

To make a test, fasten the panel to a leveling table and adjust to a level position. Place the Rocker on the panel and set it in motion so that the bubble in the left hand tube travels slightly beyond the mark on the tube. Start to count swings when the bubble just fails to travel beyond the mark. Begin with zero. Stop the count when the bubble in the right hand tube fails to travel beyond its mark. The number of swings multiplied by 2 is the Rocker value. Alternately, the sum of the two successive determinations may be used.

To calibrate the Rocker, adjust the angle of the left hand tube to about 22.5° with the horizontal and that of the right hand tube to about 16°. Place the Rocker on a level sheet of polished plate glass and proceed as directed above. When in correct adjustment, the Rocker swings 50 times in 60 ± 0.5 s.

If 50 swings are not obtained, minor adjustments may be made by means of the weight on the vertical screw. Lowering the weight increases the number of, and at the same time, accelerates the speed of the swings. Major adjustments may be made by changing the angles of the tubes. Changing the angle of the right tube has a greater effect than an equal change in that of the left tube.

By widening the angle between the two tubes, the number of swings can be increased to one hundred or more, thus increasing the sensitivity. However, at wide amplitudes, the swings become somewhat more violent and too much should not be attempted in this direction. The rockers should be wiped off frequently with soft paper or a clean cloth. Solvent should be used, if needed.

In using the Rocker or the pendulums, it is essential that the film support be firm. Any movement absorbs energy and lowers apparent hardness. Thin panels may bend; warped panels may rock. To eliminate this source of error, H. F. Payne designed a holder, called the Cyanamid Holder. It is essentially a small screwpress. It eliminates slight curvatures and holds panels firmly. It takes panels up to 6 in. (15 cm) in width.

Films on heavy gage metal with a plane surface or films on plate glass or other rigid material may be supported on lumps of stiff putty or molding clay.

Another aid to proper use of the Rocker is a shield to protect it from air currents. One such shield is shown in Fig. 40.

Moore [*67*] studied the reproducibility of Sward rocker hardness measurements and found that a single measurement came within one unit of the average seven out of ten times. A deviation of more than two units appeared no more than 8 out of 100 times. Boscoe [*68*] explored the influence of atmospheric pressure and compared Sward rocker hardness with that obtained using other methods. He found that the greatest differences were due to differences between individual Sward rockers. This was also observed by Nielson [*69*], and Baker et al. [*70*] did a study on variations in results due to subjective differences in observers making the measurements. Pierce et al. [*60*] also studied various factors which influence the value of Sward hardness such as temperature, humidity, film thickness, substrate, and air pressure.

On analysis of the papers by Baker, Elleman, and McKelvie [*70*] and Pierce, Holsworth, and Boerio [*60*], a possible explanation of why ASTM Subcommittee D01.23 and Task Group D01.23.14 had difficulty with the data became apparent. They may have overlooked the information (Table 5) that two out of three Sward rockers were outside the proposed mass specification, 100 ± 10 g, proposed for D 2134, Test Method for Determining the Hardness of Organic Coatings with a Sward-Type Hardness Rocker.

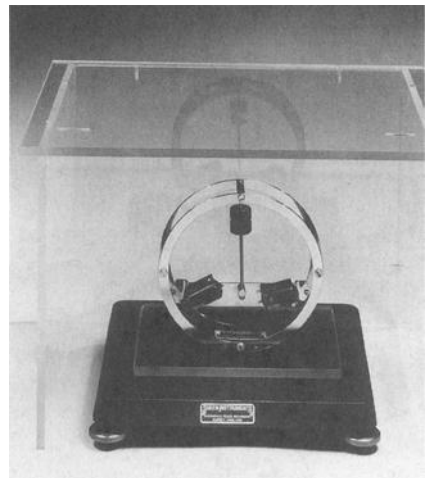

FIG. 39–Sward-Type Rocker Hardness Tester by Sheen, Ltd. (Courtesy of The Paul N. Gardner Company, Inc.)

Baker, Elleman, and McKelvie used the equations from Parker and Siddle and Persoz to derive the following formula to calculate the number of Sward rocker rocks (N)

$$N = \frac{tb}{2\pi} = \frac{1}{2\pi\gamma}\log\frac{(\theta_0 + \varphi)}{(\theta_n + \varphi)} \cdot \sqrt{\frac{Mga}{I} - \gamma^2} \qquad (13)$$

where

a = distance of center of gravity from instantaneous center,
θ = angle between the vertical and the plane containing the instantaneous center of rotation and the mass center,
θ_0 = initial amplitude of the rocker, and
θ_n = amplitude of the rocker after N rocks.

Mathematical analysis of pendulums, balls, and rockers, have been made by B. Persoz [*59*], Baker et al. [*70*], D. G. Flom [*71*], and P. E. Pierce et al. [*60*]. Persoz developed the relatively heavy (500-g) pendulum shown in Fig. 35. Baker et al. found that heavy rockers with a high moment of inertia appeared to give the best results. Flom investigated the relation of rolling friction to the dynamic shear modulus for polymers and emphasized the importance of elastic hysteresis losses in rolling friction (not to mention the viscous damping effect). They demonstrated that, for the case of a rigid sphere rolling on a viscoelastic surface, the following relationship existed

$$\mu = K \tan\delta\,(W/Ga^2)^{1/3} \qquad (14)$$

where

μ = coefficient of rolling friction,
$\tan\delta$ = dynamic loss tangent,
G = shear modulus,

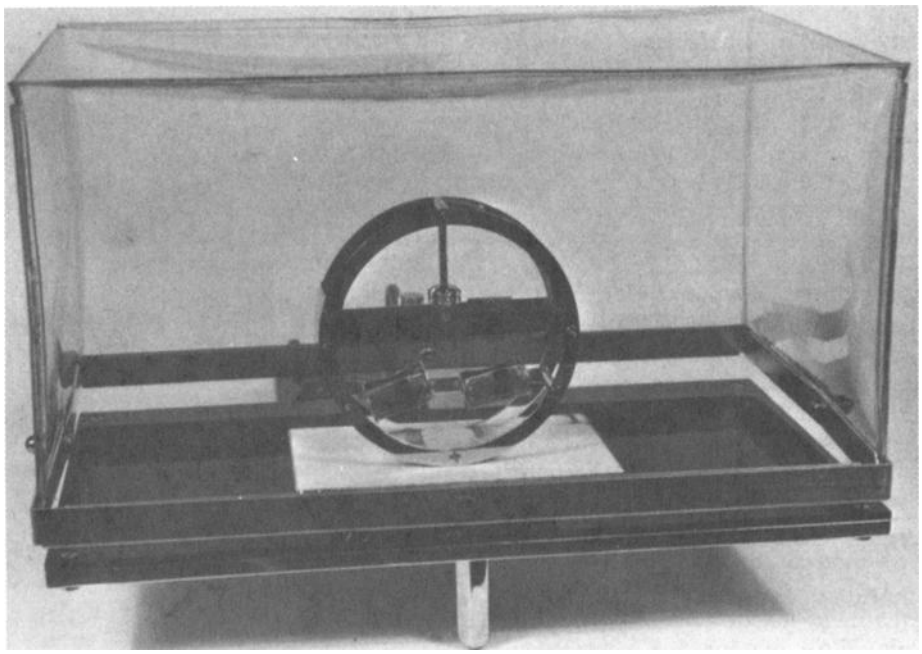

Fig. 40–Sward Rocker with shield for protection from draft.

TABLE 5—Comparison of Sward rockers.

Dimension	Rocker Number 1	2	3
Value of a (cm)	0.896	0.400	1.175
Moment of inertia I about center of gravity (cm·g^2)	2085	1616	1829
Period, T (s)	1.093	2.10	0.95
Mass, M (g)	114.2	87.4	105.4
Radius, r (cm)	5.075	5.075	5.075
Value of θ_0	44°	42°	43°
Value of θ_n	27°	27°	27°

a = sphere radius,
W = load, and
K = a constant.

For the Sward rocker, a and W are constant and Eq 14 becomes

$$\mu = K'G^{-1/3}\tan\delta \tag{15}$$

Pierce et al. showed, among other things, that the coefficient of rolling friction was inversely proportional to the Sward rocker hardness number, N. This can be expressed as

$$\mu \propto 1/N \tag{16}$$

Substituting this in Eq 16 and rearranging gives

$$G^{1/3} = NK''\tan\delta \tag{17}$$

In a plot of Sward rocker hardness against $G^{1/3}/\tan\delta \times 10^{-4}$, a linear relationship was found for hardness up to about 60; but for harder films, the plot curved and asymptotically approached a value of 100. This indicated that the Sward rocker was optimized for the range of hardness below 50, which corresponds to the range of hardness most frequently encountered with organic coatings. R. A. Cass [*71*] compared the Sward rocker hardness with the (tensile) elastic modulus of vinyl acetate copolymer coatings working in a range of film thickness from 1.2 to 125 mils. At constant film thickness he found the following relation between the hardness, N, and the elastic modulus, E

$$E = KN^3 \tag{18}$$

If we assume that E is very nearly the same as G, although it is well known that $E \cong 3\ G$ or less but not unity, substituting into Eq 18 and rearranging gives

$$G^{1/3} = NK' \tag{19}$$

which, according to Pierce et al., is the same as Eq 17 if we assume that $\tan\delta$ for the series of films studied is approximately the same. Cass went further in his analysis and arrived at the final equation

$$E = K_tN^3/t^3 \tag{20}$$

where

E = elastic modulus,
K_t = constant for varying thickness,
N = Sward rocker hardness number, and
t = film thickness.

However, by examining Cass' data we are able to go one step further, because the data show

$$K_t = 39t^{3.54} \tag{21}$$

hence

$$E = 39N^3t^{0.54} \tag{22}$$

showing, as was stated earlier, that the Sward rocker hardness is related to, or is a measure of, the modulus (stiffness) of a material as a function of its thickness. However, this is true only within certain limitations—the film must be thick enough and the substrate hard enough so that only the film properties are being measured.

Pierce et al. found hardness to increase as film thickness decreased to less than a few mils (their data were very limited). They also showed that softer substrates yielded lower hardness values for identical coatings, which simply means that the organic coatings were not thick enough for the measured hardness to be uninfluenced by the substrate. It is also obvious that the hardness value measured using a Sward rocker can be influenced by a "skin effect," or hard outer surface, while the bulk of the film is relatively soft.

Uses of the Sward Rocker—It is redundant to state that the Sward rocker is known and used all over the world. Canadian Government Specification Board standardized it in Method 116.2, Hardness, in Canadian Government Specifications 1-GP-71, Methods of Testing Paints and Pigments. We have seen that it can measure the coefficient of rolling friction and, within certain limits, measure the dynamic mechanical properties such as shear modulus or compliance of materials.

In addition to these it has been specified in ASTM Method D 2134. Softening may be encountered when a plasticized material comes into contact with an organic coating. However with regard to softening by plasticizers, it has been observed in the author's laboratory that, in some instances, the indentation hardness of the coating is unaffected, while the Sward rocker hardness decreases. This is due to an almost invisible film of plasticizer that has exuded out onto the surface of the coating, thereby acting to dampen the oscillations of the rocker.

BYK-Gardner, Inc. has distributed a graph which compares König hardness values with Sward Rocker hardness values and Persoz hardness values with Sward Rocker hardness values. These graphs are shown in Fig. 41 and Fig. 42.

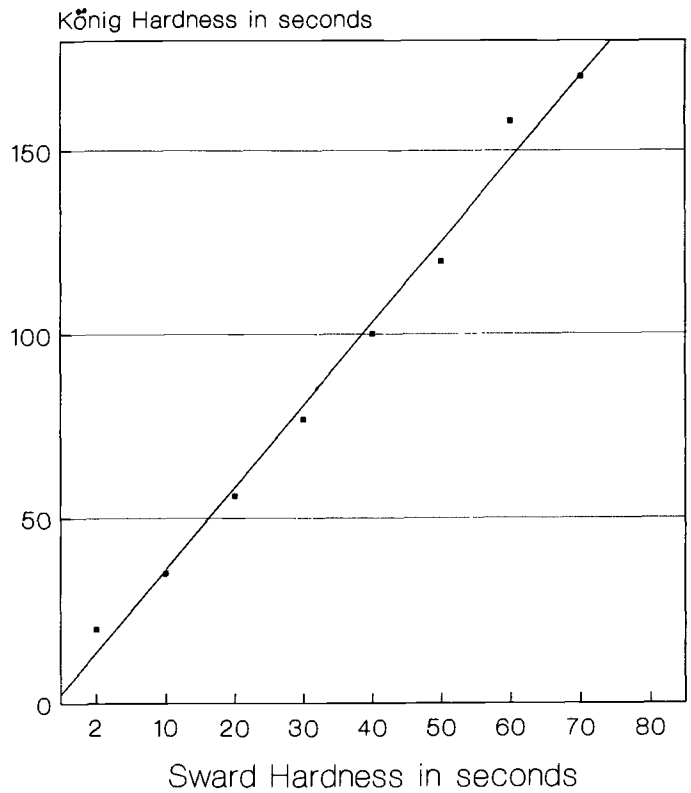

FIG. 41–Comparison of König hardness values with Sward Rocker hardness values.

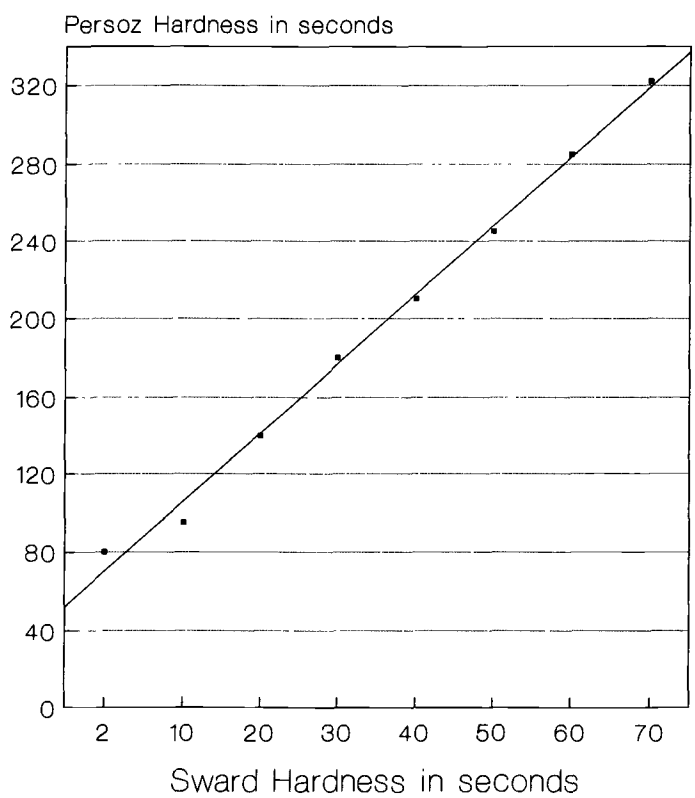

FIG. 42–Comparison of Persoz hardness values with Sward Rocker hardness values.

Rebound Hardness Testing

The rebound hardness test measures the mechanical properties of a material during very short time intervals. The test, which uses very simple apparatus, is performed by dropping an elastic steel ball from an initial height h_0 onto a flat test surface. The rebound height h_1 of the ball is measured. The impact resilience or hardness of the sample is the ratio of the rebound height to the initial height. The impact process occurs over a very short time interval (10^{-3} to 10^{-4} s) [*72*]. The resilience R is related to the loss tangent of the material [*73-75*].

$$R = h_1/h_0 = \exp(-\pi \tan\delta) \tag{23}$$

This loss tangent applies to a very fast impact process.

The results depend on geometric factors such as the thickness of the plate and the radius of the ball [*75*], as well as on the coating thickness and hardness of the substrate. Hard substrates, such as window glass, give good test results. The test has been used in a number of investigations of coatings [*46,76*]. A more elaborate form of the rebound apparatus has been developed by Raphael and Armeniades [*77*]. Their ADL Rebound Tester has provision for temperature control and can operate from liquid-nitrogen temperatures to several hundred degrees centigrade.

ADL Ball Rebound Apparatus—The ADL Ball Rebound Hardness Test Apparatus, developed by Arthur D. Little, Inc.'s M. Gordon and B. Grievenson [*78*] consists essentially

of a penetrometer and a brass block containing a heating element enclosed in a glass dome that can be subjected to a vacuum. The brass block can be heated from 0 to 300°C at rates of up to 30°C per minute. The specimen block can be cooled very quickly by sucking a stream of cold CO_2 gas through a side arm straight upon the specimen disk. The polymer film to be tested is mounted on the brass block, which has a circular perforation through which the ball hits the specimen disk. The mounted specimen is placed inside the glass dome, which can be evacuated or filled with an inert gas. The test ball (⅛ in. steel ball bearing) is released electromagnetically from the top of the dome. The rebound height is measured against an illuminated scale at the back of the dome. The rate of testing (i.e., the interval between successive ball rebounds) may be adjusted from 3 to 10 s per test. A similar apparatus was used by Jenckel and Klein [79] investigation of the relationship between ball rebound energy absorption and temperature in polymers.

Shore Scleroscope—Shore scleroscopes, developed by Shore [*35*], have been manufactured since 1907 as the pioneer American standard for testing the hardness of metals and other materials. They consist of a calibrated glass tube with a diamond-tipped metal "impactor" located inside. The hardness is measured by the height that the impactor rebounds. This instrument is available in various models depending upon the application. They are used to determine the hardness of thick elastomers, but results are greatly influenced by the substrate when thin polymers are tested. The American Bowling Congress (ABC) specifies a Scleroscope hardness for coatings used on bowling pins. However, the hardness of the thin clear coating is insignificant when compared to the plastic substrate and maple wood core.

PHYSICAL CONCEPTS OF MAR RESISTANCE TESTING

The mar resistance of an organic coating is its ability to withstand scratching, scuffing, and/or denting actions, which tend to disfigure or mar (change) the surface appearance of the coating. Mar resistance, as defined above, is a resistance of the surface of the coating to permanent deformation, as a consequence of the application of *dynamic* mechanical forces. In this sense it is distinguished from print resistance, pressure mottling, and block resistance, in which the applied mechanical forces are static. Some examples of potential marring of organic coatings are: sliding an ash tray or other object across a desk or other item of furniture, rubbing one's belt buckle, zipper, or buttons along the organic coating on an automobile as it is being washed, a child sliding a toy or other object along a wall, refrigerator door, etc., and a woman dragging a wash basket full of wet clothes off the top of a washer or dryer.

When we refer to the scratching associated with marring, we are really referring to relatively fine surface scratches. This distinguishes the type of scratch encountered in mar testing from that encountered when attempting to evaluate hardness or adhesion by means of various types of scratch tests. There are, in general, three different ways in which materials are scratched when being tested for mar resistance:

1. Single scratches made with a needle or other sharp instrument.
2. A large number of scratches made by abrasive particles falling or impinging on the specimen.
3. A large number of fine scratches made by an abrasive medium being rubbed against the specimen, called scuffing.

In No. 2 and No. 3, the results are similar in that there is a loss of gloss or a haze produced on the surface of the specimen being tested. Also, the abrasive medium in No. 3 may not be an abrasive per se, but can be a type of fabric.

Regarding single scratches made with a needle or other sharp instrument, two schools of thought have existed as to exactly what constitutes a mar. One school of thought considers the end point to be any marring, whether a depression or a scratch. The other school considers a mar to have occurred only if, within the scratch depression itself, skin rupture of the organic finish has occurred as evidenced by light scattering. This skin rupture is gaining wider acceptance, because it can be quantified or measured and given a number. Also, the skin rupture mechanism, as evidenced by light scattering, is identical to that encountered in No. 2 and No. 3.

Finally, there is another type of mar that has not been mentioned yet, because it does not fit into the definition expressed at the beginning of this section on mar resistance. This is the streaking or marking mar wherein the organic coating itself is not necessarily physically damaged, but it has been marked or streaked by a transfer of material to the coating. The most common example of this occurs when a coin, such as a nickel, is rubbed across the coating. If the metal is transferred to (streaks) the coating, the coating is said to be marred. This same mechanism occurs when a fingernail is used. The acceptance or use of this type of marring or mar resistance seems to be losing ground to the scratching types, and, at the risk of being redundant, a test for it has been never quantified or standardized.

General Motors Corp.'s Engineering Standards Group wrote, in 1988, GM9150P, Resistance to Marring or Scuffing. In the test method a Bronzette Gem paper clip, No. 1, is allowed to traverse a coated panel with a weight of 750 g applied to it. The coated specimen is pulled towards the operator at a speed of approximately 37 mm/s. The coated specimen is then rotated 90° counterclockwise. This is then repeated until the four directions are completed. The panel is then examined for marring or scuffing. A satisfactory coatings shows no marring or scuffing. An unsatisfactory coatings shows marring or scuffing. Rejected specimens are reinspected after a minimum of 15 min to be certain that the marring is not superficial and does not disappear upon standing.

Ford Motor Co.'s Quality Laboratory and Chemical Engineering Group wrote, in 1973, BN 8-4, Resistance to Scuffing. In the test method, a Taber abraser is used to determine the resistance to scuffing of materials such as painted substrates, vinyl, genuine leather, and luggage compartment mats. A special scuffing head is used.

Single Scratch Methods

BTL Balanced Beam Mar Tester—This method [*80*] was developed in 1945 by R. J. Phair of the Bell Telephone Laboratories (BTL). The apparatus is shown in ASTM Method D

2197: Test Methods for Adhesion of Organic Coatings by Scrape Adhesion [*53*]. In mar testing, the rounded tool is replaced by a chromium-plated phonograph needle. The apparatus consists of a balanced beam to which is secured a platform for supporting weights, a rod at an angle of 45° which holds the scratching needle, and a sliding or movable table on which to support and move the specimen. Initial adjustments are performed to ensure that the apparatus is level and that the end of the needle is directly in line with the weight support rod.

The procedure differs from that employed in adhesion testing in that the panel is drawn toward rather than away from the operator. A 50-g minimum load with 50-g increment creases is used. The end point is reached when the upper surface of the paint film has been ruptured. A breakdown point is distinguished from depressions in the finish by holding the marred specimen nearly at eye level in flat lighting so that no highlight reflections are visible. The least weight required to make a line which shows a distinct whitish reflection from the subsurface of the finish, but not from the base, is the mar value. Care is taken to avoid reflections from the side walls of depressions in the finish which are not cut through.

The mar point can also be observed by inspecting the marks under a microscope of 80 to 100 power. The deepest section of a depression will scatter the light where marring has occurred if it is illuminated along its length and at an angle of about 20° from the plane of the specimen. The appearance of a depression mark without marring is illustrated. Mar values of 200 g or more are usually indicative of sufficient resistance to withstand the scarring actions encountered in normal assembly of telephone apparatus.

In making a determination, the specimen is placed on the movable table with a starting load of 50 g on the weight platform. The needle is lowered slowly onto the specimen, with the end of the apparatus nearest the needle being directly in front of the operator. The movable table is pulled toward the operator with a slow, steady motion, at a rate of 1 to 1½ in. (25 to 38 mm)/s, for a distance of at least 3 in. (76 mm). At the end of each stroke the needle is raised off the specimen, and the specimen is moved slightly to the side. This procedure is repeated with a 50 g increase in load each time until the surface of the organic coating has been disrupted or ruptured.

Mar resistance is expressed as the load in grams required to rupture the surface of the coating as evidenced by light scattering. A mar or breakdown point is distinguished from depressions in the coating by holding the marred specimen nearly at eye level in flat lighting, so that no highlight reflections are visible. The least weight required to make a line that shows a distinct light scattering or whitish reflection in the depression made by the needle is the mar resistance value of the organic finish. Care must be taken to avoid reflections from the wall of depressions in the finish which are not cut through.

Years ago when telephone sets were made of metal, it was found that the baked black enamel used on the metal base of the desk type telephone would get through the numerous assembly operations in an unmarred condition if the value of mar resistance was 200 g or better. Materials having mar resistance levels of less than 200 g would not necessarily suffer damage to a degree sufficient to expose the base metal, but were rejected in many cases on the basis of unsatisfactory appearance.

ASTM Task Group D01.23.14 Hardness, Abrasion and Mar Resistance ran a preliminary round-robin test seeking a candidate apparatus around which they could write a test method. The results of the round-robin tests are shown in Table 6.

As a result of their findings, they wrote D 5178: Test Method for Mar Resistance of Organic Coatings [*53*] using the equipment R. Phair originally designed for adhesion testing. Several operators have expressed a lack of interest in this test method as the end point is difficult to recognize. Also a mark judged to be a mar may disappear overnight.

Princeton Scratch Tester—This apparatus is somewhat similar to the balanced beam tester, but instead of having a movable specimen table, the beam assembly itself moves on a V-shaped track, the specimen remaining immobile. Also, the needle is held at an angle of 90° to the surface of the specimen.

Hoffman Scratch Tester—This device, described in the section on hardness in this manual, has also been used to determine mar resistance. However, its use as a mar tester has never gained wide acceptance. The scratches obtained are usually quite large and often go down to the substrate.

Rondeau Scratch Tester—The same criteria that apply to the Hoffman scratch tester just mentioned also apply to the Rondeau Scratch Tester.

TABLE 6—ASTM Task Group D01.23.14 on hardness, abrasion and mar resistance. Results of round-robin tests on mar.

Sample/ Collaborator	Hardness (Pencil)				Eraser (Rubs)		Coin (Mar)		Erichsen (Swing)	Scrape Adhesion (Balanced Beam)[b]		RCA Tape Abrader
	1	2	3	4	1	4	1	4	5	2	3	4

Impinging Abrasive Method

Falling abrasive particles are used as the principle in ASTM D 673: Test for Mar Resistance of Plastics [*81*]. This principle was also adopted as Method 1093: Mar Resistance, of Federal Test Method Standard No. 406. However, on 4 Jan. 1982, the Federal Government canceled this test method and replaced it with ASTM Test Method D 673. As indicated by the titles, the test was designed for but not limited to plastics. Therefore it can be used for testing mar resistance of organic coatings. It was developed by Boor in 1942 [*82*] and adopted as tentative by the ASTM in the same year. The test consists of allowing a measured stream of No. 80 carborundum particles to fall onto the specimen. Then, the degree of marring or mar resistance is evaluated by means of gloss measurements in accordance with ASTM D 1003: Test Method for Haze and Luminous Transmittance of Transparent Plastics [*81*]. It should be noted that, according to the U.S. Naval Ordnance Laboratory [*83*], the method is useful for both research and development and design criteria. A similar test was developed by the British in 1942 [*84*]. Instead of measuring the loss of gloss, the change in light transmission through the specimen was measured. Of course this restricted one to the use of transparent materials. Incidentally, it appears that G. G. Sward first suggested the loss of gloss of a surface by a definite amount of falling abrasive [*85*].

The apparatus consists of a hopper, motor, tube, support assembly, specimen holder, and the optical equipment required to measure the gloss and loss thereof. Uniform distribution of abrasive is obtained by rotation of the conical hopper at 7 rpm as abrasive flows through holes 0.070 in. (1.8 mm) in diameter. The abrasive flow rate is about 225 g/min. Usually, several abrasion tests with increasing amounts of abrasive are made, that is, 200, 400, 800, 1200, and 1600 g.

A special light projector and glossmeter are used to measure the gloss of the specimens. The following equation is used for calculating the percentage of gloss.

$$\text{gloss, percent} = 100\frac{I_1 - I_2}{I_1} \tag{24}$$

where

I_1 = photoelectric cell reading at the specular angle (45°), and

I_2 = photoelectric cell reading at the 60° angle (15° off specular).

The percentage gloss of the abraded or marred spots is plotted against the respective amounts of abrasive used to obtain a characteristic curve for each different material. Since such curves for different materials are often found to change slope irregularly, they may cross each other, and the rating of a series of different materials using a given amount of abrasive may not be representative of their relation at other amounts of abrasive. One way to arrive at an overall performance is to average the percentage of gloss at the various amounts of abrasive or the area under each curve.

In 1988, Committee D-20 stated in the Precision and Bias section of Test Method D 673: "a meaningful precision statement cannot be developed at this time because of the small number of laboratories presently known to be using this test method."

Scuffing Methods

Taber Abraser Mar Test—Use of the Taber Abraser for a mar test for polyester resins was studied by Sherr and Martin [*86*] employing ASTM D 1044: Resistance of Transparent Plastics to Surface Abrasion [*81*]. They measured the increase in haze (transmission) of abraded transparent plastics after 100 and 200 cycles/revolutions of the specimens. J. M. Carter[7] from U.S. Plywood Corp. modified this ASTM method so that it could be used to measure the mar resistance of organic coatings on opaque substrates. His method consisted of observing for the first visually perceptible mar, wear track, or change in gloss. The number of cycles required to cause such a change is expressed as the mar resistance of the coating. This method was used in some preliminary round-robin work in the mid-1960s.

The following procedure was adopted for a second round-robin test:

> *Mar resistance is* expressed as the number of abrasion cycles required to produce a visually perceptible mar, wear track, or change in gloss. The pair of CS-10F Calibrase wheels to be used shall be mounted on their respective flange holders, taking care not to handle them by their abrasive surfaces. The 1000 g loads shall be fixed to each side. The ST-11 stone shall be mounted fine side up or the ST-11 disk shall be mounted abrasive side up on the turntable and the wheels shall be refaced for 25 cycles, brushing the residue from the stone during the process. Adjust the suction pickup to just clear the surface of the track. The abrasive wheels shall be refaced after each test. CAUTION—Do not touch the surface of the wheels after they are refaced. The specimen shall be mounted on the specimen holder or turntable with the coating side up. Adjust the suction pickup to just clear the surface of the track. The Calibrase wheels and 1000 g loads shall be mounted as above. After each cycle or revolution of the specimen, stop the turntable and observe for the first perceptible sign of wear track starting to show. Observe by looking at an angle of 45° incident to the specimen with a light source in a line with and at right angles to the incident angle. A reading shall not be considered valid unless the mar includes at least 75 percent of the possible circumference of the wear track and as wide as the width of the Calibrase wheels.

In 1992, Task Group D01.23.14 Hardness, Mar and Abrasion Resistance initiated round-robin work using a test method developed by E. I. du Pont Co. for automotive finishes. The same Taber abraser used in Test Method D 673 is employed, but changes of gloss rather than transmitted haze are being measured.

Erichsen Scar-Resistance Tester—This instrument [*87*], shown in Fig. 43, is in frequent use throughout the world to measure coating surface damage. This device was designed to replace the traditional fingernail mar test. It contains a scarring tool in the form of a disc mounted on a screw and under pressure from a helical spring. The spring applies a force which is adjustable of 0 to 20 N. The instrument is placed onto the surface so that it rests on the two guide wheels and the marking wheel, which is locked then presses onto the surface with the preset force from the spring. The scar resist-

[7]Private communication between J. M. Carter and E. M. Corcoran.

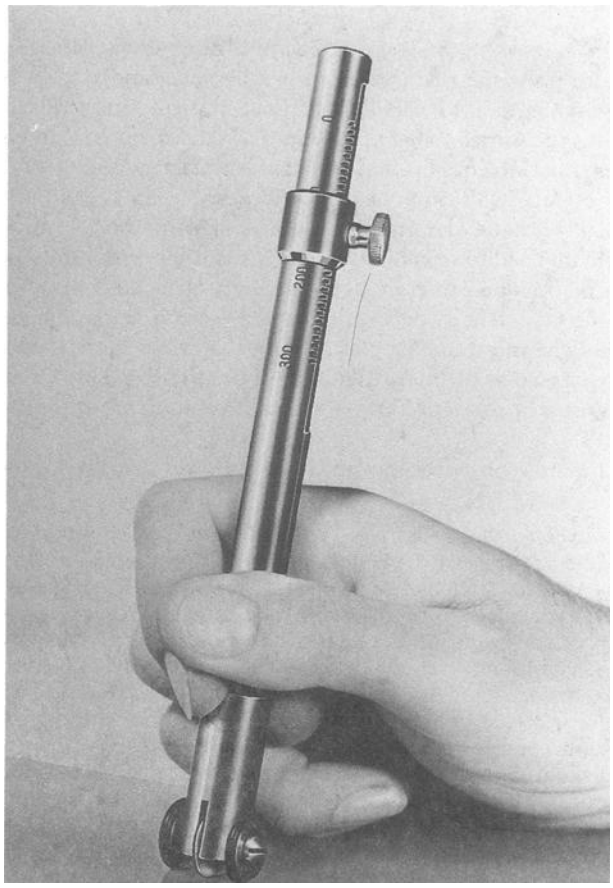

FIG. 43–Scar-Resistance Tester. (Courtesy of Erichsen GMBH & Co.)

ance result is the spring force at which the surface just shows a mark.

FDC Fine Scratch Test—The Furniture Development Council, London (FDC) designed a test in 1957 to determine the resistance of newly formed nitrocellulose lacquer films to damage when scratched, but it may be used on any type of coating. It consists of determining the loss of gloss of the organic coating when it is rubbed with a wool blanket.

A rubbing head with an area ¾ in. in diameter, under a load of 4 lb, is rotated on the specimen at 10 rpm for 2 min (20 rotations). The head is covered with No. 778, No. 3 Super White Blanketing from James Kenyon & Son, Ltd., made from 52/6S Good Quality English Wool, plain weave, 26 picks per inch, 32 ends per inch, 17½ ounces per square yard, scoured, and milled finish. Blanketing produces more scratches than most other common materials and is also more reproducible. A disk of blanketing may be used twice, once on each side.

Tests are made on films applied to two black glass plates. Five tests are made on each plate. A 45° gloss meter is standardized at 100 on an unscratched portion of the film, and the gloss of each scratched area is measured. For a difference in gloss to be considered significant, the difference in gloss between the marred and unmarred area must be greater than:

1. 1.7 for gloss of between 88 and 100, and
2. 2.7 for gloss below 88.

Miscellaneous Methods

Belt Buckle Test—At least as late as 1969, one of the major automotive companies used a belt buckle as one method of evaluating the mar resistance of the organic coatings on their automobiles. However, the exact method is not known to this writer.

Coefficient-of-Friction Mar Test—One of the leading manufacturers of mar resistance additives for organic coatings uses a sort of coefficient-of-friction test to evaluate mar resistance. This test consists of wrapping a 500-g weight in cheesecloth, placing the weight at one end of a test panel and slowly lifting the weighted end of the panel. The angle at which the weight slips off is taken as an indication of the coefficient of friction. The lower the angle, the better the mar resistance.

Coin Mar Test—A leading manufacturer of organic coating resins uses a nickel (five-cent piece) to evaluate the mar resistance of pigmented organic coatings. The manner or method that is used makes it a streaking or marking type of mar test. The test consists of dragging a nickel over a pigmented coating and seeing how much metal is transferred to the coating, as manifested by the size and color of the streak.

Fingernail Mar Test—Another leading manufacturer of mar resistance additives for organic coatings uses a fingernail to evaluate mar resistance. To make a test the back of a fingernail is dragged along the surface of the coating. If the coating is marked, it is considered to be marred. This is also a streaking or marking type of mar test. Others have used the edge of a fingernail in a similar manner.

Stress Phenomena in Organic Coatings

by Dan Y. Perera[1]

INTEREST IN THE STRESS PHENOMENA in organic coatings is relatively new. The importance of understanding and measuring this stress became evident as facts accumulated about its role in coating degradation [*1–10*]. This is also supported by the fact that many coatings used today (e.g., thermosets) are more susceptible to developing high stresses than traditional ones (e.g., alkyd paints). It is now quite clear that stress can affect coating adhesion and/or cohesion and provoke delamination and/or cracking.

Since the development of stress is involved in practically all stages of coating life (film formation, exposure to various climatic conditions), its measurement is essential for a better understanding of coating behavior.

In addition, the measurement of stress can be used to evaluate other important characteristics of a coating, such as the glass transition temperature (Tg) and the critical pigment volume concentration (CPVC).

ORIGINS OF STRESS IN ORGANIC COATINGS

Stresses originate in organic coatings as a result of their adhesion to the substrate. Good adhesion is, on the one hand, indispensable for adequate substrate protection, but on the other hand prevents the normal movement of a coating.

The three main causes which provoke stress in an organic coating are [*11*]:

1. Film formation.
2. Variation in temperature.
3. Variation in relative humidity (RH).

The stresses induced by film formation, variation in temperature, and variation in RH are known, respectively, as internal, thermal, and hygroscopic. The latter two stresses are also referred to as hygrothermal (S^{HT}).

It is important to realize that, due to the coating adhesion to its substrate, stress exerts its action mainly in a plane parallel to the substrate [*6,12,13*]. Therefore, one can write

$$S = \frac{E\epsilon}{1 - \nu} \tag{1}$$

where

S = stress,
E = elastic modulus,
ϵ = strain, and
ν = Poisson's ratio.

Stresses are especially damaging at edges [*14*] where they cannot cancel each other or in the middle of the plate if defects or heterogeneities are present.

Film Formation

During film formation and regardless of the mechanism involved (evaporation of solvent, coalescence, chemical reaction, or their combination), in almost all cases the coating tends to contract. If this contraction is prevented by coating adhesion to its substrate and/or the mobility of macromolecular segments is hindered, a tensile stress will develop in the coating.

In the literature a certain confusion reigns about the denomination of the stress arising during film formation. For example, for solvent-based coatings an author may use these terms: cure stresses, solvent removal stresses, residual stresses, shrinkage stresses, internal stresses. For simplification, I suggest referring to the stress arising during film formation as internal stress (S^F).

If a liquid paint is applied on a substrate [*8*] and the development of stress is measured as a function of time, a number of stages can be observed (Fig. 1).

In Stage 0, the coating is still liquid and is mobile enough to permit volume contraction, and consequently no stress develops.

In Stage 1, the film starts to form, the volume contraction is restricted and stress develops.

In Stage 2, a number of processes can occur. Depending on the coating composition, the evolution of stress can include various combinations of increasing, decreasing, and stationary stress levels. If no damage occurs to the film (cracks, microfissures, loss of adhesion), a decrease in stress results from relaxation processes which occur from the moment the stress develops but only become evident at this stage. It also follows that the measured stress values are a result of two opposite processes, one tending to develop stresses in the coating (in this case due to the volume shrinkage) and the other tending to decrease them (due to stress relaxation).

Examples of stress development as a function of time for latex coatings [*15*] above and below the CPVC are shown in Fig. 2.

It is important to add that stress starts to develop in a coating when its Tg is at least equal to the experimental temperature [*6*]. For solvent-based coatings (Fig. 3), this is

[1]Head of Department, Coatings Research Institute (CoRI), Ave. P. Holoffe, B-1342 Limelette, Belgium.

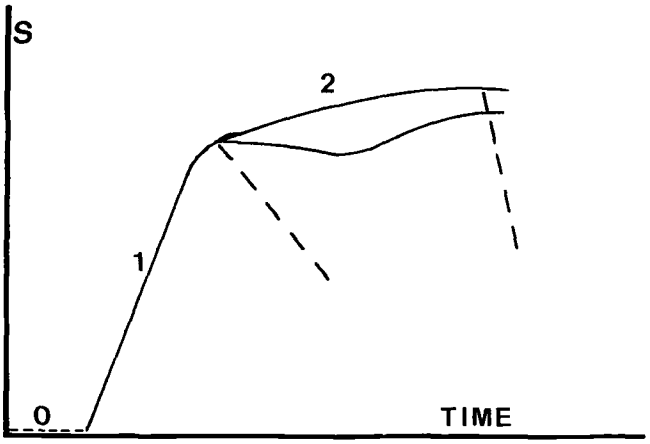

FIG. 1–Schematic description of stress (*S*) dependence on time.

also confirmed by the fact that stress appears when Phase 2 of the evaporation kinetics (the diffusion process) starts [*16*]. At this point in the evaporation, referred to as solidification, the solvent volume fractions are equal to the solvent concentration necessary to bring the Tg of the coating to a temperature equal or higher than the experimental one [*6,17*].

If Eq 1 is extended to accommodate the specific effect of internal strain, ϵ^F [*6*], then

$$\epsilon^F \simeq \frac{V_S - V_t}{3V_S} = \frac{\Delta V}{3V_S} \tag{2}$$

where

V_S = volume of coating at solidification, and
V_t = volume of coating at time t after solidification.

One can write [*18*] that

$$S^F = \int_{V_t}^{V_S} \frac{E}{1-\nu} \cdot \frac{1}{3V_S} dV \tag{3}$$

Despite the limitations of Eq 2, which assumes that the strain is isotropic and linear, Eqs 2 and 3 enable one not only to better understand the factors affecting the S^F but eventually to calculate it approximately.

Variation of Temperature

When coated substrates are exposed to variations in temperature, dimensional changes are induced. If the thermal expansion coefficients of the coating (α_F^T) and the substrate (α_S^T) are different, which is usually the case, a thermal stress (S^T) will develop in the coating [*2,7,11,19,20*].

Since the thermal strain, ϵ^T is given by

$$\epsilon^T \simeq (\alpha_F^T - \alpha_S^T)\,\Delta T \tag{4}$$

the combination of Eqs 1 and 4 gives

$$S^T = \int_{T_2}^{T_1} \frac{E}{1-\nu}(\alpha_F^T - \alpha_S^T)\,dT \tag{5}$$

Determination of Tg

A schematic description of the stress dependence on temperature [*18*] is represented in Fig. 4.

Such a dependence indicates the possibility of determining the Tg of a coating from the stress measurement. This is due to the fact that E, α_S^T, and ν (see Eqs 1 and 5) also show a profound change at Tg.

Below temperature *a* the coating is in the glassy region, and above temperature *b* the coating is in the rubbery region.

The linear dependence of S on temperature in the glassy region greatly facilitates the measurement of Tg. This linearity is due to the fact that in this region E, α_F^T, and ν are practically independent of temperature.

Three examples of the stress dependence on temperature and Tg determination by thermal stress measurements [*18*] are shown in Fig. 5.

When the stress magnitude in the rubbery region is small (e.g., elastomers, coatings with a low degree of cross-linking),

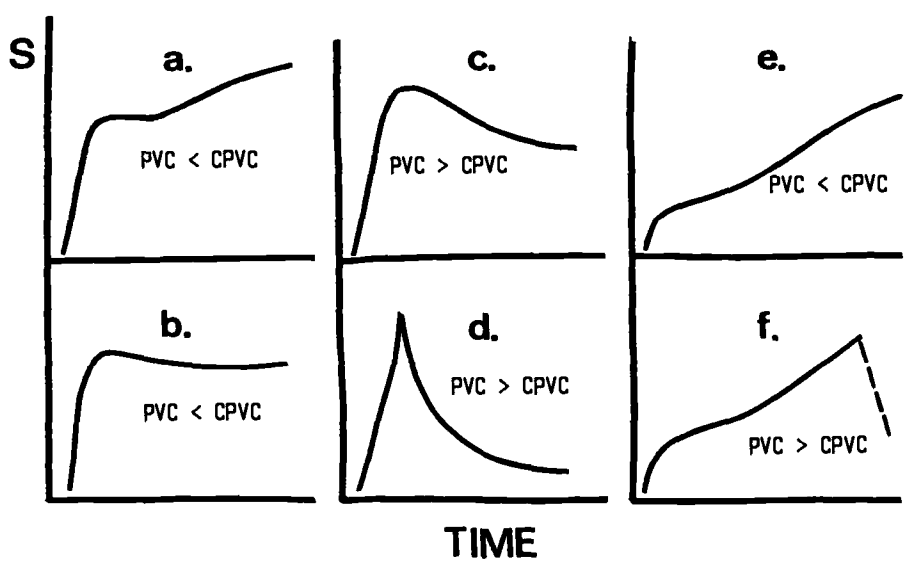

FIG. 2–Schematic description of stress (*S*) dependence on time for latex coatings [*15*]: (a) and (b) PVC < CPVC; (c) and (d) PVC > CPVC; (e) PVC < CPVC in the presence of a poor coalescent; (f) PVC > CPVC in the presence of a poor coalescent.

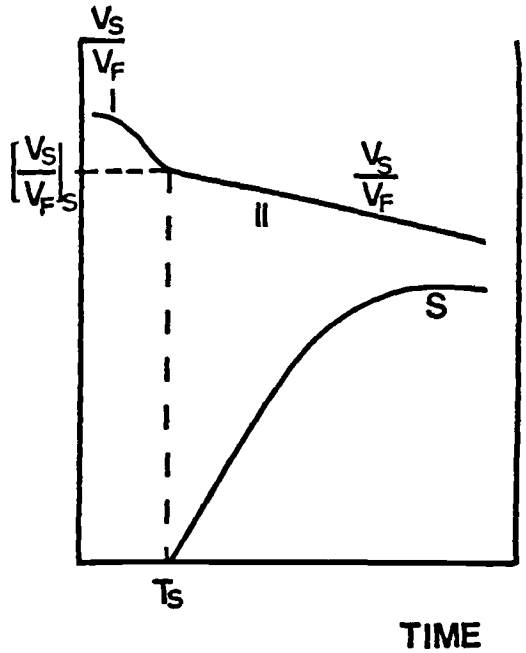

FIG. 3–Schematic representation of the dependence of V_S/V_F and stress (S) on time [*16*]. V_S = volume of solvent present in the film; V_F = volume of the dry film.

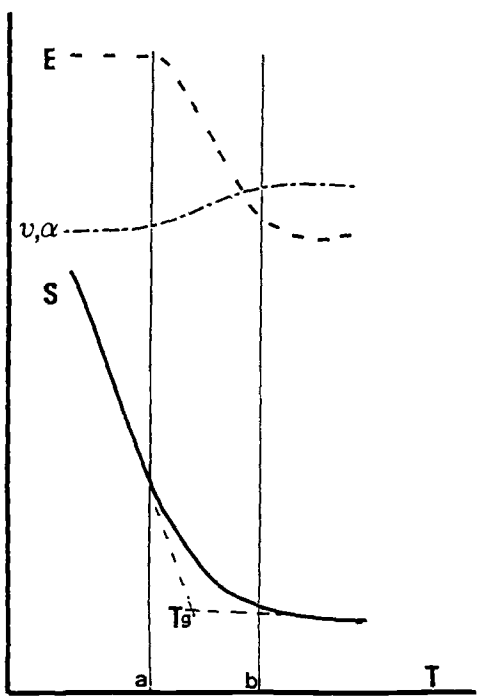

FIG. 4–Schematic representation of dependences of S, E, α_F^T, and ν on temperature (T) [*18*].

the Tg can be determined with fair accuracy just by carrying out a few measurements in the glassy region and then extrapolating the straight line to $S^T = 0$.

For coatings with a significant stress in the rubbery region (e.g., highly cross-linked thermosets), the measurement of stress in this region might provide a way to approximately determine the cross-link density, ν_e [*21*].

Since in accordance with the molecular theory of rubber elasticity in its simplified form [*22,23*]

$$E_r = 3\nu_e R T_r \tag{6}$$

and

$$S_r = 2E_r \epsilon_r \tag{7}$$

giving

$$\nu_e = \frac{E_r}{3RT_r} = \frac{S_r}{6RT_r\epsilon_r} \tag{8}$$

where R, S_r, E_r, and T_r are, respectively, the gas constant, the stress, the elastic modulus, and the temperature at the beginning of the rubbery region. If S_r is measured and ϵ_r is known or determined from separate measurements (e.g., by thermomechanical analysis, TMA), ν_e can be calculated.

Others have used the evaluation of Tg by stress measurements to investigate the effect of a pretreatment on certain pigments [*24*], the state of cure of baking enamels [*21*], and the modification of epoxy coatings [*19a,25*].

Variation of Relative Humidity

Dimensional changes induced by absorption and desorption of water as a result of variation in RH is another cause of stress development in a coating [*11,26,27*]. As in the case of temperature, if a mismatch between the expansion coefficients of the coating and the substrate exists, a hygroscopic stress (S^H) will arise in the coating.

Since the hygroscopic strain ϵ^H is given by

$$\epsilon^H \simeq (\alpha_F^H - \alpha_S^H)\,\Delta\,\mathrm{RH} \tag{9}$$

one can write that

$$S^H = \int_{\mathrm{RH}_1}^{\mathrm{RH}_2} \frac{E}{1-\nu}(\alpha_F^H - \alpha_S^H)\,d\,\mathrm{RH} \tag{10}$$

where α_F^H and α_S^H are, respectively, the hygroscopic expansion coefficients of the coating and the substrate.

Some examples of the S^H dependence on RH is given in Fig. 6.

INTERDEPENDENCE OF STRESSES

While in previous subchapters the various stresses (S^F, S^T, S^H) were discussed separately, in practice they can act together in such a way that the total stress (S_{tot}) is small or, as in many cases, very important [*11*]

$$S_{tot} = S^F \pm S^T \pm S^H \tag{11}$$

The positive and negative signs are arbitrarily chosen. The positive sign denotes a coating tendency to contract (tensile stress) and the negative sign a coating tendency to expand (compressive stress). S^F is practically always positive.

Equation 11 indicates the existance of two climatic conditions which might provoke a high stress in a coating:

1. Low temperatures and RH's induce high tensile stresses (e.g., a dry, cold winter).
2. High temperatures and RH's induce high compressive stresses (e.g., a humid, warm summer).

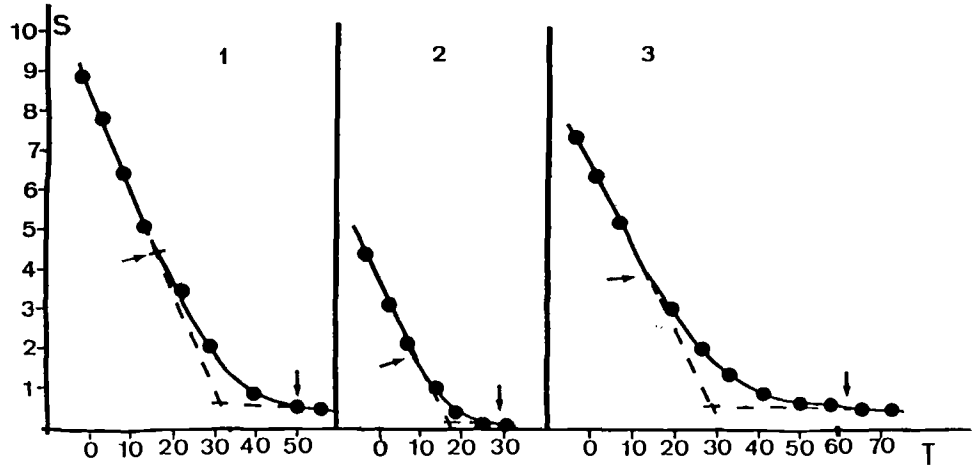

FIG. 5–Stress (*S*, MPa) dependence on temperature (*T*, °C) for three coatings at RH ≃ 0% [an epoxy (1), a polyurethane (2), and an epoxy/melamine system (3)] [*18*].

According to Eq 11 and depending on the type of coating and the way it was cured, a number of situations can arise. For example, for a thermosetting coating cured at a high temperature (i.e., at $T > \text{Tg}$, RH = 0%) and then exposed to different RH's, since $S^F \approx 0$, the S_{tot} is given by

$$S_{tot} = S^T - S^H \tag{12}$$

In Fig. 6, for one coating, the stress is positive regardless of RH, meaning that S^T is always higher than S^H; but cases where negative stress values are obtained are not rare.

It could be demonstrated [*11*] that the same coating conditioned in an identical environment but with different previous histories can develop different values of stress. Thus, a coating cured under isothermal and constant RH conditions (e.g., 21°C and 50%) will develop a total stress given by

$$S_{tot} = S^F - S^H \tag{13}$$

Now, if the coated substrate is first heated at $T > \text{Tg}$ for sufficient time to enable a maximum stress relaxation and then brought back to the initial conditions (i.e., 21°C and 50% RH)

$$S_{tot} = S^T - S^H \tag{14}$$

The results obtained [*11*] show that in certain cases (e.g., for an epoxy coating), the S_{tot} can be very different [S_{tot} (Eq 13) = 5 MPa; S_{tot} (Eq 14) = 0.4 MPa].

Interesting cases are those where the Tg of a coating is close to or below the experimental temperature once they are immersed in water or exposed to a high RH [*28*]. Under such conditions S^F or S^T can relax and therefore $S_{tot} = S^H$.

Such a situation is illustrated schematically in Fig. 7 and for a particular epoxy coating in Fig. 8.

Once a coated substrate is immersed in water one can observe first the development of a hygroscopic compressive stress followed by its decrease. The time necessary to reach zero stress is mainly dependent on the type of coating. The withdrawal of the coated substrate from water provokes first the development of a relatively high tensile hygroscopic stress followed by its decrease. The decrease in stress (Curves 2 and 4 in Fig. 7) is due to relaxation processes facilitated by the low Tg of the coating. The much higher stress values attained after the immediate withdrawal of the coated substrate from water (Curve 3 in Fig. 7), in comparison with the initial stress ($S_{tot} = S^F - S^H$ or $S_{tot} = S^T - S^H$) are due to the high hygroscopic tensile stress ($S_{tot} = S^H$).

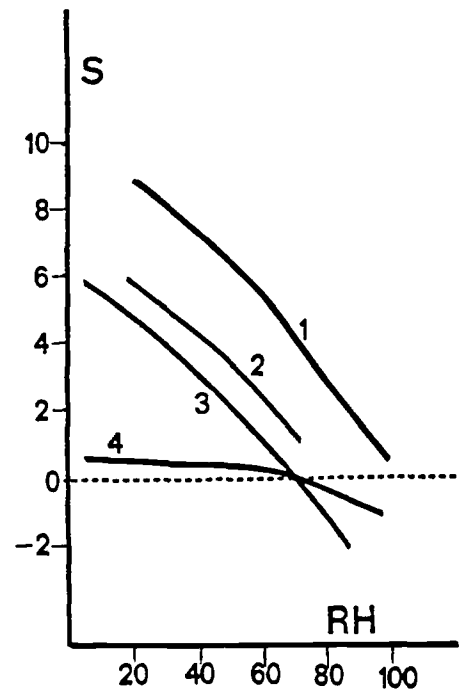

FIG. 6–Stress (*S*, MPa) dependence on relative humidity (RH, %) for a polyester powder coating (1); an epoxy (2); a polyurethane (3); and a latex coating (4) [*27*].

The above findings are important not only for understanding the mechanism of the stress development in organic coatings but also for practical reasons such as choosing the experimental conditions of natural or accelerated weathering tests, i.e., the magnitude of stress developed in a coating might depend as much on natural climatic conditions as on the type and order of cycle selected in the laboratory.

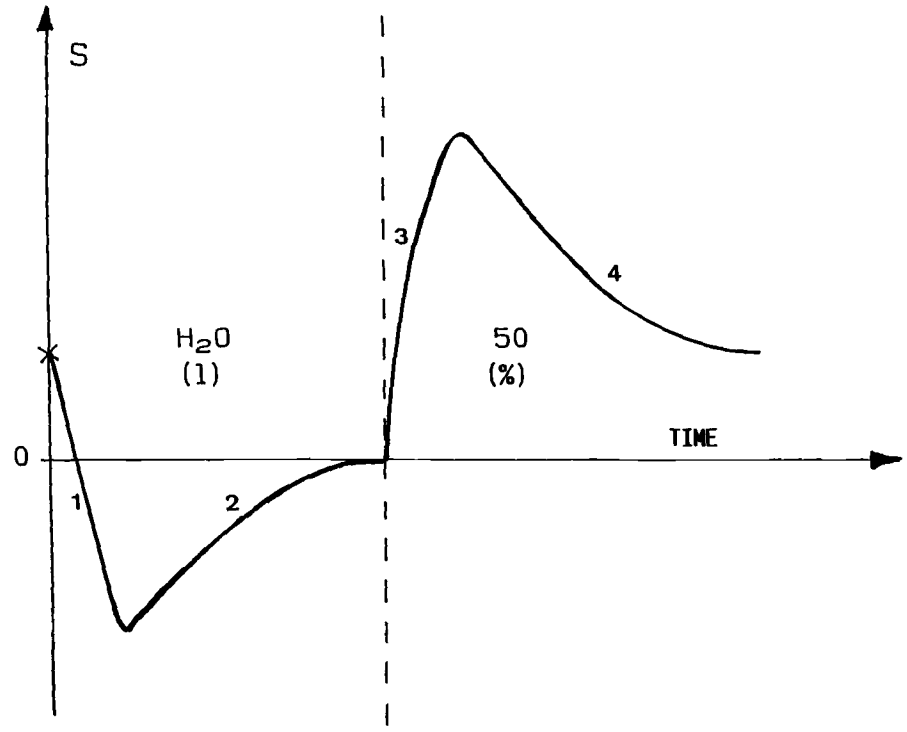

FIG. 7–Schematic description of the stress (*S*) dependence on time at two experimental conditions (water and 50% RH). *X* = the initial stress [*28*].

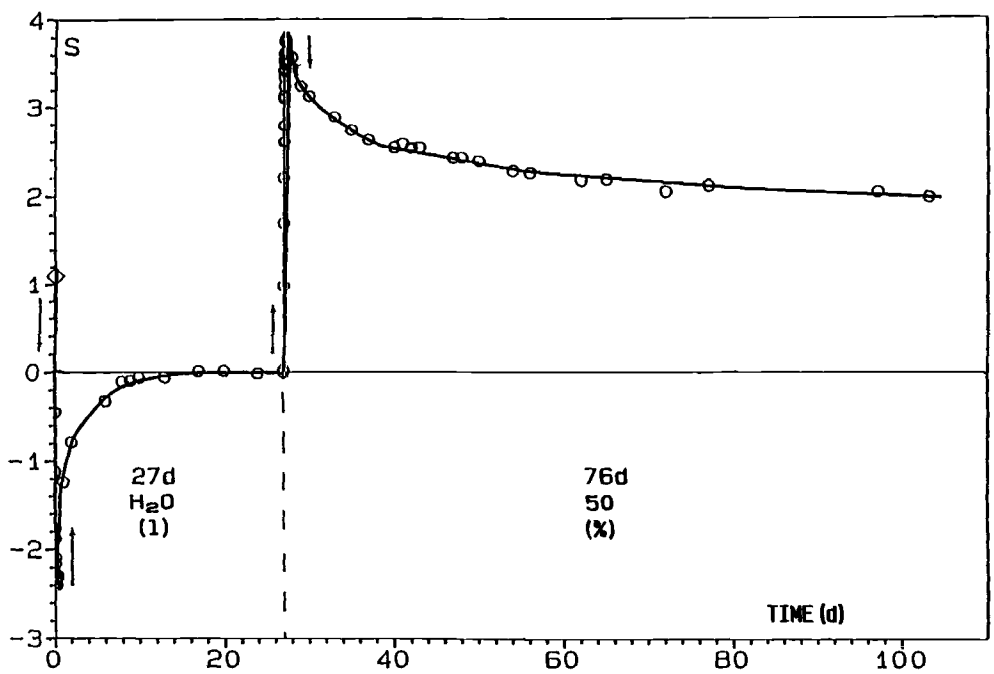

FIG. 8–Epoxy coating. Stress (*S*, MPa) dependence on time (*d*, day) at two experimental conditions (water and 50% RH); ◇ = initial stress [*28*].

STRESS MEASUREMENT

Equations 1, 3, 5, and 10 show that, if one knows the values of E, ϵ, and ν of a coating, then in principle the various stresses can be calculated. However, except for relatively simple cases, this is difficult because the above coating characteristics can be time, temperature, and relative humidity dependent.

Therefore, efforts were made to directly determine the stress arising in a coating. Among the methods one can find in the literature are: optical [*29–32*], strain gages [*19a,33,34*], brittle lacquer materials [*35*], X-ray diffraction [*36*], and cantilever (beam) [*2,4,8,11,26,37–43*].

The cantilever (beam) method appears to be the most widely used and is suitable for determining the stress in an organic coating. This method makes use of the fact that for a

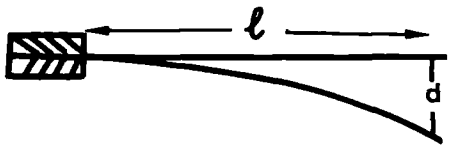

FIG. 9–Schematic description of the vertically fixed at one end cantilever (beam) method [*67*].

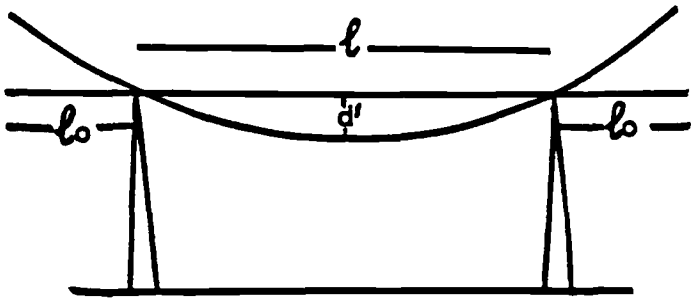

FIG. 10–Schematic description of the freely supported beam method [*67*].

coating under stress, applied on a substrate, the coated substrate will deflect in the direction which relieves the stress. Since the deflection can be measured and the elastic properties of the substrate are known from separate determinations, the stress can be calculated.

Two variations of the cantilever (beam) method are described in the literature: a one-sided coated substrate either (1) fixed vertically at one end [*4,8,26,37*] (Fig. 9) or (2) freely supported on two knife edges [*2,11,41,43*] (Fig. 10).

The stress analysis of (1) is more complicated and shows that to eliminate the effect of clamping on the coated substrate deflection, its measurement should be made at a distance higher than 80 mm from the clamping point [*8*]. Variation (2) is much simpler to analyze and can be designed to eliminate the effect of weight loss on the coated substrate deflection by choosing the right distance between the two knife edges [*43*].

Each variation has its advantages, but if correctly used they should give identical results. For example (1) is more suited to evaluating stress in water [*28*] and (2) to determine the effect of temperature [*2,11*].

Among the techniques used to measure the deflection of coated substrates, one can mention: capacitive transducers [*42,43*], laser [*44*], travelling microscope [*4,8,26*], automatic micrometer [*11*].

A commercial apparatus, the CoRI stressmeter (Fig. 11), is based on Variation (2) and the mathematical analysis described in Ref *43*. This apparatus is almost completely automatic and enables one to measure the stress from about −5 to 100°C under a variety of RH's.

A number of mathematical equations are proposed in the literature to calculate the stress, but in the author's opinion those proposed by Corcoran [*40*] are the closest to the real situation (e.g., considers the fact the stress develops in two directions)

$$S = \frac{dE_S t^3}{3l^2 c(t + c)(1 - \nu_S)} + \frac{dE(t + c)}{l^2(1 - \nu)} \tag{15}$$

$$S = \frac{4d' E_S t^3}{3l^2 c(t + c)(1 - \nu_S)} + \frac{4d' E(t + c)}{l^2(1 - \nu)} \tag{16}$$

where

d = deflection of the substrate (Fig. 9),
d' = deflection in the middle of substrate (Fig. 10),
E_S = elastic modulus of the substrate,

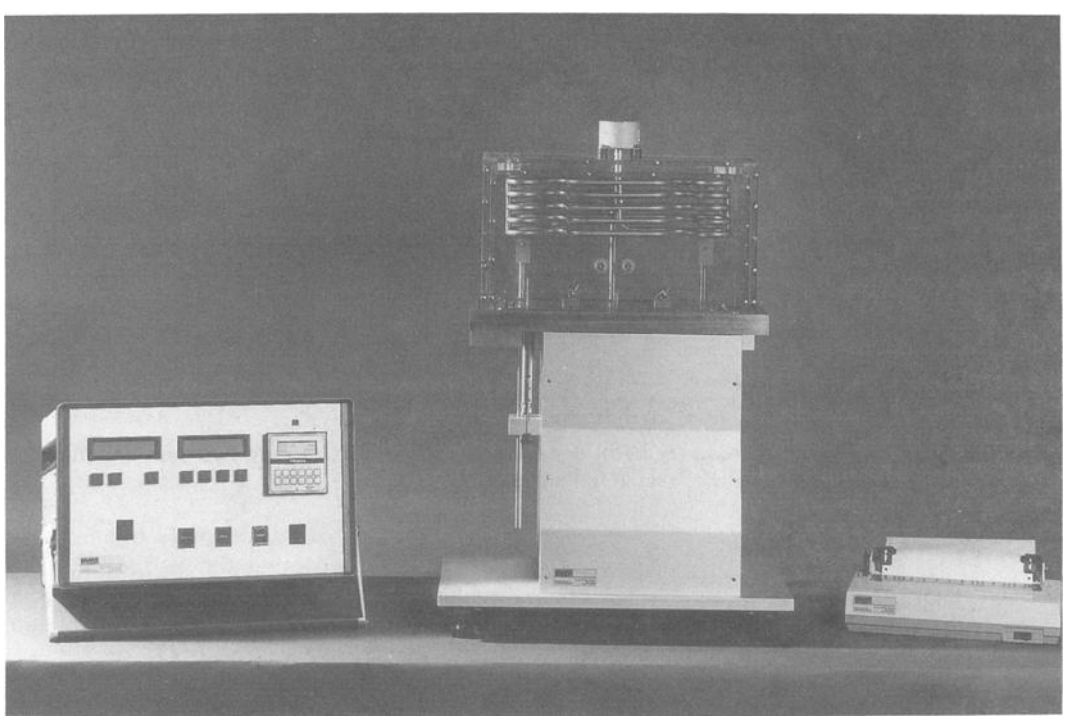

FIG. 11–CoRI stressmeter apparatus (Courtesy of Braive Instruments, Liege, Belgium).

ν_S = Poisson's ratio of the substrate,
t = thickness of the substrate,
c = thickness of the coating,
l(Eq 15) = length of the coated substrate between the point at which it is clamped and the point at which the deflection is measured (Fig. 9), and
l(Eq 16) = distance between the two knife edges (Fig. 10).

Equations 15 and 16 assume, among other things, good adhesion between the coating and the substrate, isotropic elastic properties of the coating and the substrate, the elastic limit of the substrate is not exceeded, and the stress is constant throughout the coating thickness.

The second term in Eqs 15 and 16, which contains a number of coating properties difficult to determine, can be neglected if $E_S \gg E$ and $t \gg c$.

Most commonly, stainless steel or cold laminated steel [*4,8,11,26,42,43*] shims are used. Other substrates such as aluminum can also be used.

The elastic modulus, E_S, of each shim can be determined prior to use with the CoRI stressmeter by applying Eq 17

$$E_S = \frac{Pl^3}{4d't^3b} \tag{17}$$

where

P = weight placed in the middle of the substrate,
b = width of the substrate, and
d', l, t = as in Eq 16.

It is important to add that, although it is not difficult to make the measurements, nevertheless great care is necessary. One should always use the correct substrate thickness, adequately condition it, and precisely calibrate the apparatus.

EFFECT OF COATING COMPONENTS

Since E, ϵ, and ν (Eqs 1, 3, 5, and 10) are known to be affected by the coating components, one should expect the same to hold for stress development. This section will briefly review the influence of pigmentation, solvents, and binder.

Pigmentation

It has been shown that pigmentation, both the pigment volume concentration (PVC) and the type of filler (i.e., pigments and extenders), affects the development of internal stress [*7,41,45–50*]. To illustrate this, examples are presented in Figs. 12 to 17.

Figures 12 and 13 show, respectively, the stress dependence on time for a thermoplastic binder in solution and a latex, filled with a titanium dioxide (TiO_2). Some PVCs are above the CPVC, and some are below the CPVC.

The different stages occurring during the film formation, discussed previously, can be recognized. In Stage 1 stress increases relatively rapidly. For latex coatings, this stage corresponds to the transition phase of the evaporation kinetics when the greatest part of the coalescence occurs. In Stage 2 (which corresponds to Phase 2 of evaporation kinetics), depending on the PVC and the type of filler, the stress can decrease or first decrease and then increase. For PVC < CPVC, this decrease is mostly due to the relaxation process, but for PVC > CPVC is mostly due to relief processes such as filler/binder dislocations and/or formation of microfissures.

Determination of the CPVC

The plot of the maximum internal stress (Sm) as a function of PVC enables one to determine the CPVC of a coating. Some examples are presented in Figs. 14 and 15.

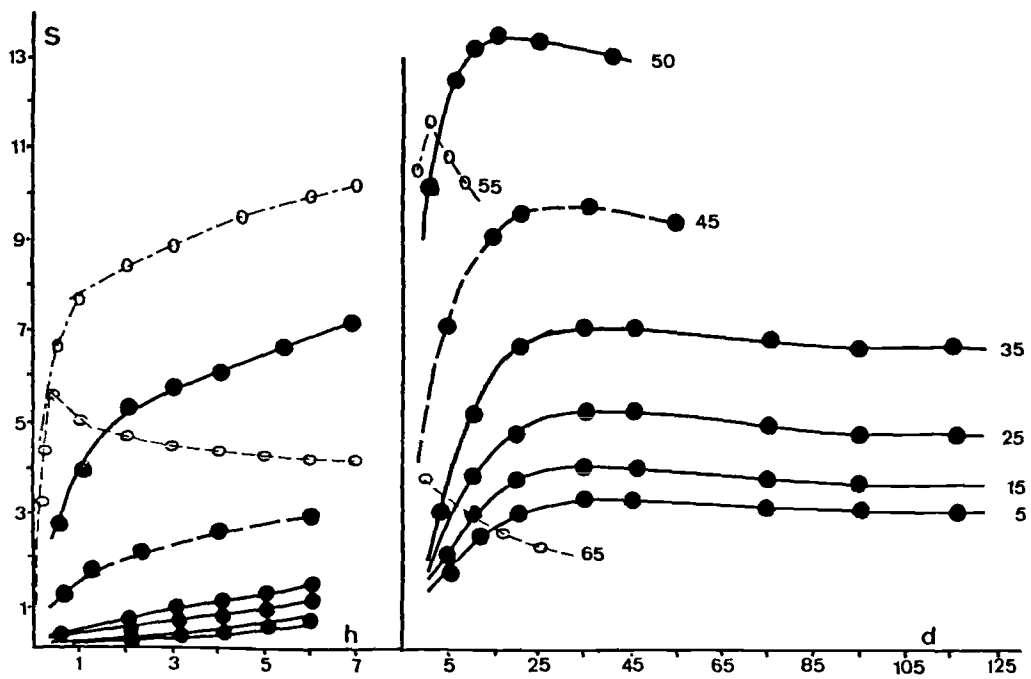

FIG. 12–Stress (*S*, MPa) as a function of time [hour (h) and day (d)] for a polyisobutyl methacrylate filled with TiO_2. The numbers in the figure indicate the different PVCs (%) investigated [*48*]. CPVC = 51%.

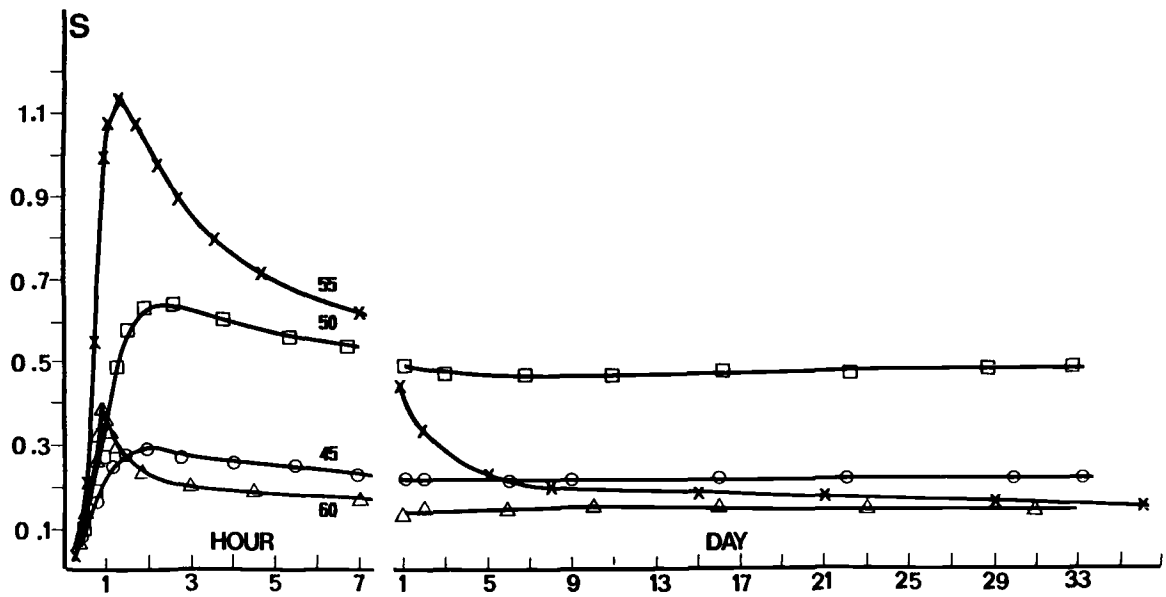

FIG. 13–Stress (*S*, MPa) as a function of time for a latex (vinyl acetate/vinyl versatate copolymer filled with TiO_2) [*50*]: 45% (○); 50% (□); 55% (X); 60(△). CPVC = 52%.

These figures, as well as other results presented in Refs *48* and *49*, clearly indicate that *Sm* is a function of PVC. *Sm* increases with PVC up to a certain PVC and then decreases. This PVC corresponds to the CPVC, indicating the possibility of accurately determining this characteristic [*51,52*] from stress measurements, and agrees well with the CPVCs calculated or determined by other methods (density, various mechanical properties).

The dependence of *Sm* on PVC can be understood if one considers Eq 1 and the way E, ϵ, and ν are affected by the PVC.

For PVC < CPVC, E increases with increasing PVC because the E of an inorganic filler is in general higher than that of an organic binder [*53*]. For PVC > CPVC, E decreases as a result of the increasing film discontinuity [*22,54*]. Since in general ϵ and ν are decreased (or are little affected) by the PVC, it follows that the increase of *Sm* with PVC is mainly due to the effect of PVC on E.

Figures 14 and 15 also show that the magnitude of *Sm* is dependent on the type of filler. There are fillers which induce a higher stress (e.g., TiO_2, red iron oxide) than others (e.g., $CaCO_3$, talc). This is due to the filler/binder interaction (reinforcing effect), which is determined by the nature and, in particular, by the surface area and the acid/base character of the binder [*55*].

Examples of $Sm = f(\text{PVC})$ for coatings containing a mixture of fillers are presented in Figs. 16 and 17.

An examination of the results obtained with binary and ternary filler coating systems indicates that the stress Sm_t can be calculated by means of an additive rule

$$Sm_t = n_1Sm_1 + n_2Sm_2 + \cdots + n_iSm_i = \sum_{x=1}^{x=i} n_xSm_x \quad (18)$$

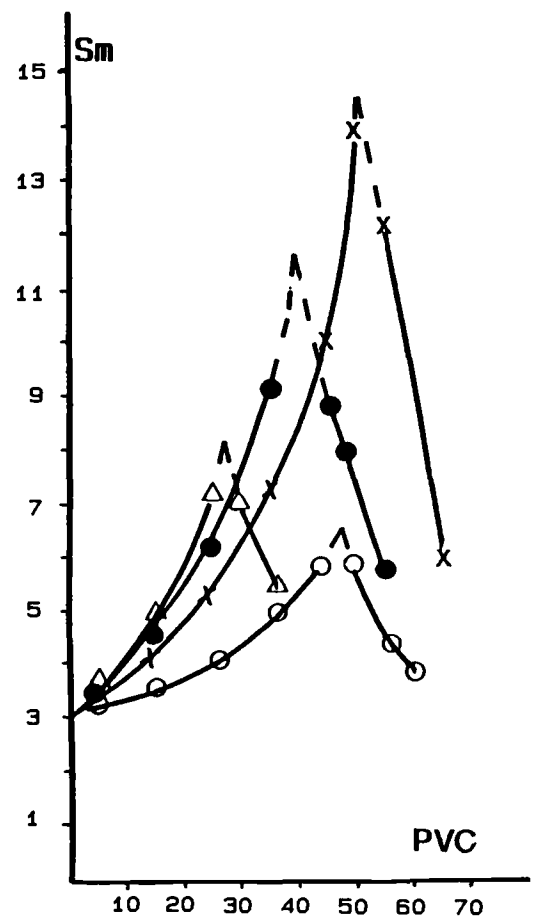

FIG. 14–Maximum internal stress (*Sm*, MPa) as a function of PVC (%) for a solvent-based thermoplastic binder filled with a TiO_2 (X), a red iron oxide (●), a yellow iron oxide (△), and a talc (○) [*48*].

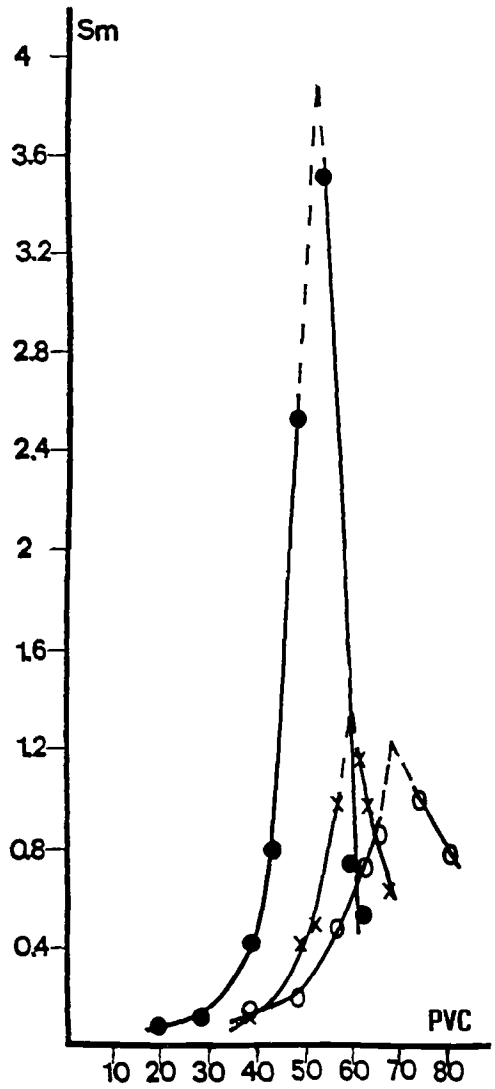

FIG. 15–*Sm* (MPa) as a function of PVC (%) for a styrene acrylic copolymer filled with a TiO_2 (●), a calcium carbonate (X), and talc (○) [*49*].

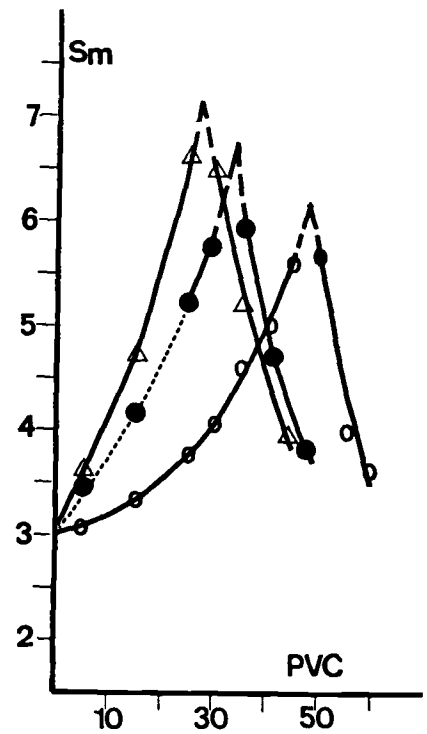

FIG. 16–*Sm* (MPa) as a function of PVC (%) for a thermoplastic binder in solution containing a yellow iron oxide (△), a talc (○), and their mixture (n = 0.5) (●); n = pigment volume fraction [*67*].

where

n_1, n_2, n_i = volume fraction of different fillers present in the mixtures, and

Sm_1, Sm_2, Sm_i = maximum stress of different single filler systems at a given Λ below or equal to 1 (Λ = reduced PVC, PVC/CPVC).

In the literature one can also find simplified methods to determine the CPVC of latex coatings based on the same principle. They simply compare the force [*56*] or the deflection induced by the internal stress for flexible plastic substrates [*57*] (Fig. 18) coated with paints of different PVCs.

These methods can be useful, but one has to be aware that they are valid only if both the thickness of the various paints and the time necessary to reach the maximum stress are the same.

Solvents

The presence of solvents in a coating can affect the magnitude and especially the rate of development of internal stress. This is illustrated in Fig. 19.

For thermoplastic binders in solution, the slower the evaporation of a solvent from a coating, the slower the development of internal stress and vice versa. One should note that the coating cast from fast-evaporating solvents (Curve 1, Fig. 19) produces slightly higher stress values than those cast from more slowly evaporating ones (Curves 3 and 4, Fig. 19).

The results obtained were explained by using Eq 1, the principle of plasticizing effectiveness of solvents and the stress relaxation favored by the presence in the coating of the slower evaporating solvent [*16*].

For coatings containing a mixture of solvents (Fig. 20), both the development rate and the stress magnitude are mainly determined by the presence in the film of the less volatile solvent(s).

The situation may be different if the film formation is a result of solvent evaporation and cross-linking processes (e.g., epoxy and polyurethane coatings). Under such circumstances the coating containing faster evaporating solvents can develop smaller stress values [*58*]. For such coatings, the volume of solvent present in the film after most of the cross-linking has occurred (Eq 2) and which determines the magnitude of ϵ^F will increase the slower the solvent evaporates. If the stress relaxation process is negligible, it follows that for

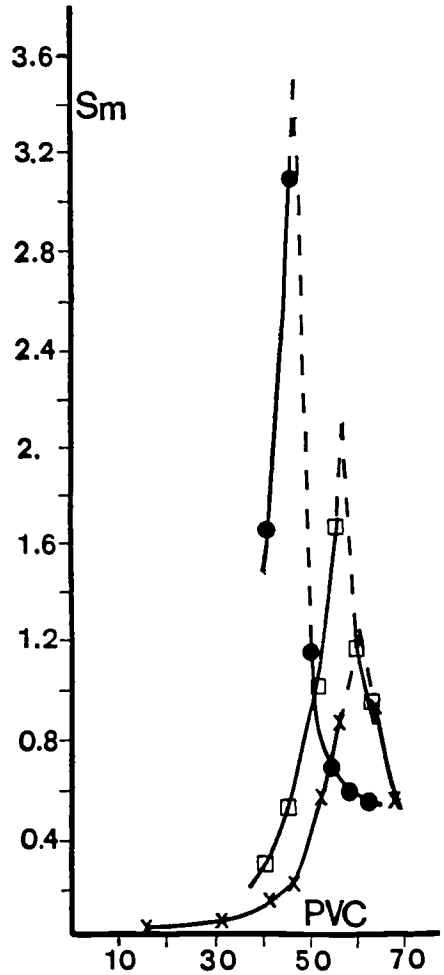

FIG. 17–*Sm* (MPa) as a function of PVC (%) for a latex binder containing a TiO_2 (●), calcium carbonate (X), and their mixture: TiO_2 (n = 0.4)/$CaCl_3$ (n = 0.6) (□) [*49*].

such coating systems the faster the solvent evaporates the smaller the internal stress.

The influence of solvents on internal stress is also evident for latex coatings where certain solvents, for example the coalescents, play an important role in the film formation process [*15,50,59*].

Examples of how the level and the type of coalescent affect internal stress are presented in Figs. 21 and 22, respectively.

Figure 21 shows that: (1) the coalescent level affects the time necessary to reach the maximum stress, and (2) for each formulation, there is an optimal coalescent level to obtain a tight continuous coating developing the lowest internal stress.

In Fig. 22, the results obtained with three solvents used in latex coatings are given. One can see that the type of solvent influences both the value and the development rate of the internal stress.

As in the case of thermoplastic coatings, the influence of solvents on internal stress development in latex coatings was explained [*15,50,59*] by taking into consideration the plasticizing effectiveness [*17,60*], the molar volume, and the steric hindrance of solvents. The plasticizing effectiveness affects the internal stress magnitude, while the molecular dimensions affect the evaporation kinetics and consequently the rate of the stress development.

Binder

To understand the role of the binder, the essential component of an organic coating on stress development, one can consider once again the general Eq 1 (see also Eqs 3, 5, and 10) and/or the Tg of a coating with respect to the experimental temperature.

Equation 1 indicates that the stress is directly affected by the magnitude of E, ϵ, and ν of the binder. The smaller the values of E, ϵ, and ν, the smaller the magnitude of stress.

With respect to the Tg, it should be remembered that the binders having their Tg below or close to the film formation temperature (T) develop a negligible internal stress, while those having their Tg $> T$ develop an important one. This is due to the fact that at $T >$ Tg, the mobility of the binder molecular segments is high and the stress arising during film formation can partially or totally relax. Moreover, it can be shown that for a thermoplastic binder in solution having a Tg $> T$, the lower the Tg of the binder, the less will be the solvent in the film after its formation (see Eqs 2 and 3) and therefore the smaller the internal strain and stress in the dry coating [*16*].

In brief, any change occurring in the molecular structure of a binder (e.g., crosslinking, crystallinity, molecular weight, steric hindrance) might induce a change in E, ϵ, ν, and Tg and thus affect stress development.

STRESS VERSUS ADHESION AND COHESION

It is accepted that the stress arising in a coating can reduce the adhesion and cohesion, two crucial properties of an organic coating for obtaining durable coatings [*1–10,61–65*].

The way the stress affects adhesion is described in detail in Refs *61* and *62*. It is shown that the application of an energy balance analysis [*66*] leads to the factor β acting against adhesion

$$\beta = cU_r \approx c\frac{E\epsilon^2}{1-\nu} \tag{19}$$

where U_r is the recoverable strain energy.

Because it is the energy that expresses the effect of ϵ, tensile or compressive strains are identical in their effect [*61*].

To accommodate the effect of stress [*18,27,67*], Eqs 1 and 19 are combined

$$\beta \approx cS\epsilon \tag{20}$$

Equation 20 indicates that adhesion is directly affected by c, S, and ϵ and the larger their values the higher the tendency of the coating to detach from its substrate. Thus, if a high stress arises in a coating, in order to prevent its detachment, it should be applied in a thinner layer.

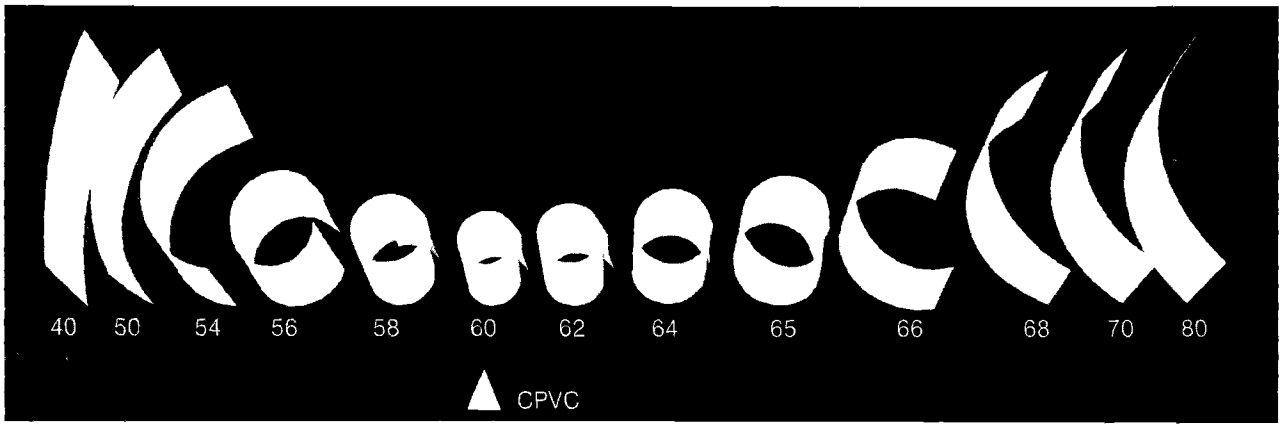

FIG. 18–Determination of the CPVC by comparing the curvature of painted plastic substrates [*57*].

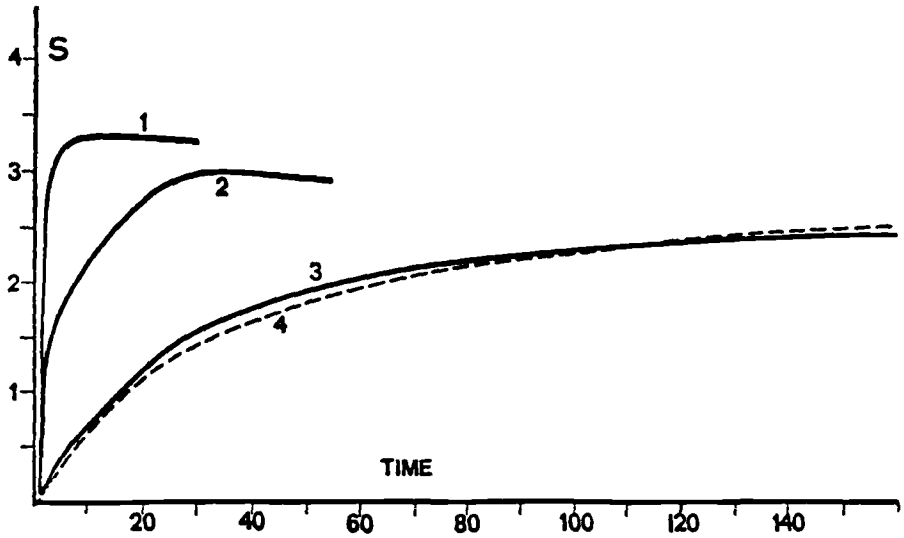

FIG. 19–Stress (*S*, MPa) as a function of time (day) in a thermoplastic varnish cast from methyl ethyl ketone and ethyl acetate (1); toluene (2); xylene (3); methyl isobutyl ketone and isobutyl acetate (4—), at 52% RH and 21°C [*16*].

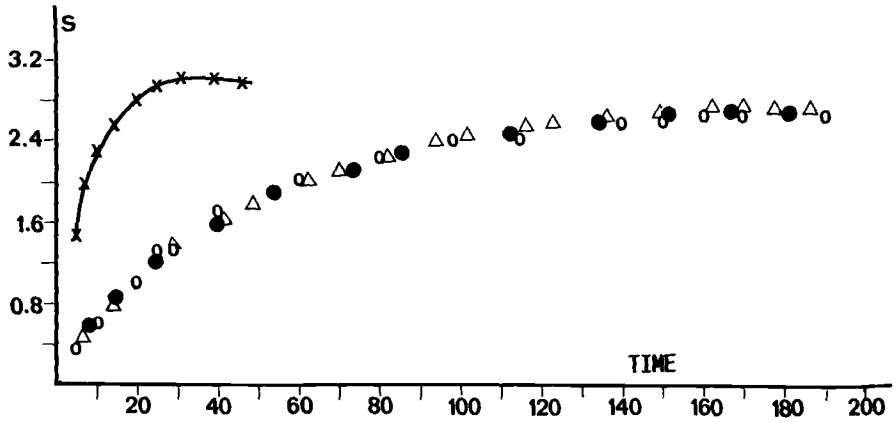

FIG. 20–Stress (*S*, MPa) as a function of time (day) for a thermoplastic varnish cast from toluene (X); isobutyl acetate (○), and their mixtures [1/1 (W/W) (●) and 1/3 (W/W) (△)] [*16*].

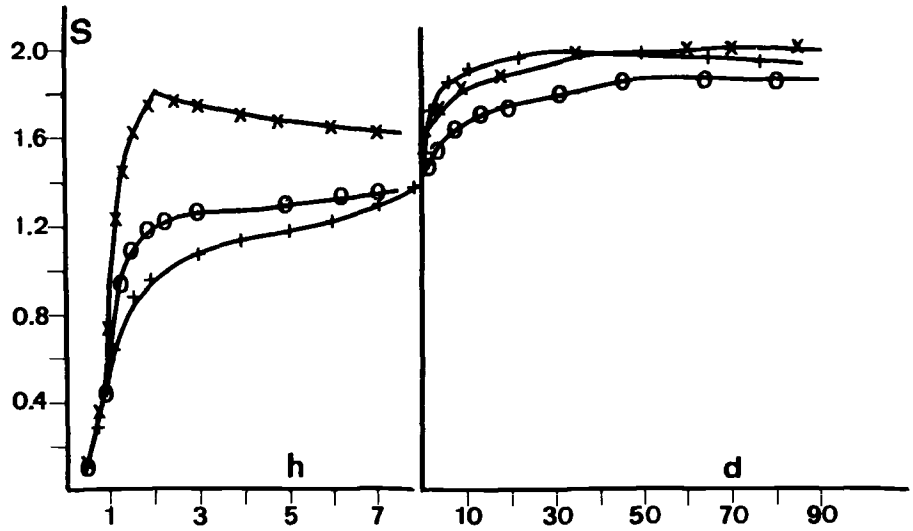

FIG. 21–Stress (*S*, MPa) as a function of time (h, hour; d, day) for a styrene acrylic latex paint containing different amounts of Texanol 5% (X); 10% (○); 15% (+): percent Texanol by weight of binder solids [*50*].

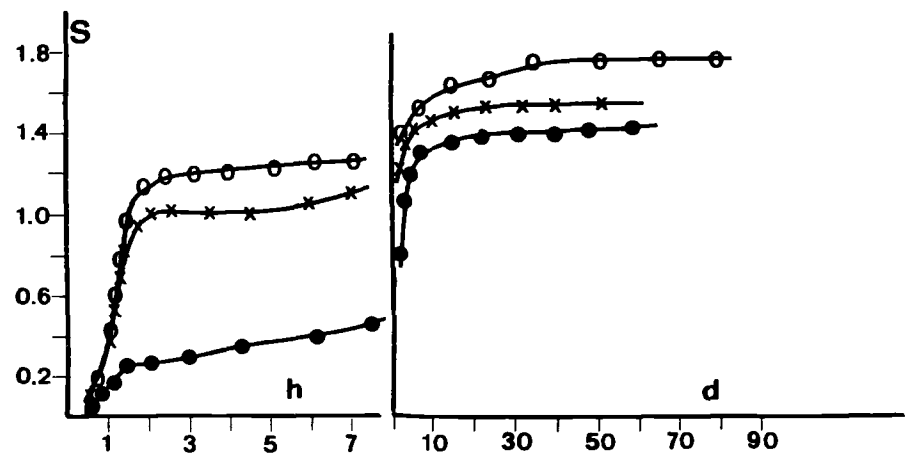

FIG. 22–Stress (*S*, MPa) as a function of time (h, hour; d, day) for a styrene acrylic latex paint containing Texanol (○); Dalpad A (X); Dalpad A + propylene glycol (●) [*50*].

Since stress develops in most organic coatings, the product $cS\epsilon$ should also be considered in adhesion tests performed in laboratories. The corrected mathematical equations for pull off and peeling at 90° are given by Eqs 21 and 22 [*61,67*], respectively

$$\sigma \approx \left[\frac{2K}{c}(\gamma - cS\epsilon)\right]^{1/2} \tag{21}$$

$$\frac{F}{b} \approx \gamma - cS\epsilon \tag{22}$$

where

σ = stress applied to pull the coating from the substrate,
K = bulk modulus of the coating,
γ = interfacial work of adhesion,
F = force applied to peel the coating, and
b = width of the coating.

Equations 20, 21, and 22 also indicate the possibility of determining the adhesion of a coating (i.e., the factor γ) without applying any external force. This is due to the fact that at a particular film thickness a spontaneous detachment should occur [*61*]. Unfortunately, this method can only be used for badly adherent coatings. For all other coatings, extremely high film thicknesses, difficult to apply and cure, would be necessary.

If the adhesion forces exceed the cohesive strength of a coating and the stress developed is high, damage will preferentially occur in the coating (cracking, fissuring) rather than at the coating/substrate interface. The verification of this principle can be realized by determining the stress and the ultimate properties of a coating. Since most of organic coatings are viscoelastic, it is essential that these properties be evaluated under the conditions (strain rate, temperature, RH) corresponding to the stress development in the coating. The presence of stress concentrations (e.g., existence of heterogeneities) in the coating and of a fatigue process are factors decreasing the overall stress at which the coating will crack.

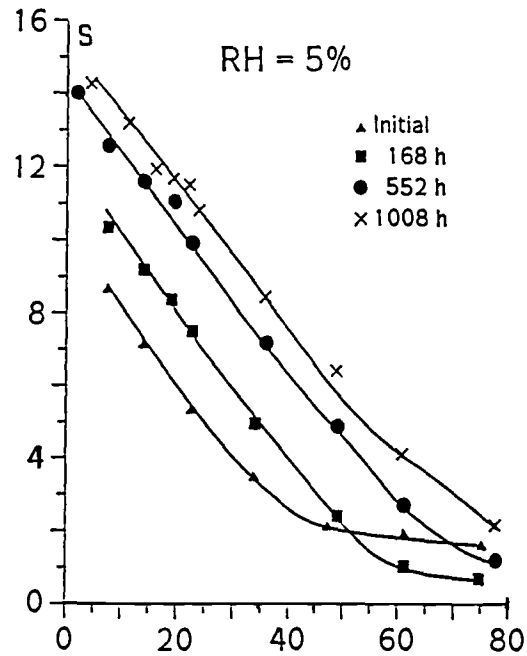

FIG. 23–Stress (*S*, MPa) as a function of temperature (*T*, °C) for a primer/clearcoat system after different periods of weathering [*9*].

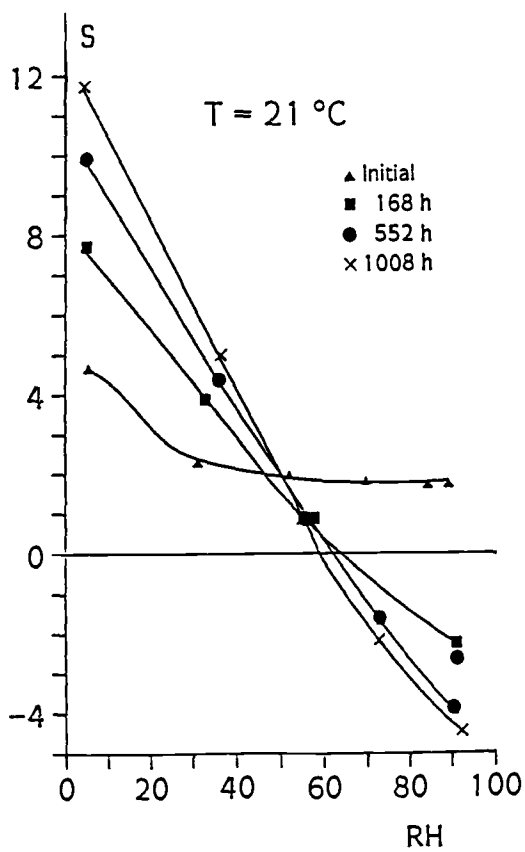

FIG. 24–Stress (*S*, MPa) as a function of RH (%) for a primer/clearcoat system after different periods of weathering [*9*].

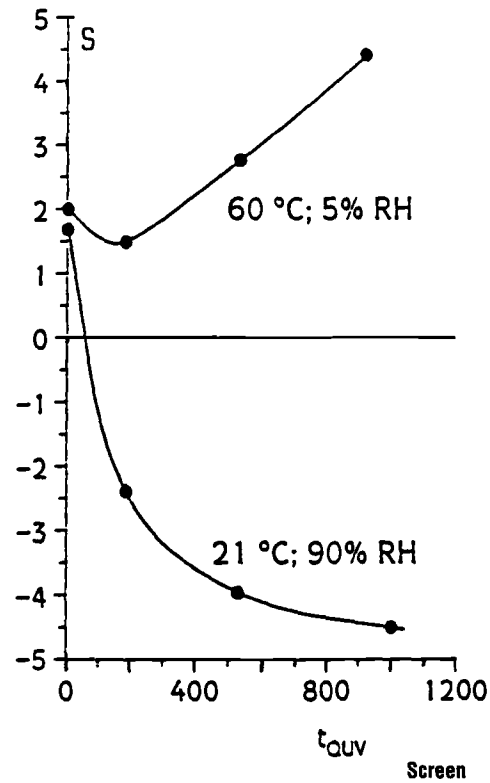

FIG. 25–Stress (*S*, MPa) as a function of time of weathering (t_{QUV}, hour) for a primer/clearcoat system at two climatic conditions [*9*].

WEATHERING AND STRESS DEVELOPMENT

In most cases when organic coatings are exposed to weathering (accelerated or natural), they undergo chemical and physical modifications which are expressed in the change of Tg, E, α, ν, and cross-link density. Under such circumstances and according to Eqs 1, 3, 5, and 10, one can also expect to see changes in stress development.

Confirmation of this and the role played by stress in the coating deterioration is given in Ref 9.

In this study a clearcoat/basecoat system exposed in a QUV apparatus to alternating dry and wet cycles cracked after about 1000 h.

By measuring the stress as a function of temperature and RH, it has been shown that weathering provoked: (1) an increase of Tg, which in turn induced higher tensile stresses (Fig. 23), and (2) an increase of coating sensitivity to moisture, which induced higher compressive stresses (Fig. 24).

The representation of the stress as a function of time of weathering for two experimental conditions similar to those present in the accelerating apparatus (Fig. 25) indicates that every time the experimental conditions changed (every 4 h) the coating was exposed to an increasing stress.

The processes thought to lead to fissuring of the clearcoat are described in Fig. 26.

Briefly, the chemical degradations induced by UV, water, and oxygen, which decrease the coating cohesion, combined

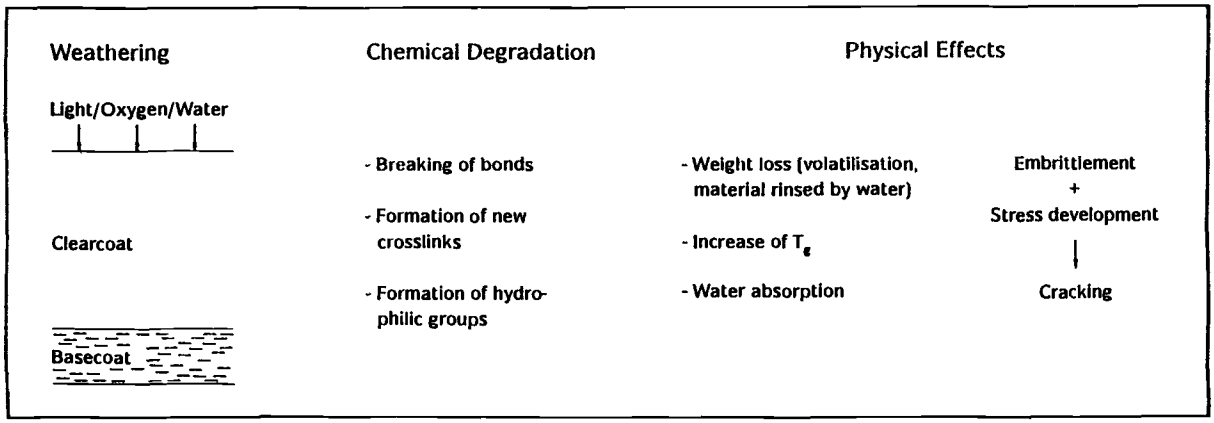

FIG. 26–Schematic representation of processes causing crack formation in a clearcoat [9].

with the fatigue process at steadily increasing hygrothermal stress levels are the causes of the coating degradation.

Slip Resistance

by Paul R. Guévin, Jr.[1]

AN OVERVIEW OF THIS SUBJECT as it relates to the coating industry was published in 1978 [*1*]. This chapter is an expansion and update of that paper. Although a majority of the instruments and test methods for slip resistance were developed in ASTM committees with responsibilities other than for paint, they all can be used to measure the slip resistance of paints and coatings.

Specific standards for slip resistance and its testing mainly refer to flooring and other pedestrian walkway areas. At this time there are no coefficient of friction (COF) standards in the coating industry. One industry, the floor polish industry, established a COF value of less than 0.5 as a slippery surface and a value of greater than 0.5 as a not slippery surface [*2*]. OSHA has proposed that the COF for working surfaces, such as walkways and around machinery, in a plant be not less than 0.5 [*3*]. The U.S. Department of Justice has proposed a minimum COF of 0.6 for level walking surfaces and of 0.8 for ramps for its Americans with Disabilities Act [*4*]. If these proposals become law, painted walking surfaces must meet or exceed these standards.

ASTM ACTIVITY

Many studies of COF measurement by various ASTM committees occurred over the past 20 years. For the most part, these studies have been divided into specific committees with a task group of Committee F-13 on Safety and Traction for Footwear undertaking the task to improve communications between the various groups studying COF and thus prevent duplication of effort.

Task Group D01.23.15 on Slip Resistance is involved with measurement of paint and coatings COF. The group has developed a test method that describes a slip-angle test apparatus and a horizontal-pull slip meter that functions under wet and dry conditions and that can be used to measure both static and dynamic COF.

Other areas of activity dealing with the COF include ceramics [*5*], plastics [*6*], polishes [*7*], skid resistance [*8*], and footwear [*9*]. A study by the Consumers' Union [*10*] indicated a need for good measurement of slipperiness. Evidence in 1976 indicated that available instrumentation was inadequate and that results obtained with it did not correlate with practical observations. The National Institute of Occupational Safety and Health funded a project that dealt with slipperiness and safety of workers engaged in structural steel erection [*11*].

Definitions

The following are useful, specific definitions that have been developed by ASTM Committee D-21 on Polishes and found in ASTM Test Method for Static Coefficient of Friction of Polish-Coated Floor Surfaces as Measured by the James Machine (D 2047) [*12*].

Coefficient of Friction—The ratio of the horizontal component of force required to overcome friction, to the vertical component of the object weight or normal force applied through the object, which tends to cause the friction.

Dynamic Coefficient of Friction—The ratio of the horizontal component of force required to cause a body to slide at a relatively constant velocity to the vertical component of the weight of the object or force applied to it. The relatively constant velocity used to cause the body to slide over the surface is to be not less than 0.125 ft/s nor more than 0.5 ft/s (38 to 152 mm/s). The vertical component shall result in a contact pressure of not less than 1 psi (6.9 kPa) nor more than 13 psi (90 kPa) applied uniformly over the area in mutual contact.

Friction—The resistance developed between the physical contacting surface of two bodies when there is movement or tendency for movement of one body relative to another parallel to the plane of contact.

Slip Resistance—That property of a floor surface that is designed to prevent slipping. A surface having a static coefficient of friction of 0.5 or greater as measured in accordance with ASTM D 2047 is considered to be a slip-resistant surface.

Static Coefficient of Friction—The ratio of the horizontal component of force applied to a body that just overcomes the friction or resistance to slipping to the vertical component of the weight of the object or force applied to it. The vertical component shall result in a contact pressure of not less than 1 psi (6.9 kPa) nor more than 13 psi (90 kPa) applied uniformly over the area in mutual contact.

In a general sense, slipperiness can be defined as the tendency or liability to cause something to slide suddenly or involuntarily. In many cases, an organic polymer surface (i.e., a coating) is involved. In terms of the flooring market area, for which these definitions were written, the flooring surface

[1]Consultant, P. R. Guévin Associates, P.O. Box 811, Westerville, OH 43086-0811.

Copyright© 1995 by ASTM International

could be an alkyd enamel on a porch or deck, a vinyl- or polyurethane-coated athletic gymnasium floor, a waxed vinyl-composition floor tile, an epoxy-coated concrete factor floor, and so on. Slipperiness can be considered as being made up of two factors, skid resistance and slip resistance. Skid can be defined as an act of sliding without rotation and slip as a slide that occurs suddenly or involuntarily.

CONCEPT OF THE COEFFICIENT OF FRICTION

Slip is a word that has many meanings [*13,14*]. In certain areas of the coating industry, slip is considered to be the ability of an object to move in a relatively free or unencumbered but controlled manner when one sheet of metal passes over another sheet as in a coating-line feeding operation, when it moves along a conveyor system in coating, printing, fabrication, or packaging operations, and the like. The coating must have proper "slip" or "lubricity" to allow the coated object to pass through the coating system to a further fabrication or packaging section of the line. In fact, slip is very important to fabrication operations wherein the coated object is in contact with a tooling system as in fabrication of bottle caps, or with other metal surfaces in bending operations, etc. Yet, other coatings such as floor coatings are designed to decrease this ability to move easily under an applied force. In either case, the frictional resistance between objects is being modified and controlled with such control being attained by the inherent properties of the materials used for the coating or use of additives in the coating. It is important to understand that at times low friction is desired and that at other times reasonably high friction is desired.

Friction is the property that determines the degree of slip or resistance to slip that exists. Both static and dynamic or kinetic friction are important properties of coatings. Static friction is the amount of friction between two surfaces at the precise instant when one commences to move over the other. Dynamic friction is the friction between two surfaces when they are moving past one another without interruption. The coefficient of static friction is usually equal to or greater than that of dynamic friction [*15*]. The coefficient of friction, μ, is a measure of slip with a high coefficient of friction denoting poor slip and a low coefficient of friction denoting good slip [*16*]. This parameter is the ratio of the force F (frictional force) required to move one surface over another surface to the total force W pressing the two surfaces together

$$\mu = F/W$$

A current theory of the mechanism of dry friction describes the force of friction arising from the shear strength of minute interaction areas or areas of true contact between the contacting surfaces. These interaction areas are distributed in a more or less random manner over the total apparent contact area. This can be expressed by the following relation for the friction force

$$F = s \cdot A$$

where s is the average shear strength of the interaction areas, and A is area of actual contact. Since it is the interaction areas that actually carry the normal load W between the two surfaces, the following relation also exists

$$W = \rho_m \cdot A$$

where ρ_m is defined as the flow pressure of the softer material in the vicinity of these local areas of true contact. When A is eliminated between these equations, the friction coefficient is obtained

$$\mu = F/W = s/\rho_m$$

Friction is the universal force between surfaces that opposes sliding motion. When surfaces of bodies are in contact, the interactive force at the surface may have components both perpendicular and tangential to the surface. The perpendicular component is called the "normal force," and the tangential force is called the "friction force." When there is relative sliding between the bodies, the frictional force always acts in the opposite direction of this motion.

Most dry surfaces behave approximately and within limits according to Coulomb's frictional law. Coulomb found that just before motion, the friction between two surfaces is slightly greater than when the surfaces are in steady motion relative to each other, that the frictional force is proportional to the normal force pressing the surfaces together, and that this force is independent of both the contact area and, except at the start, the speed of relative motion of the bodies. The constant ratio of the tangential force to the normal force is known as the "coefficient of friction" (COF) and depends on the nature of the two surfaces. To initiate sliding against friction, it is necessary to apply a tangential force at least as great as the COF and the normal force before the onset of motion take place. The applied tangential force is resisted by the equal and opposite force of static friction, and the force required to overcome static friction is usually greater than the force needed to sustain uniform sliding motion.

DETERMINATION OF THE COEFFICIENT OF FRICTION

Three types of instruments are used to measure the COF, and these are illustrated in Fig. 1 [*17*]. These are drag-type meters that are based on $\mu = F/W$, pendulum-type meters that measure the energy loss of the pendulum as an indirect indication of the dynamic friction, and articulated-strut devices that are based on the direct and fundamental principle of the resolution of forces that take place when an object slides down an incline as described below. The angle at which a flat or plane surface must be inclined for a solid object to slide with a steady speed down the incline is the "angle of friction." The tangent of this angle is the COF between the solid block of material and the inclined plane

$$\mu = \tan\phi$$

The principle involved in this equation is used in the slip-angle apparatus described in ASTM Test Methods for Measuring Static Friction of Coatings Surfaces (D 4518) [*18*]. The state of the art of slip-resistance studies through 1975 has been summarized by Brungraber [*19*].

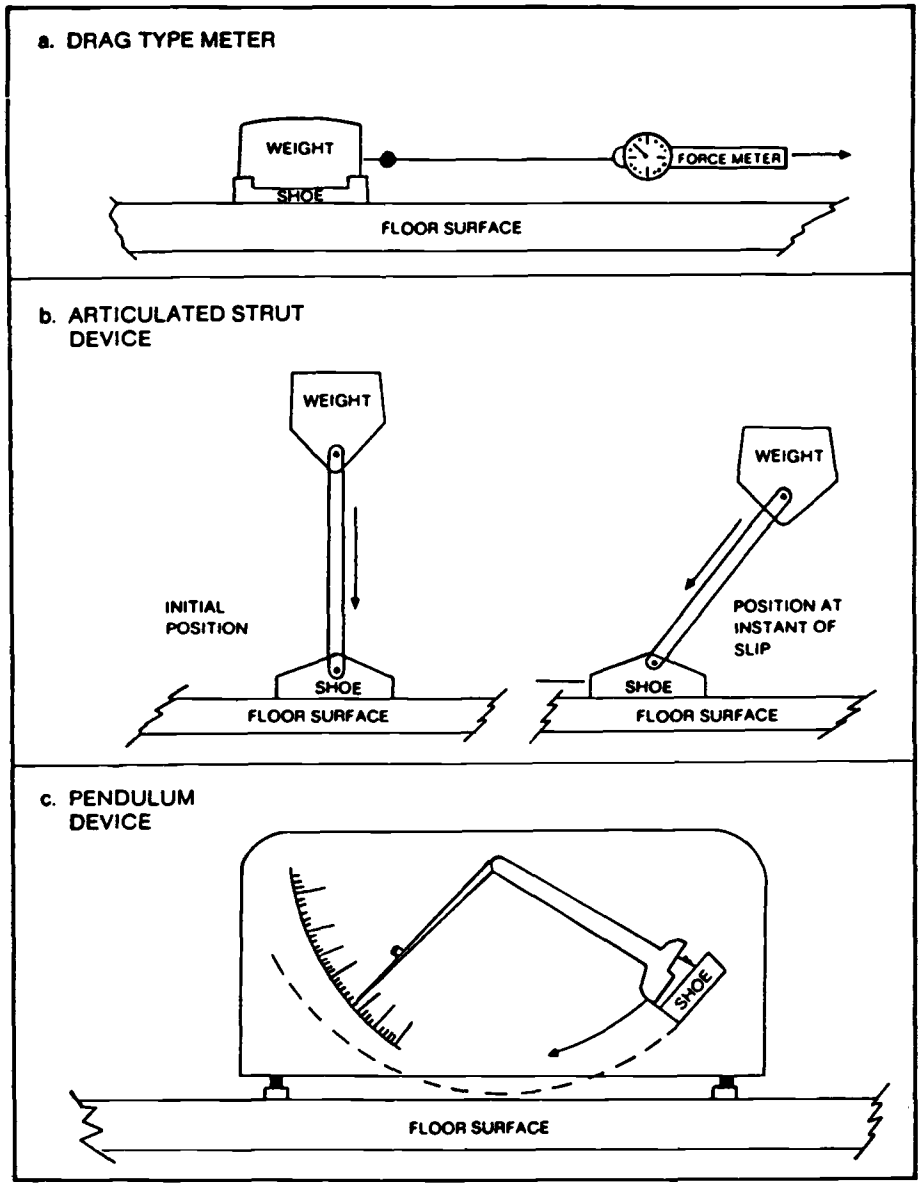

FIG. 1–Schematics of different friction measurement devices (courtesy of the National Institute of Standards and Technology).

SENSOR MATERIALS

It is obvious that two surfaces are required for COF measurements of any surface, and the sensor material, or surface against which the specified compound is tested, should be defined and specified. It is essential to obtaining meaningful, reproducible results that the sensor material be selected to represent use conditions and be well defined. Properties such as uniformity (surface character including flatness, roughness, chemical composition, resilience, and shear modulus), permanence in that chemical and physical characteristics should not change with time, and availability in a usable form that does not require excessive preparation should all be considered when selecting a sensor. Both sensor material and test material should be reported when the coefficient of friction is given.

The sensor material may be composed of the same compound as the test compound or different. In most ASTM studies of flooring, leather is used as the primary sensor material. It is commonly used in the manufacture of shoes, and, probably more important, it has the lowest COF of any shoe-sole material. Although the rationale for its selection is not well documented, leather conforming to Federal Specification KK-L-165C is specified as the sensor material. Where a nonleather sensor material is to be used, rubber conforming to ASTM Test Method for Rubber Property—Abrasion Resistance (NBS Abrader) (D 1630) [*20*] is used. Neoprene has been used in certain round-robin studies. In other instances, three leathers with three levels of oil content, two Kraton® thermoplastic elastomers, and 15 different rubbers were used to generate statistical data [*21*] for ASTM Test Method for

Static Slip Resistance of Footwear Sole, Heel, or Related Materials by Horizontal Pull Slipmeter (HPS) (F 609) [22].

LUBRICANTS

In those instances where slip is to be increased (friction decreased), a variety of slip agents or lubricants are available. These include micronized polyethylene powders and silicones. See Table 1 for more slip agents. Many slip agents also function as abrasion-resistance and mar-reduction agents. In certain instances, they can be used as antiblock agents. Lubricants are often used in the plastics processing industry where they function as melt viscosity reducers, flow agents to improve flow onto metal surfaces, and, at times, costabilizers. Factors that should be considered in selecting a lubricant include melting point, polarity, and solubility. Of course, the lubricant should not interfere with adhesion or any cross-linking mechanism that is used. Common lubricant families as well as selected specific lubricants are listed in Table 1. Polyethylene and polytetrafluoroethylene are available in a powder or micronized form in a variety of particle sizes [23], and silicones are available as formulated products designed for use in the coating industry [24,25]. The micronized polymers are incompatible and act as a filler that rises to the coating surface where they function as tiny "ball bearings" that decrease friction and often improve abrasion and mar resistance.

METHODS FOR DETERMINING COEFFICIENT OF FRICTION

The test methods and equipment described below were developed for flooring materials. However, they can be applied to testing the slip resistance and COF of paint and coatings on various substrates against themselves as well as against a variety of substrates.

ASTM Test Method for Determining the Static Coefficient of Friction of Ceramic Tile and Other Like Surfaces by the Horizontal Dynamometer Pull-Meter Method (C 1028-84) [26] utilizes a pull meter-and-heel assembly to measure the COF of tile and like materials. The test method specifies a standard ceramic tile with an average COF between 0.45 and 0.55 and a neolite sensor material. Currently consideration is being given in an ASTM subcommittee to modifying this device for improved reproducibility or discontinuing the method.

ASTM Test Method for Static and Kinetic Coefficients of Friction of Plastic Film and Sheeting (D 1894) [27] is concerned with determination of static and dynamic COFs. The test method specifies only the force-measuring instrument since the test method uses a plastic film or sheet sliding over itself. One company that manufactures slip-resistance coatings intended for compliance with OSHA and ADA requirements specifies this test method for determination of product COF.

ASTM Test Method for Static Coefficient of Friction of Polish-Coated Floor Surfaces as Measured by the James Machine (D 2047) [12] is the only slip-resistance test method recognized by the floor-polish industry. Unfortunately, its use is limited to the laboratory since it is not portable. Sensor materials of leather and rubber are specified.

Method A of ASTM Test Methods for Measuring Static Friction of Coating Surfaces (D 4518) [18] involves a platform containing a sled that is slowly raised until the angle of movement is reached. Method B involves a horizontal-pull tester. Some laboratories have modified their Instron tensile testers to perform similar operations. This approach has the advantage of providing a graphic record of the forces involved.

Other ASTM methods for measuring friction include ASTM Test Method of Measuring Surface Frictional Properties Using the British Pendulum Tester (E 303) [28], ASTM Consumer Safety Specification for Slip-Resistant Bathing Facili-

TABLE 2—Canadian government standards for coefficient of friction.

	Static COF			Sliding COF		
	Dry	Wet	Oily	Dry	Wet	Oily
For leather with:						
Epoxy coating	0.75	0.75	···	0.50	0.50	···
Polyurethane coating	0.85	0.85	···	0.50	0.50	···
For rubber with:						
Epoxy coating	1.00	0.90	0.70	0.80	0.80	0.40
Polyurethane coating	1.00	0.85	1.00	0.85	0.85	0.70

TABLE 3—Devices for measuring the coefficient of friction.

Device	Manufacturer	Comment	Reference
		DRAG-TYPE FRICTION MEASURING DEVICES	
Dynamometer Pull Meter	Chatillion Inc.	Tests are being discontinued by ASTM C21.06	
Gardco Washability Wear Friction Tester, Model D 12VF	Paul N. Gardner Co. Inc.	Instrument is being evaluated at several companies	[*27*]
Coefficient of Friction Tester, Model FM-1055 and -1055F	Paul N. Gardner Co. Inc.	Meets ASTM D-1894-78 requirements. Model F has a force transducer for strip chart readout.	[*27*]
Instrumentors Slip/Peel Tester Model SP-101B	Instrumentors, Inc., Cleveland, OH; available from IMASS, Accord, MA	Designed to meet ASTM D 1894	
Floor Friction Tester, Model 80	Technical Products Co.	Portable device	
TMI Slip & Friction Tester, Models 32-06	Test Machine Inc., Amity, NY	Flat bed plate laboratory horizontal pull slipmeter	
TOPAKA® Horizontal Slip Tester	Pioneer Eclipse Co.	Described in ASTM D-21 Proposal P 128	[*7*]
Universal Slip-Resistance Tester	William English Ltd.	Device has been removed from market	[*29–32*]
Whiteley Model HPS III Slip Master	Whiteley Industries, Inc.	Can be used to test in accordance with ASTM F 609	
		DYNAMIC PENDULUM-TYPE SKID RESISTANCE TESTER	
British Portable Skid Resistance Tester	Road Research Laboratory, Crowthorne, Berkshire, England	ASTM E 303 utilizes this device	[*28*]
Sigler Coefficient of Friction Machine	Frazier Precision Instrument Co., Hagerstown, MD	Specified in Federal Test Method Standard No. 501a	[*33–34*]
Tortus Floor Friction Tester	Ceramic Research, Penkhall Stake-on-Trout, England	Very good for microinvestigations of floor surfaces	[*35–38*]
		ARTICULATED STRUT TESTERS	
Ergodyne Slip-Resistance Tester	William English Ltd., Alva, FL	Small and lightweight in nature	
James Machine	AIDE, Inc., Racine, WI	Used in ASTM D 2047. Considered to be a comparison standard testing device.	[*12,39*]
NBS/Brungraber Slip Tester, Model Mark I and Model Mark II	Slip-Test Inc., Lewisburg, PA	Mark I useful on dry surfaces and Mark II useful on wet surfaces	[*5,32,40–41*]
Model 9505 Mobility/Lubricity Tester	Altek Co., Torrington, CT	Used to measure slip resistance such as beverage exterior can coatings	

ties (F 462) [*22*], ASTM Test Method for Static Coefficient of Friction of Shoe Sole and Heel Materials as Measured by the James Machine (F 489) [*22*], and ASTM Test Method for Static Slip Resistance of Footwear, Sole, Heel, or Related Materials by Horizontal Pull Slipmeter (HPS) (F 609) [*22*].

Few slip-resistance standards exist in most industries, including the coating industry, even though there are many painted surfaces in pedestrian walkways. The United States Navy has two specifications—MIL-D-23003A Military Specification-Deck Covering Compound, Nonslip, Rollable and

MIL-D-24483A Military Specification-Deck Covering, Spray-On, Nonslip—that specify COF values. Both specifications use horizontal slip testers.

The Canadian Government Specification Board adopted two standards for deck coatings based on the above U.S. Navy specifications. One involves nonslip epoxy coatings, 1-GP-192, and the other nonslip involves polyurethane coatings, 1-GP-200. The COF specifications for these materials are given in Table 2. This information points out some important aspects of slip resistance measurements. First, value differences in slipperiness of various shoe-sole materials under different conditions are used. Second, it points out the importance of specifying the nature of the shoe-sole material. Overall, leather has lower COFs than rubber.

TEST DEVICES FOR MEASURING THE COF

As mentioned earlier, there are three types of devices used to measure the COF, namely drag, pendulum, and articulated strut-based devices. The drag-type meters can be subdivided into two classes: (1) horizontal-pull slip meters that are portable, inexpensive, and used directly on a floor or other surface under test and (2) bench-top slip meters that are used primarily in the laboratory. Both of the devices in these subclasses are sometimes referred to as "fish scale-type testers." The devices are simple, motorized power units with force-measuring devices such as dynamometers. One such device, developed at an insurance company [*42*], has been used by an ASTM subcommittee in a round-robin study [*21*] to evaluate walkway slipperiness [*43*]. Use of such devices has been validated in another study [*44*]. General results from some ASTM members indicates that pendulum-type devices are not applicable for further consideration in the measurement of the COF.

Pendulum-type COF devices [*12,33–34*] consist of a pendulum that is faced with a certain shoe-sole or heel material. The pendulum can be adjusted to sweep a path across a flooring surface so that the contact pressure between the facing and the floor follows a predetermined, time-dependent pattern. The pendulum's resultant loss of energy is purported to be a measure of the dynamic friction.

Articulated-strut meters [*12,39–41*] involve application of a known, constant vertical force to a shoe that is faced with a particular sole or heel material along with application of an increasing lateral (forward) force until slip occurs. The ratio of the lateral force at slip to the known vertical force is the static COF. The vertical force is applied to the top so that the article tested is only subjected to a vertical load. As the test progresses, the articulated strut is slowly inclined so the test article continues to be under a constant vertical load and in addition under an increasing horizontal or tangential load until slip occurs. The tangent of the angle that the articulated strut makes with respect to the vertical at the instant of slip is taken to be the ratio of the horizontal and vertical components of the force applied to the show and thus is the COF.

Devices of the three types are summarized in Table 3.

51

Prevention of Metal Corrosion with Protective Overlayers

by William H. Smyrl[1]

THE PREVENTION OF CORROSION BY SURFACE PROCESSING enjoys significant economic leverage, and, as evidence, one may cite the widespread use of coatings, films, and inhibitors for metals and semiconductors in many service environments. All engineering metals used in modern technological societies are unstable with respect to corrosion, and the result is a loss of properties. Natural oxide films provide protection against continued attack for some metals, and alloying extends the life of other metals by developing highly stable passive films. Where metals may not be protected by oxide films, other modification methods have been developed to reduce corrosive attack. In reality, the improvement of corrosion resistance of metals by modification of the surface has been practiced since the invention of metal tools. Some of the earliest techniques to prevent corrosion involved coating with greases or natural oils. More modern methods were developed in the 19th and 20th centuries and include multiple coatings, zinc galvanizing, electroplating of other pure metals, and vacuum physical vapor deposition of mostly pure metal coatings by electron beam and sputtering techniques. The metal coatings are better barriers than organic films because of the lower permeability of the former to moisture, oxygen, and ions. Inhibitors or conversion coatings and primers for paints are cheaper than metal coatings and are used widely by paint manufacturers even though they remain highly proprietary in nature.

The use of organic coatings to protect metal surfaces is practiced widely. Much of the use is for atmospheric exposure of motor vehicles as well as for structural units such as bridges and buildings. The successful implementation of existing technologies has greatly reduced the effects of corrosion of automobiles, for example, in the past decade in response to consumer demand. Despite many recent advances, coating technologists and scientists acknowledge that much is unknown and that new processes and understanding are the keys for further progress [*1*]. Defects in the metal substrate and in the overlayers are among the primary concerns because they are the source of localized corrosion phenomena. Defects may occur on length scales from atomic-level lattice vacancies to arrays of defects at grain boundaries (for crystalline materials) or to random pores or cracks (for example, in noncrystalline films). Avoiding such defects by proper quality control is a major concern in coatings science and technology.

[1]Professor, Corrosion Research Center, Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, MN 55455.

In the discussion that follows, aspects of corrosion that involve thermodynamics and kinetics will be developed as a basis for the description of the specific nature of corrosion of metals under protective films and overlayers. Some emphasis will be given to protection of thin metal films and microstructures that are particularly sensitive to corrosion and whose successful protection provides a basis for advancing protection technology in general.

CORROSION IN AQUEOUS SOLUTIONS

The driving force for a reaction is the change in Gibbs free energy, ΔG, for reactants to products. Mathematically, this may be expressed by

$$\Delta G = \sum_{\text{products}} G - \sum_{\text{reactants}} G$$

The summation signs are used as a general notation to indicate that all reactants and products are included in the calculation. From the nature of the free energy function, this calculation applies to initial (reactants) and final (product) states and is independent of intervening states. The reaction may be investigated under controlled reversible conditions such as in an electrochemical cell or under irreversible conditions such as in corrosion, and the same total free energy change (ΔG) will be appropriate. A quite general predictive capability may be applied to specific corrosion reactions since all the available thermodynamic data may be used for corrosion calculations directly. This enables the position of final equilibrium of the corrosion system to be established. The thermodynamic calculations have the limitation that no information concerning the *rate* of the reaction is provided, only what the final state will be for the process.

The value of ΔG for reactions of elements to form a compound, all in their standard states at a particular temperature, is the standard free energy of formation of the compound, $\Delta G^0_{f,T}$. Here, the subscript T denotes the temperature. Description of the detailed calculations are beyond the scope of this discussion, but several excellent textbooks are available [*2,3*].

The most extensive tabulations of thermochemical data for chemical compounds in their standard state at 25°C are in a series of National Bureau of Standards publications [*4*]. These are NBS Technical Notes 270-3, 270-4, and 270-5, which supersede the older NBS Circular 500 for the elements they cover. These tabulations also update the older data of

Copyright© 1995 by ASTM International

Latimer [5]. The book by Latimer [5] remains a valuable reference because of the description of techniques to estimate thermodynamic quantities where reliable data are sparse. Lewis and Randall [3] tabulated thermodynamic data, including data for aqueous solutions of a number of electrolytic solutions that are valuable for corrosion calculations. There is overlap between this tabulation and the JANAF thermochemical tables [6], but the latter also tabulate the standard enthalpy and free energy of formation of chemical compounds at several temperatures along with $-(G^0 - H^0_{298})/T$.

Oxide and hydroxide solubility are strongly influenced by the pH of the aqueous phase. Pourbaix recognized this and summarized the thermodynamic stability of metal-aqueous systems by the use of potential-pH diagrams. The thermodynamic data tabulations already quoted [3–6] should be utilized for detailed calculations, however.

Usually when studying corrosion, one is not concerned with the conditions for thermodynamic stability, but rather with the rate of attack and how it may be altered in basically unstable conditions because only a limited number of systems have absolute or *thermodynamic stability*. As a practical matter it is necessary to accept some rate of corrosion and/or to control or mitigate the rate of attack. Thus *kinetic stability* is always relative and subject to interruption if control is not maintained. Controlling the rate of degradation may be accomplished, for example, by the use of cathodic or anodic protection, the use of inhibitors, the maintenance of protective surface films, or buffering the composition of an otherwise aggressive solution. All these techniques are used widely to extend the life of metallic structures with continuing improvement.

Corrosion reactions are electrochemical in nature. The kinetics of the corrosion reactions are then related to the kinetics of the electrochemical reactions that occur during the corrosion process. The reactions involve not one but at least two electron transfer reactions, and the reactions are not in series but are in parallel. Coupling of parallel or simultaneous reactions is a fundamental feature of the corrosion process. Each of the simultaneous reactions may consist of multiple steps, respectively, as described above, but the simultaneous, independent reactions are coupled electrically. The independent reactions occur on the same surface at the same time, but also at the same potential. The reactions may be coupled chemically as well, e.g., through pH effects, but this is not essential. The specific relation that defines the coupling of simultaneous corrosion reactions on an isolated metal surface is

$$\sum_{\text{anodic}} I_a = -\sum_{\text{cathodic}} I_c$$

There will then be zero net current to the corroding metal electrode. The relationship is written in terms of currents (I_a and I_c) rather than current densities for reasons which will be discussed. The potential at which the balance is satisfied is the mixed or corrosion potential. It is determined by the rates of the simultaneous reactions and is not defined by the state of the system in a thermodynamic sense. The corrosion potential always lies between the equilibrium potentials of the anodic and cathodic processes, respectively.

As a summary, the general corrosion of metallic materials in aqueous solutions is well understood. The anodic or oxidation reaction of the metal is superimposed on a cathodic reaction, and the two are balanced locally on a homogeneous surface. The rate of the reaction is a function of both the rate of metal dissolution and the rate of the cathodic (reduction) reaction. Each reaction may be influenced in general by the composition of the solution, especially the pH and the electrolyte anion, and by the nature of the (oxide) films, if any, which may be formed at the metal/electrolyte interface. If several oxidizing species are present in the solution, each may act in parallel so that the total rate of metal dissolution is increased. For example, most metals will react directly to displace hydrogen from water and to produce an oxide of the metal or some other corrosion process. The addition of oxygen will increase the rate of corrosion of the metal, usually in direct proportion to the concentration of the oxygen added. The specific details will vary with each metal to reflect the thermodynamic, kinetic, and mass transfer driving forces that are acting [7].

Heterogeneous surfaces are commonly observed in corrosion situations and are of the three general classes: (1) the inclusion of foreign metal impurities on the metal surface, (2) the nonuniform coverage of the surface by a film, either an oxide film or an artificial coating in aqueous solutions, and (3) nonuniform conditions in the electrolyte environment. All these are of great importance because localized, or nonuniform, corrosion of metals may be caused by any of the three. A form of galvanic corrosion and pitting corrosion is caused by the first type of heterogeneity, while crevice and pitting corrosion are produced by both (2) and (3).

Restrictions of geometry, e.g., in crevices and corners, prevent mixing of solutions everywhere, and local buildup of reaction products or the exhaustion of an oxidant may occur. The local kinetics will be relatively independent of that in other regions except that there may be coupling through the electric field and electrical current may flow between a localized corrosion site and the surrounding surface. This may lead to nonuniform corrosion, particularly where the buildup of products increases the aggressiveness of the local solution. In this case, corrosion will be most severe, not where the concentration or flux of the bulk solution oxidant is highest but where it is lowest. Crevice corrosion is considered to be an example of this type of attack, and the aggressive solution within a crevice or pit is one which is more acidic than the external solution.

Anodic dissolution, plus hydrolysis of the product metal ion, causes an increase of hydrogen ion concentration. On the other hand, reduction of either hydrogen ions or dissolved oxygen reduces the hydrogen ion concentration. If the net corrosion reaction plus hydrolysis would lead to an increase of hydrogen ion concentration, the process may occur independently of any other process and would accelerate with time to some steady state where diffusion out of the occluded region would limit the buildup. If the corrosion reaction plus hydrolysis leads to no net change in H^+ concentration, an acid solution in a crevice or pit could only be created by separation of the anodic and cathodic regions. Concentrating the cathodic reaction on the outer surface would occur naturally if dissolved oxygen, for example, were the primary bulk oxidant. Coupling this with a net anodic reaction (plus hy-

drolysis) in the inner region for an overall current balance would lead to a steady state crevice or pit.

For separation to occur as described above, a quite general condition imposed on the corrosion kinetics must be obeyed. The outside surface must support a cathodic reaction, and it must be supported at a potential that is positive of the potential of the anodic reaction in the crevice. The direction of current flow through the solution establishes this criterion. A qualitative laboratory test may be used to identify metal solution combinations that could cause localized attack by the mechanism described above. The test involves the corrosion kinetics on the metal of interest. Cathodic currents must be observed on the metal in the exterior solution at potentials that are positive of the anodic region for the crevice conditions or the separated reactions will not support increased anodic dissolution in the isolated region. This is a very definitive test, and very few metal-environment combinations match the criterion.

Ohmic drop restricts the penetration of current into a small-gap, occluded region [*8*]. This causes the anodic reaction to be distributed over a relatively small region, which concentrates the attack. At greater depths in the gap, the metal is isolated from the external surface reactions. Newman [*9*] calculated the limited depth to which a reaction may penetrate inside a circular geometry, in this case a cathodic protection reaction. The reaction is concentrated near the opening.

Composition gradients are considered to be important for pitting and differential aeration corrosion as well. For pitting corrosion, similar conditions to those for crevice corrosion are considered important. Pits may be initiated in ways that are different from crevice corrosion, e.g., at foreign metal inclusions. However, the propagation of pits depends largely on a locally aggressive solution. Stirring to eliminate concentration effects will stop the growth of pits. Differential aeration could also drive corrosion at locally variable rates under an electrolyte film of nonuniform thickness. The diffusion-limited flux of oxygen through the film would be directly proportional to the film thickness. If the local corrosion rate is limited by the oxygen flux, the attack will be most severe at low film thicknesses. For active/passive metals, increase of the oxygen flux may exceed the peak current for active dissolution and cause the metal to adopt the passive state. In this case, then, thin films of electrolyte will *reduce* the corrosion rate.

ATMOSPHERIC CORROSION OF METALS

Most atmospheric corrosion tests have been conducted in environments such as indoor atmosphere, outdoor atmosphere, and laboratory tests under simulated conditions. Indoor corrosion studies have been performed for the electronics, computer, and communication industries for the development of more durable materials with desirable structural, magnetic, and electrical properties. On the other hand, outdoor studies aimed at understanding corrosion behavior are highly dependent on atmospheric weather factors, especially in marine and urban areas. The latter studies have been performed in the automobile, marine, and aircraft industries. Laboratory tests attempt to use accelerated methods under simulated atmosphere or aqueous conditions. Electrochemical methods have been used extensively in such tests to analyze and monitor the corrosion behavior of metals.

Several weather factors are known to influence outdoor corrosion [*10–13*]. Precipitation, ambient and dew-point temperatures, atmospheric pollutants, wind direction and wind velocity, and solar radiation can be considered as weather factors in outdoor and/or urban corrosion tests. Among these factors, moisture or relative humidity, temperature, and pollutants such as sulfur dioxide and chlorides are the most important variables.

Relative humidity is known to be the most important factor in determining the atmospheric corrosion rate. It has been reported that rapid acceleration of corrosion occurs beyond a certain value of relative humidity, defined as the critical humidity [*14–15*]. The period in which the relative humidity exceeds the critical humidity is called the time-of-wetness, and this factor is quite significant in determining atmospheric corrosion rate of metals [*16*]. In addition, in the presence of a pollutant such as sulfur dioxide, the critical humidity at which corrosion is enhanced to a significant extent will decrease with increasing pollutant concentration [*17–18*].

It has been reported that comparatively large aggregates of water are present on oxyhydroxide surfaces at humidities below 40% [*19*]. Even on clean metal surfaces obtained under ultrahigh vacuum or reducing conditions, significant quantities of water are adsorbed on air-formed films when exposed to the environments containing only oxygen and water vapor for more than a microsecond [*13*]. As a result, monolayers of adsorbed water may provide the medium for electrochemical microcells that may drive a heterogeneous corrosion process. Water may also exist in the form of complex mixtures with oxides, hydroxides, and mixed oxyhydroxides [*19–20*].

The corrosion rate of metals is accelerated by the presence of air pollutants such as sulfur dioxide, nitrite, nitrate, hydrogen sulfide, chloride, and some kinds of salts [*10,15*]. These species may derive from gas-borne particles or from reactions at the surface. Reaction with adsorbed water monolayers yield electrolyte films that facilitate further corrosion processes. Among these pollutants, sulfur dioxide, chlorine gases, sulfur gases, and ozone are important species that promote corrosion in the presence of water.

The corrosion-accelerating effect of sulfur dioxide with humidity has been reported by many investigators [*10,13,15*]. Vernon [*15*] suggested that sulfur dioxide may change the pH in electrolyte films present on metal surfaces and enhance the corrosion rate. Rice et al. [*13*] also suggested that sulfur dioxide is readily soluble in water to form sulfurous acid; these local acidic regions accelerate oxide formation, and the corrosion rate is also enhanced by other electrochemical effects. It has been reported that wetting of the metal surface is promoted in the presence of ammonia, and the water droplets contain higher concentrations of sulfates than for the same concentration of sulfur dioxide with no ammonia [*10,22*].

The effect of chlorine gas or chloride on atmospheric corrosion has been reported [*10,13*]. In aqueous electrochemical corrosion studies, the chloride ions usually enhance pitting corrosion of many metals and also degrade the oxide surfaces. Rice et al. [*13*] reported that chlorine gases reduce the surface pH and yield hygroscopic corrosion products that influence the amount of adsorbed water. A direct relationship

between the amount of chlorides in corrosion products and atmospheric corrosion rates was reported by Sereda [*10*].

The effect of ozone gas on copper and silver corrosion has been known to be significant, while cobalt, nickel, and iron are insensitive to ozone [*13*]. It has been reported that ozone may enhance the corrosion rate of metals sensitive to H_2S.

The atmospheric corrosion rate can be measured either in field tests in different atmospheres or with accelerated tests in the laboratory. The field tests require long exposure times and yield complicated data that prevent detailed analysis. Accelerated tests are performed under simulated atmospheric conditions, and they are the easiest way to acquire more information with various setup conditions. However, it may not be possible to simulate practical service conditions.

There are several methods to monitor and control the corrosion rates by means of either field or laboratory tests. The conventional method is the weight loss determination, which requires long-term exposure unless a continuous method is used that involves the quartz crystal microbalance [*23–24*]. Another method is the electrical resistance method and measurement using electrochemical cells. Electrical resistance methods use the changes in the electric resistance of thin wires or foils to monitor failure, but they cannot be used for determination of the instantaneous corrosion behavior [*25–27*].

Electrochemical methods have been developed to take advantage of the electrochemical basis for atmospheric corrosion [*28–29*]. Corrosion currents can be monitored electrochemically, and the instantaneous value of current can be detected. One way to monitor atmospheric corrosion with an electrochemical method is to design a cell that will work under thin electrolyte layers (less than 500 μm) with consideration of the effects of corrosion products and dilute pollutants [*30*].

Electrochemical methods for monitoring atmospheric corrosion have been well reviewed by Mansfeld [*30–31*]. Most of the studies have been aimed at macroscopic measurement of time-of-wetness that is associated with electrochemical corrosion [*10,12,16,17*]. Galvanic cells with electrodes of different metals have been commonly used [*16,32*]. Sereda [*10*] has developed galvanic cells of platinum-iron and platinum-zinc couples to determine the time-of-wetness. Time-of-wetness was arbitrarily defined as the interval during which the external potential exceeded 0.2 V. This figure was the period during which the relative humidity was greater than 85% [*12,16*]. Tomashov [*33*] has used sandwich-type galvanic cells of iron-copper, iron-zinc, iron-aluminum, and copper-aluminum. They concluded that the method was suitable for fast determination of the corrosivity of the atmosphere and that the direct measurement of corrosion rate for testing metals was possible.

Several investigators [*17,34–36*] have used galvanic cells consisting of steel-copper and electrolytic cells consisting of individual metals (steel, zinc, or copper) to which an external potential was applied. They concluded that the cell current gave qualitative agreement with the weight-loss data. Recently, extensive studies have been performed by Mansfeld and his coworkers [*30–31,37–39*]. They used galvanic cells and electrolytic cells which consisted of two electrodes and three electrodes. Galvanic cells such as copper-steel, copper-zinc, steel-zinc, steel-aluminum, and aluminum-zinc couples were used to study the effects of pollutants, relative humidity, and so on. They used the electrolytic cells such as two- and three-electrode cells for studies of the corrosion kinetics and for the measurement of corrosion currents. The polarization resistance method was used to determine atmospheric corrosion kinetics under thin electrolytic layers. Mazza et al. [*40*] have used a galvanic cell that consisted of a sandwich formed of bronze covered by its artificial corrosion products on which a high-porosity gold film was applied. They monitored the corrosion current with a zero resistance ammeter and obtained instantaneous and continuous information on the corrosion rate of the bronze. Tosto and Bruco [*41*] used galvanic cells of copper-steel to obtain the relation between the corrosion content and relative humidity. They found that the corrosion current depended on relative humidity (RH).

As a rapid electrochemical method for monitoring atmospheric corrosion, measurements of electrode potential using a suitable reference electrode have been developed by several investigators [*42–43*]. Although the method gives no absolute data on corrosion rates, it is a fast and easy method for on-site investigations. Thin film methods to measure corrosion rates were discussed by Howard [*44*]. Pourbaix and his coworkers [*42,45*] developed an accelerated electrochemical wet and dry method that was designed to use alternate immersion cycles in an electrolyte bath. The electrode potential was monitored when the steel electrode was in the wet part of the cycle. They concluded that their method was selective and yielded reproducible data.

Electrochemical cells designed to simulate thin electrolytic films formed during atmospheric corrosion have been developed by several investigators [*46–47*]. Fishman and Crowe [*47*] have studied the thin film of electrolyte with a potentiostatic polarization technique. The corrosion current increased with an increase of relative humidity. They concluded that the resultant corrosion rates were consistent with those reported from long-term weight loss measurements. Fiaud [*46*] created a thin electrolytic film (80-μm thickness) using the device similar to one developed in the field of thin layer electrochemistry [*48*]. Platinum and nickel were used as electrodes and sodium sulfate (Na_2SO_4) solution was used as the electrolyte with change of pH by addition of sulfur dioxide (H_2SO_4). SO_2 gas was introduced into the electrolyte through a membrane. They observed the depolarization effect of SO_2, oxidation of SO_2, and reduction of SO_2 with use of cyclic voltammetry and linear polarization techniques.

CORROSION OF THIN METAL FILMS AND MICROSTRUCTURES

Corrosion of a metal occurs by the same fundamental reactions whether it is used in a large structure like an automobile, a bridge, or a heat exchanger, or in a small structure characteristic of magnetic, optical, or microelectronic devices, or under a protective layer [*49*]. The uniqueness of each application is tied up in the definition of the environment to which the metal is exposed or which develops with time, as well as the definition of a characteristic size of the corroding material. Since the time to failure of a material (i.e., its lifetime) is normally inversely proportional to the corrosion rate and directly proportional to the thickness of the corroding

material (its characteristic size), small dimensions are more susceptible to corrosion failure and loss of properties. For example (see Fig. 1), a 50-nm cobalt magnetic film may be corroded completely in about 38 h at a corrosion rate of 1 $\mu A/cm^2$. The desired lifetime is about five years, so a protective film (e.g., diamond-like carbon) must be used to moderate the rate of attack. The protective layer must be thin to read or write to the cobalt film with the magnetic head, and defects in the protective layer will lead to localized corrosion attac. Wear and friction are mechanical processes that result from the relative movement of the disk and head. The head is designed to fly very close to the disk to take advantage of the magnetic properties [*50*], but it comes to rest on the disk surface when the system is idle. Humidity and other factors affect wear and friction, and layers or films may be added to lubricate the magnetic film. Of more interest here, however, are the chemical effects that cause corrosion. Accelerated tests have been used to determine disk reliability [*51*], tests that measure the affects of wear, friction, atmospheric contaminants, humidity, oxygen diffusion, and galvanic corrosion. Also described by Antler and Dunbar et al. [*51*] is the comparison between field test experience and laboratory-simulated corrosion test results. Earlier results on microelectronics failures are reviewed by Schnable et al. [*52*], Comizzoli et al. [*53*], Wood [*54*], and Stojadinovic et al. [*55*]. Whatever the mode, the result is a loss of information at the site of degradation and the loss of properties. Better preparation and processing, or better design, may reduce flaws and defects that cause mechanical failure, but they may not reduce corrosion that is the result of the natural instability of the metal in an aggressive environment. Rarely are the thin film metals stable in the environment, so techniques must be found to stabilize the structures and extend the lifetimes.

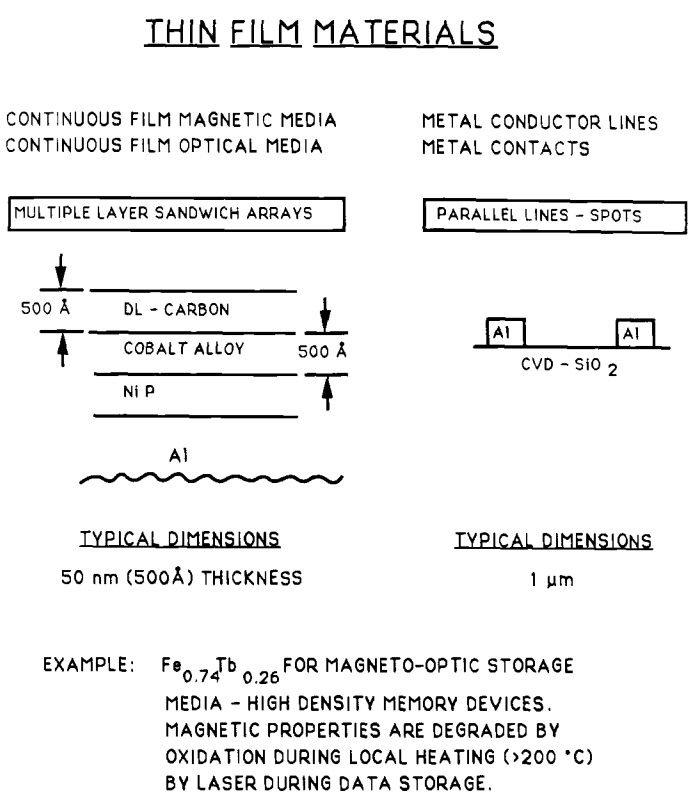

FIG. 1—Thin film materials for magnetic, optical, metal conductor lines and microelectronic contacts make them highly susceptible to have small dimensions are highly susceptible to corrosion.

In the other example of Fig. 1, aluminum interconnects in microelectronic devices have characteristic widths of 1 μm or smaller. Ionic conduction along adsorbed water layers at the silicon dioxide (SiO_2) surface can lead to electrochemical corrosion and "breaks" in the Al conductor. If the corrosion rate were 1 $\mu A/cm^2$, the lifetime of the Al interconnects would be about 48 days, rather than the 10 to 20-year lifetime desired. A protective layer is required for this application as well.

The corrosion phenomena of thin films chosen for magnetic, optical, or electrical applications have unique characteristics, but they are often similar to those observed for bulk materials [*35,50,56*]. Thin films have bulk metallurgical properties in thicknesses larger than 1 to 3 nm and have the same chemical reactions as well. Both observations lead to the general conclusion that both bulk metals and films 30 nm or thicker will have similar corrosion behavior. On the other hand, thin film materials have small grain size and are prepared for magnetic disk applications in "tracked" or grooved geometries. The small grain size causes films to have more homogeneous properties, with fewer inclusions and smaller chemical segregation effects than ordinary bulk materials. The tracks have sharp edges and dimensions to generate unique morphologies in the films. The homogeneous properties would make the films less susceptible to corrosion, but the defects generated at edges could be sites for enhanced attack. The dimensions and geometry of the tracks may lead to nonuniform chemical composition in the recesses, which would produce localized corrosion effects as well. Atmospheric corrosion has been studied under simulated conditions for thin magnetic films [*35*], and, as in other cases, it was found that the affect of humidity and atmospheric pollutants was synergistic. The level of humidity may influence the condensation of thin moisture films on surfaces, which will facilitate transport across surfaces and may cause the accumulation of water in microscopic domains. In the latter, the concentrations of dissolved contaminants may approach saturation conditions. The contamination may come from dust or inclusions of other layers [*49*]. The conditions are difficult to simulate in the laboratory because of the lack of knowledge of local conditions in the microscopic regions that are relevant to the problem. In addition, it has been difficult to make in situ measurements for conditions that simulate atmospheric-corrosion measurements, which would give a direct indication of the processes responsible for corrosive attack. Several standard tests have been developed to assess atmospheric corrosion damage [ASTM Test Method for Assessing Galvanic Corrosion Caused by the Atmosphere (G 104-89); ASTM Practice for Conducting Atmospheric Corrosion Tests on Metals (G 50-76 (1990)); ASTM Practice for Rating of Electroplated Panels Subjected to Atmospheric Exposure (B 537-70 (1992)] without addressing the mechanism of the attack.

The second topic relates to protective layers and encapsulants. Pore-free conventional protective layers over magnetic films are too thick to be compatible with the magnetic properties of thin film disk materials. In addition, poly-

mer films can change the adhesion properties of the surface and interfere with the operation of the magnetic head. Highly resistive but electroactive overlayers could lead to galvanic attack of the substrate through holes in the thin film. Sputtered diamond-like carbon films [*51,57–60*] could fall into this category (see Fig. 1).

A protective layer plated or sputtered over an active metal may have pores and defects that will permit the corrosive medium to contact the active substrate metal and thereby promote galvanic corrosion. The holes or defects may be present on a heterogeneous surface in the geometry of either regular arrays or random arrays. The mathematical modeling of galvanic behavior in plating corrosion systems has been discussed by Smyrl and Newman [*21*], where earlier work was also reviewed. They determined the current and potential distributions of galvanic corrosion system, which consisted of anodic disks in a cathodic plane as shown in Fig. 2. They solved the Laplace equation for potential with nonlinear (Butler-Volmer) boundary conditions with the use of finite difference method. The numerical modeling of galvanic corrosion in which the geometry consists of various array forms has been performed by Morris and Smyrl [*61–63*] in this laboratory. Either regular or random arrays of disks in the cathodic plane were used for the simulation of a heterogeneous surface. Most treatments of the regular array use the symmetry element derived from symmetrical geometry of the system. For mathematical simplicity, a particular hexagonal symmetry element can be approximated by a circular geometry, thus eliminating any angular dependence. For random arrays, the arrays simulated using a Voroni tessellation of the plane into random polygons as shown in Fig. 3 were used for the disk-cathodic plane geometry. The Voroni tessellation has proven to be useful for modelling the transport and mechanical properties of disordered or composite media. The geometrical properties of the Voroni tessellation and algorithms for generating the tessellation have been described by Winterfeld [*64*]. The model established by Morris and Smyrl included the Laplace equation for potential distribution with nonlinear boundary conditions, and it was solved by a finite element method. The potential distribution of the system was obtained from numerical simulation of a regular array of disks over a cathodic plane. The disks were of alternating sizes (disks with two different diameters) distributed on the surrounding plane. The models for the tertiary current distribution, which includes both potential distribution and mass conservation with use of a geometry of the random array, are in progress in our laboratory.

Since the total anodic current must be equal to the total cathodic current, the area ratio between anodic and cathodic components of the total area is an important parameter in galvanic corrosion. If the currents to each area were uniform, the area ratio is the *only* parameter that would affect the galvanic interaction for a particular combination of metals. On the other hand, Smyrl and Newman [*21*] found that ohmic effects in the electrolyte may cause a nonuniform galvanic current distribution on the component areas, and this leads to the conclusion that under such conditions some parts of the cathodic area are not important in determining the total galvanic current. The effect is even more pronounced under circumstances where the electrolyte phase is very thin, that is, galvanic current from cathode to anode flows only near

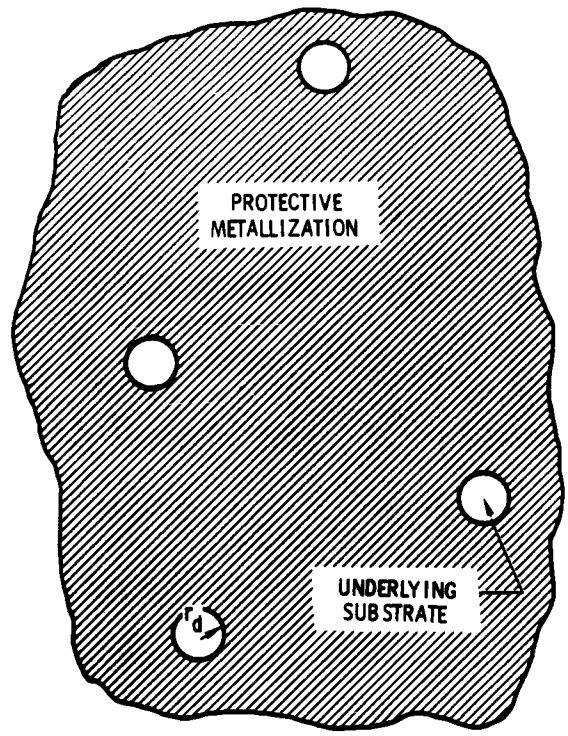

FIG. 2–Multilayer "sandwich" arrays may have underlayers exposed through holes or holidays in the overlayer, and galvanic interactions may enhance the corrosion rate in such systems.

where they join, and more remote areas of each are relatively unaffected by the galvanic coupling. It has recently been found that the *active perimeter* measure of the interactions is more relevant than the area ratio, and the former may be used to correlate the behavior of several geometries [*61–63*]. The nonuniform current distribution is also obtained if the cathodic surrounding plane is highly resistive but electroactive. For example, resistive sputtered carbon films would cause the cathodic galvanic current to flow only to areas at the periphery of holes and defects [*65*], and the total area would not be important in determining the galvanic current. However, smaller holes would increase the galvanic current at a constant area ratio because the active perimeter would increase.

In summary, investigations in bulk solution provide a basis on which to begin to analyze atmospheric corrosion behavior. As the electrolyte phase decreases in thickness, ohmic and diffusion effects become more dominant and galvanic

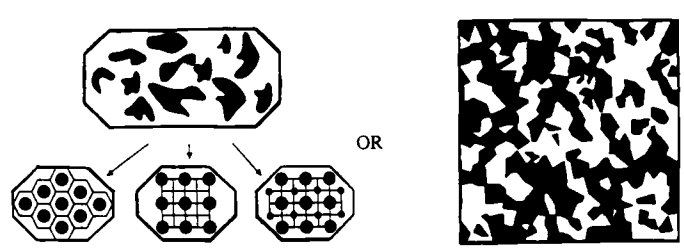

FIG. 3–Simulations of galvanic interactions in multilayer arrays have been carried out with regular patterns or with (more realistic) Voronoi tessellation representations.

coupling is strongly affected. The more remote areas will show the behavior expected for uniform exposure to an aggressive environment. Effects of local composition and local physical geometry then will become more dominant. Behavior in the local areas would be expected to be very similar to the behavior in bulk electrolyte at the same composition conditions. Further general comparisons must be developed as further research is conducted.

COATINGS AND OVERLAYERS FOR CORROSION CONTROL

In the past 15 to 20 years, an explosion of interest in surface modification techniques has mostly involved the deposition of thin films, the application of coatings, and the formation of surface alloys. The development of many of the techniques has been driven by the need for the semiconductor electronics industry to create improved processing procedures. As a spin off of the advancing technology, other fields, such as corrosion protection, have benefited from the new processes. A recent panel report [*66*] has summarized the general surface modification techniques that are used. The techniques are divided into three broad categories:

- Low-energy inorganic coating techniques. For the most part these are mature technologies that have been used for many years.
- Polymer coatings include traditional paints, thermoplastics, poly(vinyl chloride)s, epoxies, urethanes, and poly(methylmethacrylate).
- Techniques involving the use of energetic ions. The techniques have developed rapidly in the last 10 to 15 years; several have neither reached maturity nor found use for corrosion protection. Only those designated as low cost and scalable for widespread use are viable for corrosion protection, except in critical applications. In addition, most techniques that require vacuum processing are too costly for most applications.

Inorganic sol-gel films are formed from a sol through continuous stages of increasing concentration of a solid precursor. Typically, the sol is a solution of polymeric species or a suspension of "oligomers" including particles in the colloidal-size range. During deposition through states of increasing solids concentration, the sol might gel, but the gel state is often a fleeting transient that quickly empties of liquid. Nevertheless, the structures formed during this stage have varying amounts of porosity and influence the structure of the final film. This processing offers good control of composition and homogeneity at low temperatures. It is not directional nor equipment intensive. Complex shapes of arbitrary size can be coated with good uniformity. The cost of high-purity liquid precursors may be high, but for thin-film applications the materials cost would be acceptable.

Films deposited using energetic deposition techniques are dense, highly adherent, have few pinholes, and can be laid down at low temperatures. They are attractive for corrosion protection. Ion-beam-assisted deposition and ion implantation have the best adhesion properties, while RF sputtering has the best throwing power. Three important factors affecting the performance of films are porosity, adhesion, and stress. Although there are compressive stresses, in ion-implanted surfaces, for example, delamination by buckling is practically unknown. Effective porosity in the treated layer could exist due to shadowing of the surface from the beam by contaminating particles. The problem has not been observed, but the exact reason is not known. With the exception of ion implantation [*67*], only a few studies on corrosion have been done on films deposited using energetic deposition methods. Ion-beam-assisted deposition coatings are adherent and more ductile than bulk materials due to the microcrystalline or amorphous structures. The adhesion is better for the films deposited by energetic beam techniques as compared to films derived from physical vapor deposition. More details may be found in the cited report [*66*] or in the original literature.

Polymeric materials are widely used as protective coatings because they are transport barriers which limit access of reactive species (i.e., water, oxygen, ions) to the substrate surface. Leidheiser and Granata [*68*] have discussed the roles that each of these species may play in degradation processes on metal surfaces, and, in particular, the role of ion transport through bulk films and "ion channels" in films. Several techniques are discussed in this paper for characterizing ion transport: d-c measurements, electrochemical impedance analysis, under-the-coating sensing, and radio tracer measurements. Characteristic d-c resistances of 10^{11} ohm·cm^2 are observed for films without continuous aqueous pathways through the coating, as first described by Asbeck and Van Loo [*69*]. The resistance drops to the order of 10^8 ohm·cm^2 if continuous aqueous pathways exist where such pathways have high rates of transport. It is also clear that films and coatings are heterogeneous and the aqueous pathways are surrounded by regions of lower transport rates. The resistance of films may also decrease with time as the ion channels or pathways equilibrate with an external aqueous environment.

For films with high resistance and no ion channels, the impedance of the film is dominated by its geometric capacitance. For films of lower resistance, the low-frequency impedance is dominated by the sum of the resistance of the film and the resistance of the electrolyte. If corrosion proceeds under the coating because of ingress of the aqueous environment, the low-frequency impedance decreases in value. It has been argued that there is a strong correlation between the sites for corrosion under the film and the intersection of the ion channels with the underlying surface, but it has been difficult to confirm the correlation with direct observations.

The nature of the easy pathways for transport appears to be related to several factors. One of the factors is the presence of pigment and filler particles, which could facilitate the formation of aqueous pathways adjacent to the pigment or filler and would be influenced by the interaction of the particles with the polymer matrix [*68*]. The channels could also form by coalescence of voids or pores in the polymer matrix, and this would be influenced by the formation processes of the films. Aggregation of solvent in the film could be influenced by the prior history of the film, by the presence of impurities, and by retained solvent.

The presence of channels has been demonstrated to be a function of the glass transition temperature (T_g) of films as well. That is, below T_g, the polymer will be brittle unless a secondary, low-temperature relaxation exists, and this will favor the formation of microcracks and defects. Above T_g, the

film will be more flexible and less susceptible to formation of fracture channels. Armstrong et al. [*70*] have investigated the influence of T_g on ion transport and permeability in chlorinated rubber films.

Pigment and filler particles can have a beneficial influence because of the reduced transport of water, oxygen, and ions. The effect will depend on the pigment volume fraction, the chemical composition, the geometry, and the dispersion as noted by Burns and Bradley [*71*]. Equilibrium water uptake may cause plasticization and subsequent depression of T_g, as well as swelling, which counteracts the effects of reduced transport rate caused by the solid particles [*72*]. Pigments that have oxidizing character can induce passivation of the underlying metal, as observed for chromate or vanadate additives [*73*]. Other pigments may inhibit the cathodic reaction and thus suppress corrosion as well [*74*].

De-adhesion of organic coatings is responsible for enhanced corrosion rates on one hand and is the result of corrosion on the other hand. Leidheiser [*75*] has discussed de-adhesion processes which include: loss of adhesion when wet, cathodic delamination, cathodic blistering, swelling of the polymer, gas blistering by corrosion, osmotic blistering, thermal cycling, and anodic undermining. With few exceptions, the loss of adhesion processes requires that reactive species such as water, oxygen, and ions penetrate through the coating. Bonds of the coating with the surface of a steel substrate may be attacked by high pH conditions, which are the result of corrosion reactions or imposed cathodic protection conditions. In either case, OH ions are particularly aggressive and cause disbonding on steel. In a recent investigation by Stratman [*76*], disbonding was followed by monitoring the surface potential of a polymer-coated steel surface with a scanning Kelvin probe technique

A recent international meeting [*1*] reviewed the unsolved problems of corrosion protection by organic coatings, described the current understanding of the technology, and outlined some focus for further progress. In addition to the principles of barrier layer transport that have been described above, there was discussion on the effects of: (1) pretreatment of surfaces, (2) the contribution made by surface inhomogeneities of the substrate, (3) the critical size of a water phase which may be responsible for corrosive attack, (4) stress in the film and stress in the substrate, and (5) incorporation of corrosion inhibitors in protective films. Funke [*77*] later summarized the continuing uncertainties that exist in studying corrosion protection properties of organic coatings. Some scatter of behavior is caused by the age and history of the coating—fresh coatings are more susceptible to swelling and changes in composition. Disbonding may initiate at defects, but it may also occur in the absence of holidays or defects. The water that is associated with disbonding could be transported along the surface and not by permeation through the film. Ions may also move along the interface. All these considerations have considerable implications for electrochemical characterization techniques. A review of various types of organic coatings and their applications in various service conditions is provided by Tator [*78*].

SUMMARY

The atmospheric corrosion of metals is one of the most important single problems facing corrosion science and technology. From small nanostructures to large buildings and bridges, coating techniques are being developed to moderate the rate of degradation with some success. The use of low-cost coatings continues to increase as the coatings are made more impermeable and more adherent to the protected substrate. Higher-cost films applied by high-energy methods are finding wider use in critical applications where conventional coatings are inadequate. In all systems where protection is necessary, the early detection of corrosion is desirable in order to plan replacement and maintenance measures and to avoid catastrophic failures. Detection of the presence of corrosion can be accomplished in two ways: detection of the agent that causes corrosion or detection of the results of the corrosion process either on the material of interest or on a specimen of the material. Sensors and monitors are receiving greater attention in accelerated life testing of materials, and eventually they will be developed more widely for operating systems or in portable monitoring systems. The savings to industry and the public at large would be in the billions of dollars if the onset of failure processes could be detected prior to their culmination in a catastrophic event [*79*].

Natural Weathering

by Lon S. Hicks[1] *and Michael J. Crewdson*[2]

NATURAL WEATHERING DESCRIBES THE PROCESS of exposing materials to the effects of the outdoor environment. Deterioration caused by the atmosphere occurs to all materials placed in an outdoor environment. Natural weathering tests are an extremely important part of the process of determining the aging characteristics of a material. Weathering tests are used to improve the durability of exposed materials.

All materials exposed to the elements deteriorate; the rate and extent of deterioration is dependent upon the material and the severity of the exposure conditions. Weathering tests provide the means to improve the resistance of a material to those factors.

Paint is currently the single most important material tested for its weathering-resistance properties. Paint is used as a decorative item, but equally as important, paint is used as a protective layer. Painted products are found in many varied environments with equally varied effects upon exposed surfaces. Weathering tests offer an initial view of the expected performance of the paint to the environment.

Natural weathering tests are not, however, simply a case of setting specimens out in the sun and watching what happens; a meaningful test involves a more thorough understanding. A number of important factors must be carefully considered when planning and conducting a weathering test: the cause and effect relationship between the weather and the material, the subtle differences in exposure techniques, and the reporting and inspection methods employed. To achieve the most reliable test result, these fundamentals must be appreciated.

HISTORICAL

The origins of natural weathering testing of paints goes back as far as early caveman drawings in the Ice Age. We do not know if these cave dwellers painted on the outside walls, for if they did, the elements would have long since eroded away the evidence. Inside, where conditions are less severe, the paintings have survived tens of thousands of years.

The modern paint era was the catalyst for current weathering tests. Consumer awareness of deterioration propelled the search for more durable products. At the same time, paint manufacturing companies became cognizant of the fact that durable products sell better; thus they have increased their efforts to improve paint durability. At this time, the only testing was "real world," with results being returned from product surveys and consumer complaints.

The idea for exposure fences and racks to expose paint specimens moved the testing to the research and development stage and away from the after market survey. Research into improved coatings were made on specimens before the product went to market, thus reducing the possibility for failures in the marketplace.

In the early 1920s certain climates were noticed to be more severe on exposed materials than others. At the same time, Florida experienced a land boom with increased development; as the number of consumer items increases, it became apparent that life expectancy for these products was much less in the "Sunshine State" than in the Northern Temperate Zone. Prior to this time, natural weathering tests were conducted mostly in the Northeast and Midwest, where the majority of the large paint companies were situated, but the discovery of the faster weathering led several of these manufacturers (along with car companies) to set up their own exposure stations in South Florida.

Also at this time, several independent weathering stations were founded (see Fig. 1) to provide this important service to all companies. The cooperation between independent test stations and paint manufacturing companies over the last 60 years has led to a greater understanding of the cause and effect relationship between the weather and material and also to refining and improving techniques used to conduct weathering tests.

Early weathering tests were almost always at a 45° angle facing south as this was considered the optimum position (see Fig. 2). The fact that most exposure stations in the early years were all in the Northern United States made this even more so. As the focus of outdoor weathering shifted to Florida, realization set in concerning the importance of the angle of exposure and other variables affecting the outcome.

FACTORS OF INFLUENCE

The major influencing factors in the atmosphere involved in the process of weathering are:

1. Sunlight.
2. Temperature.
3. Moisture
4. Pollution
5. Biodeterioration.

FIG. 1–Aerial view of exposure site.

FIG. 2–Overview of exposure racks.

Paint will degrade when exposed to the elements in the atmosphere due to the action of these influencing factors, which cause the basic structure to break down. These factors interact synergistically to produce the deterioration of the material we see as a weathering effect.

The relative proportion of each of these factors is important in determining how the overall degradation process will occur. When the factors of influence are changed, so is the degradation produced. Any test method employed to examine weathering must be designed so that the exposure condition is as similar as possible to that of the intended end use of the material. This is the only way accurate predictions may be made concerning the expected life of the material.

An outdoor weathering test is conducted using the natural elements in an uncontrolled environment. Test fixtures and mounting techniques can be chosen to create a similar expo-

sure position as the end use. These techniques include changing angle and orientation, backing type, and the use of specially designed frames to produce a specific microclimate.

The material under test is itself a major factor in the test. The simultaneous exposure of a reference specimen with a known long-term weathering history will ensure that the testing is realistic. If the expected results are given by the reference specimen, there is a greater degree of confidence that the influencing parameters will produce the correct type of changes in the specimen, which is exposed simultaneously.

Sunlight

The effect of exposure to sunlight is the fundamental cause of the weathering deterioration of most materials. The primary component of paint weathering is photodegradation.

Spectral Power Distribution

The wavelength distribution of sunlight that reaches the Earth's surface is important because of the relative effect on the material caused by each wavelength region.

Sunlight can be divided into three major regions: ultraviolet (UV), visible, and infrared (IR). Each region has its own distinct wavelength range [*1*] (see Fig. 3).

1. *Ultraviolet*—wavelengths less than 400 nm.
2. *Visible*—wavelengths between 400 to 700 nm.
3. *Infrared*—wavelengths above 700 nm.

The relative proportion of each of these wavelength regions is shown in Table 1 and described in Fig. 4. The visible region constitutes the largest portion of the overall solar energy; however, it is the UV portion of the sun's energy that is the most destructive element. The ultraviolet can itself be divided into three distinct wavelength ranges [*1*]; only the UVA and the UVB reach the Earth's surface (Fig. 5).

Range	Wavelengths, nm
UVC	less than 280
UVB	280–320
UVA	320–400

There is no UVC at the Earth's surface as wavelengths below 295 to 300 nm are filtered out by the atmosphere [*1*]. The percent composition of the UV regions is shown in Fig. 6. Generally, the shorter the UV wavelength, the more damaging its effect on materials. The UVA and the shorter wavelength UVB are responsible for most photodegradation. Therefore the range of sunlight that comprises the smallest percentage of the solar spectrum is the primary cause for material degradation. This becomes clear when we consider the quantum theory, which describes light as discrete packages of energy called photons. The lower the wavelength, the greater the energy contained in these packets (Fig. 7).

Photodegradation occurs as a result of light energy breaking a chemical bond in the exposed material, causing a deterioration of the physical structure [*2*]. As the wavelengths become shorter, the energy of each individual packet becomes greater, allowing that photon to break progressively stronger molecular bonds. Thus, chemical structures able to withstand irradiation at 350 nm may not be able to endure radi-

TABLE 1—Relative proportion of sunlight wavelength ranges.

Range	Wavelength, nm	Irradiance, W m^{-2}	Percent
UVC	<280	0	
UV UVB	280–320	5	
UVA	320–400	63	6.1
Visible	400–800	580	51.8
Infrared	800–3000	472	42.1
Total	280–3000	1120	100.0

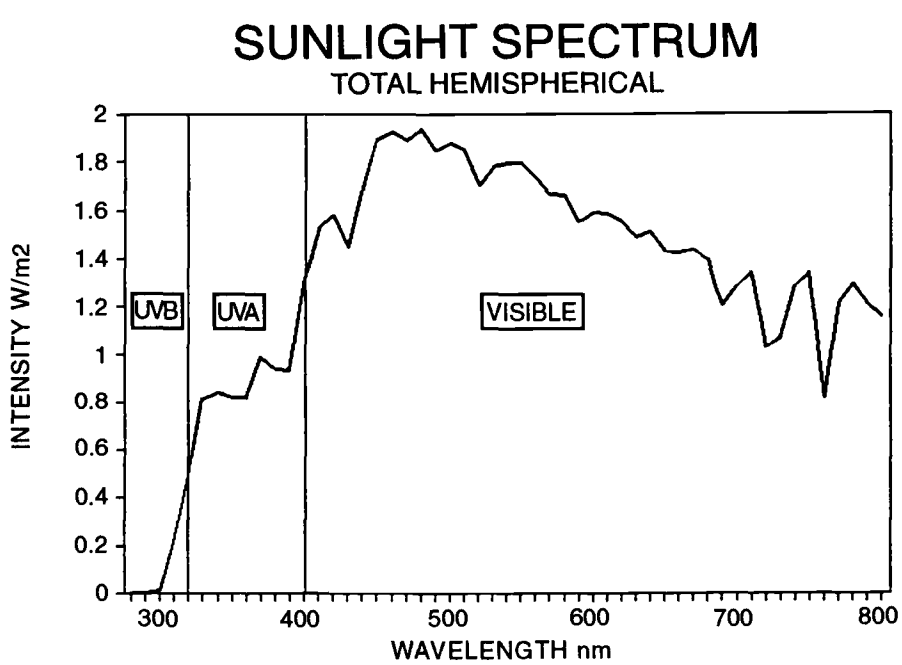

FIG. 3–Solar power distribution, Miami, Florida (solar noon, 26° tilt).

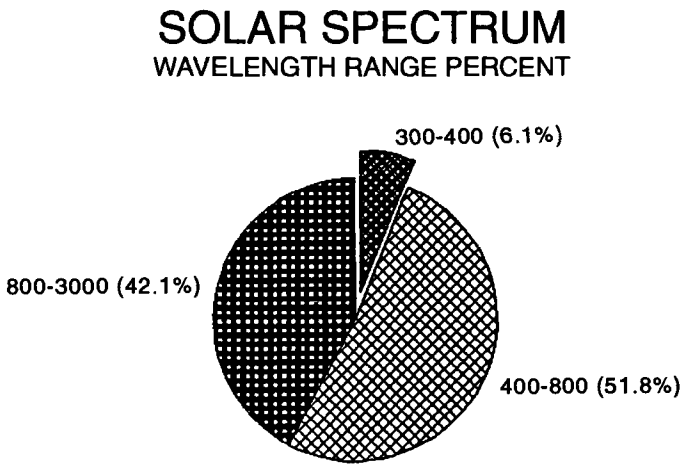

FIG. 4–Percent composition of sunlight.

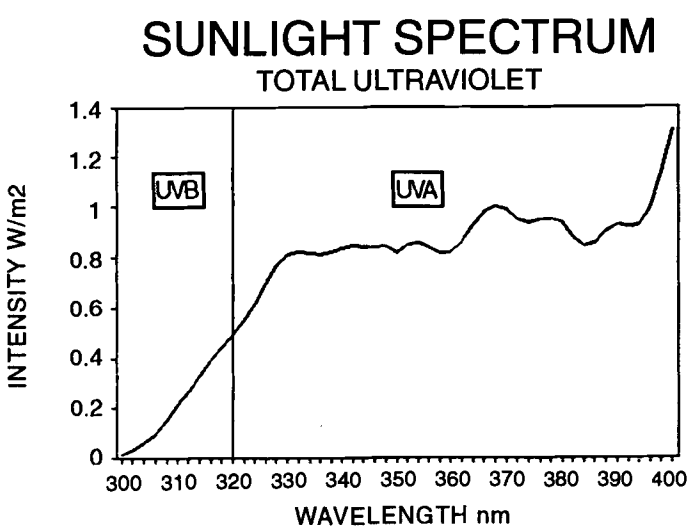

FIG. 5–Ultraviolet spectral power distribution (solar noon, 26° tilt).

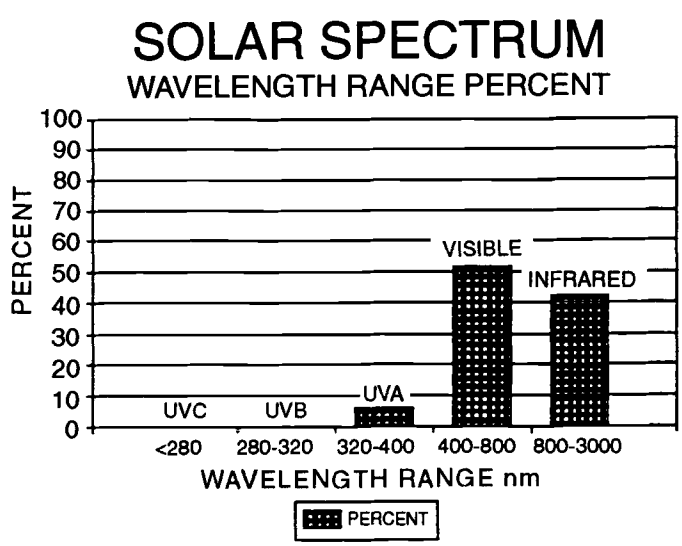

FIG. 6–Percent composition of UV, visible, and infrared.

ation at 320 nm. As the energy level in the photons increases, however, there is a reduction in quantity available. The ultraviolet wavelengths in sunlight contain these high-energy photons. So while the UV makes up only 6% of the total energy, it is that small percentage that causes the damage to occur.

The first law of photochemistry states that only light that is absorbed can cause damage. Thus, if the absorbance of damaging UV energy can be prevented or otherwise reduced, deterioration will be slowed. This premise forms the basis for much of the research in paint formulation.

The visible portion of the solar spectrum is responsible for a limited amount of physical degradation [*3*] and only in a few materials that are susceptible. Some dyes and pigments are sensitive to wavelengths in the lower regions of the visible spectrum. This manifests as color changes in most materials but without changes to other physical properties. Printed materials, paper, and dyes are affected by the visible wavelengths.

The infrared region causes heat buildup to occur on radiated specimens, but has not otherwise been associated with causing significant deterioration to occur. The IR is a factor in the deterioration because absorption of these wavelengths causes specimen temperature to rise, which in turn leads to an increase in the rate of photodegradation.

Radiant Exposure

Exposure to solar radiation causes deterioration to occur, and the more energy absorbed during exposure, the greater the deterioration. The intensity and total dosage of solar energy affect the rate and extent. Daily intensity levels are determined by the season, latitude, and atmospheric conditions of the location [*4*]. A typical day showing total and ultraviolet radiation is shown in Fig. 8.

Radiant energy is monitored and recorded using radiometers. These instruments collect incoming solar radiation from a 180° solid angle, which is identical to the energy collected by the exposed specimens. For more accurate measurement of the amount of radiant energy the paint specimen is receiving, the instrument is tilted at the same angle as the exposure rack.

The integrated total of solar radiation will be the dosage of solar energy on the sample. This total will be affected mostly by atmospheric conditions such as cloudiness: a clear day can yield as much as 30 MJ m^{-2} (approximately 700 langleys) solar energy, whereas a heavily cloudy and overcast day may be barely above zero.

Seasonal Variations

On an annual basis, the dosage of solar energy will change due to the altitude of the sun and the distance between the sun and the Earth [*5*]. This becomes more apparent when the angle of the fixed exposure rack is taken into account. Solar radiant exposure increases when the specimens are positioned at an angle normal to the incident radiation. Therefore, in the summer months in Florida, a 5° tilt angle will receive more energy than a 45° tilt angle. In the winter months, however, when the sun achieves a much lower zenith, the 45° angle receives the most energy [*6*] (Fig. 9). This seasonal difference in radiant energy levels can be seen in Fig. 10.

Over the complete solar cycle of twelve months, a fixed exposure at the same angle as the latitude of the exposure site

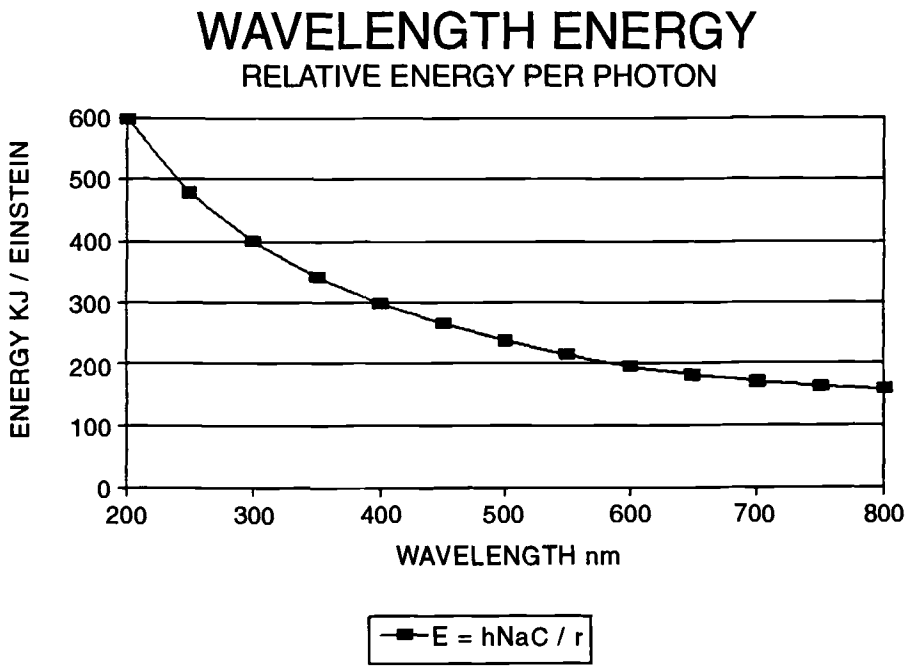

FIG. 7–Energy per photon at each wavelength in sunlight.

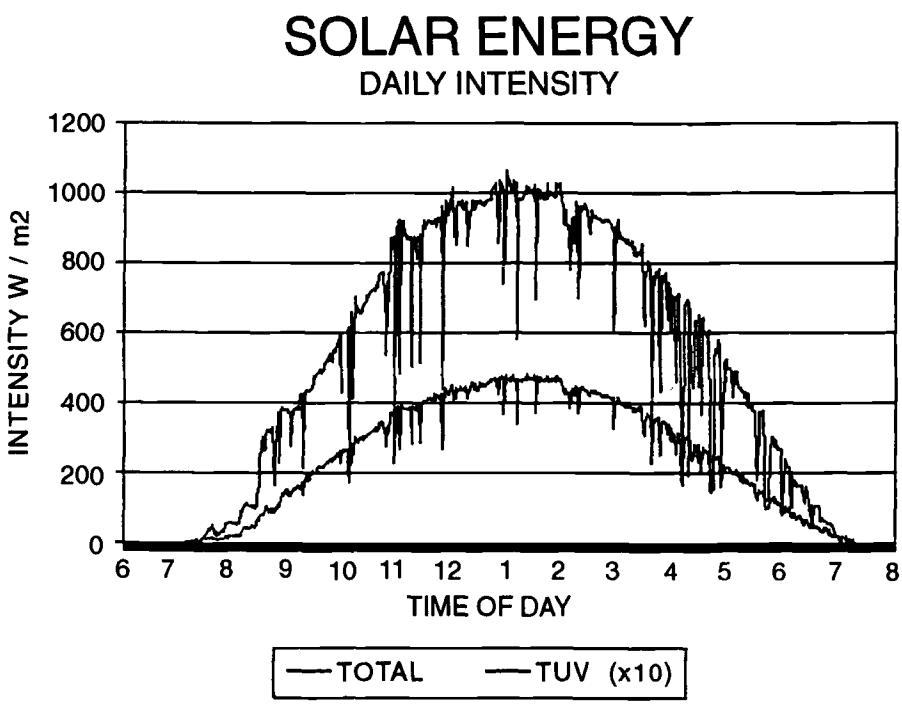

FIG. 8–Daily intensity levels of sunlight, Miami, Florida: Total and ultraviolet, 26° tilt angle. (TUV is shown by the lower line.)

will receive the most radiation, as shown in Table 2. Variable angle exposures where the tilt angle of the rack is changed seasonably to follow the zenith of the sun can be used to increase the radiant exposure by up to 10% depending on location and local climate variability. Short-term exposures, those less than one year, will be affected by seasonal differences in solar energy due to angle of exposure. This important factor must be considered when equating exposure intervals. Timing exposures by amount of radiant exposure will reduce some of these inequities. The use of total ultraviolet energy as a means of timing exposures will further help to even out the seasonal differences in the weathering effect produced. The radiant energy for one year for Miami and Arizona for each of the commonly used exposure angles is shown in Table 2.

Temperature

The temperature of a material on exposure is a primary factor whose influence must be understood in order to relate

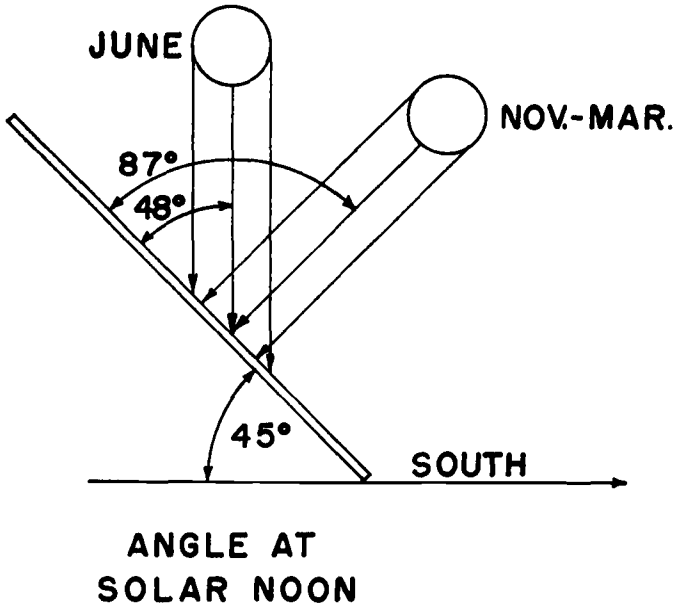

FIG. 9–Angle subtended by sunlight on exposed panel.

the cause and effect relationship of weathering. For most materials, the moderate high temperatures found in service do not cause deterioration per se. However, when the temperature rises in conjunction with solar radiation, the rate and type of deterioration can vary greatly.

In a normal first-order chemical reaction, raising the temperature of the environment by 10°C leads to a doubling of the speed of that forward reaction. However, because material degradation is not a simple one-step chemical reaction, weathering deterioration does not proceed twice as fast when the temperature is raised by 10°C. There is a definite indication, though, that once the breakdown mechanism has been initiated, an increase in thermal load will accelerate the rate of change. A general rule of thumb that has been accepted recently is that an increase of 20°C in the temperature of an exposed specimen results in a doubling of the deterioration rate.

Many chemical reactions have a threshold activation energy, i.e., the temperature level at which a sequence of events will be initiated. Therefore, as thermal input increases, higher threshold levels are surpassed and new mechanisms are initiated. This may cause a change in the overall deterioration produced if the new pathway is significantly different from that at the lower temperature.

It is therefore necessary to conduct the weathering test at the correct temperature. The comparison being made here is that of the actual end use exposure condition to that found in the test method. By having the temperature too low, the rate of change is slowed and deterioration will not be as severe. Conversely, if the temperature is too high, the rate may proceed too quickly and the effect will be more severe.

Paint specimens on exposure derive their temperature from two sources: the ambient air and the radiated infrared from sunlight. The intensity of the sunlight will determine how much higher the temperature of an exposed specimen will be above ambient. Wind speed will assist in reducing the temperatures slightly [7]. The average specimen temperature will show the same seasonal range as that for air temperature (Fig. 11), but will be determined on any given day by the level of solar irradiance (Fig. 12).

The angle of exposure, paint color, and season also contribute to determine the actual temperature at any given time. Thus the specimens are generally hotter during the day than at night, in the summer than in the winter, and on a sunny day rather than on a cloudy one. On any given day, the tem-

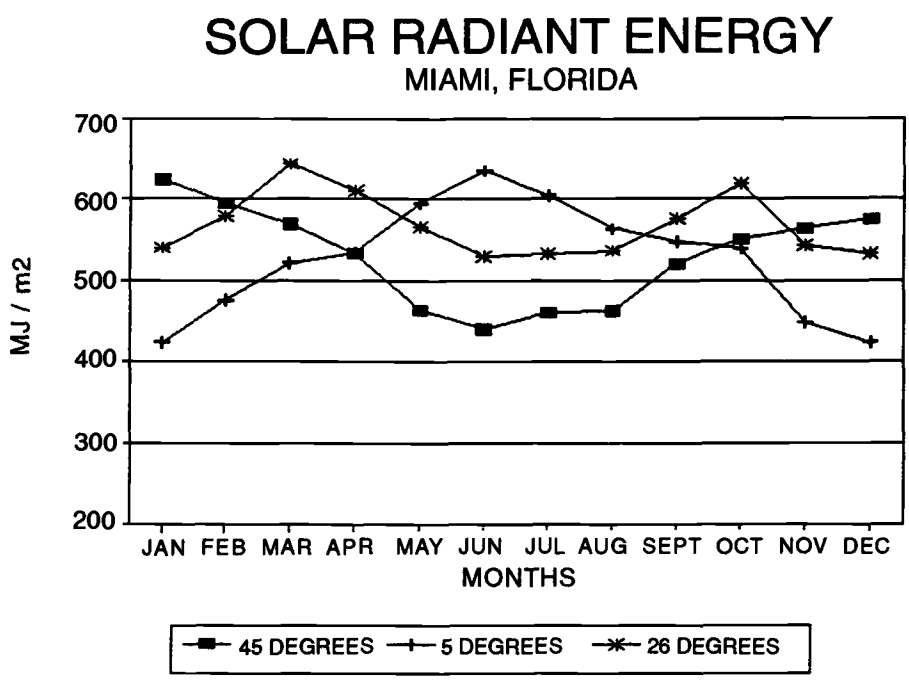

FIG. 10–Seasonal variations in solar energy measured at different fixed angles of exposure.

NOTE: VA = variable angle.

perature of an exposed paint sample will follow closely the irradiance level of the sun. The temperature of the exposed material can be manipulated even in an outdoor exposure test; these techniques are discussed later in "Accelerated Natural Weathering."

Moisture

Water is a primary factor affecting the deterioration of exposed materials. In conjunction with solar radiation and high temperatures, the moisture content in and surrounding an exposed sample is very important in determining the weathering response of that material [*8*]. The presence of water falls into two categories:

1. Gaseous.
2. Aqueous.

Relative Humidity

The gaseous phase is that which describes the moisture content of the air. The amount of water vapor contained in the ambient air is the *absolute humidity*. Warm air is able to hold more water in the vapor phase than cold air. The relationship between the actual moisture content of air and the maximum content at any particular temperature is the *relative humidity*. When the air is fully saturated, the relative humidity is 100%.

Any material placed on exposure will endeavor to maintain a moisture content equilibrium with its surroundings [*9*]. Physical stresses are created as the material loses or gains water content in order to equilibrate, as can be seen in Fig. 13. The greater the range of humidity in the enveloping atmosphere, the greater the overall stress on the material. Because moisture is a major factor in the synergistic effect of weather on exposed materials, a higher moisture content will contribute to increased degradation more than will lower moisture levels. A relative humidity value of 70% is considered the critical threshold for corrosion [*10*]. This indicates that a constant cycling of humidity levels at high values increases the rate of deterioration.

Rainfall

The effective source of visible surface moisture has two origins, and they each have a different effect on the exposed material. The distinction between the two types must be clearly understood.

Rain is an external source of water that is applied to the material via the surface layers. As most rainfall is of short duration, this effect is primarily at the surface and does not play a direct role in the deterioration of the bulk of the material.

Rainfall has the greatest influence at the surface and is responsible for washing away surface layers during periods of heavy rain. For example, rain assists in increasing the rate at which a specimen may chalk, but may also help to remove surface attachments such as dirt and mildew.

Rainfall will cause a thermal shock on exposed specimens, which can be severe in certain circumstances. When the rain occurs at a time when the material is heated from radiant exposure, the cooling effect causes a rapid drop in the temperature of the specimen. This thermal shock can cause mechanical stress as the specimen contracts. In the summer in

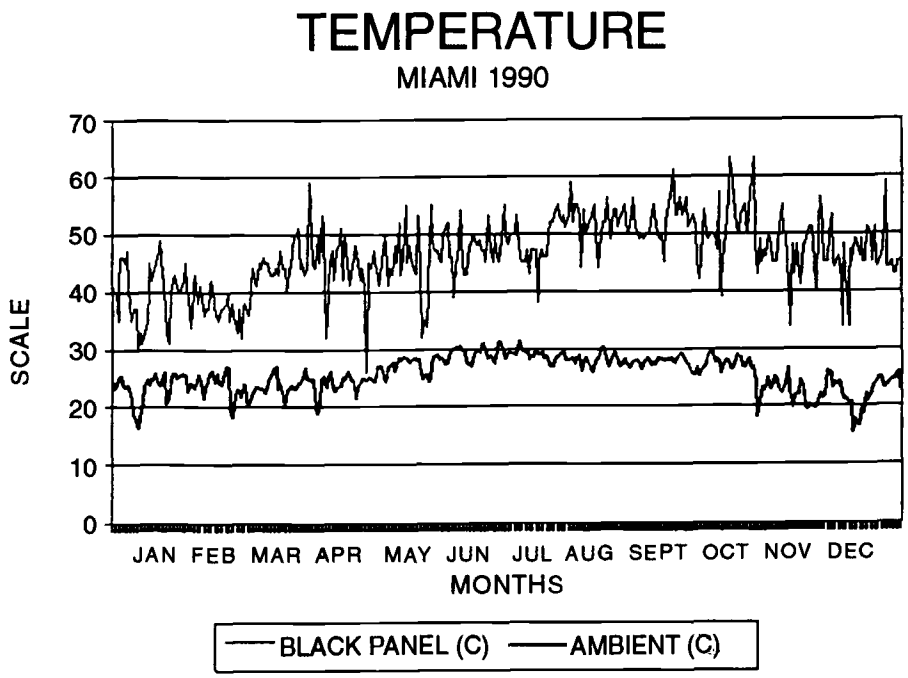

FIG. 11–Daily maximum black panel versus ambient temperature. (Lower line equals ambient temperature.)

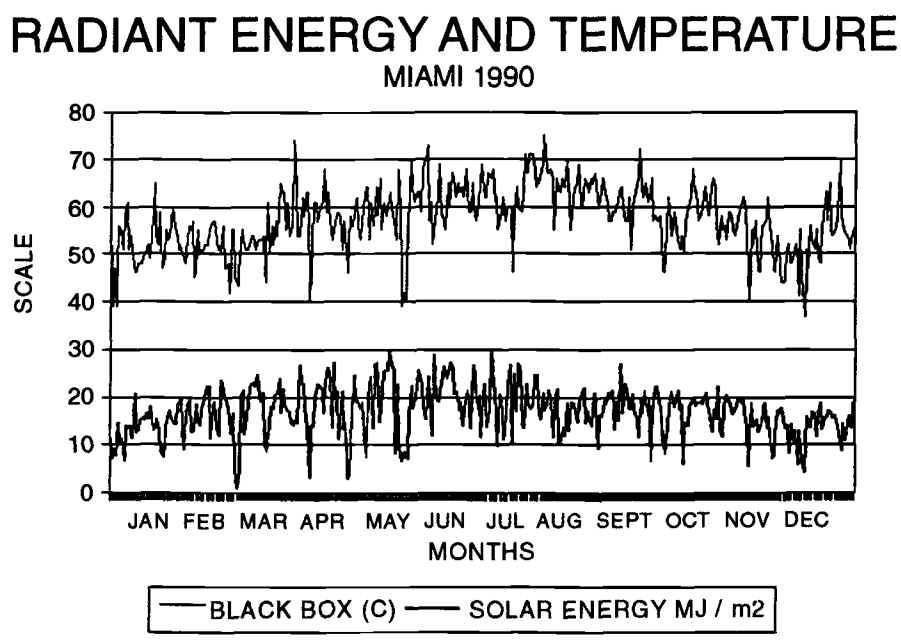

FIG. 12–Daily maximum black box temperature versus daily solar radiant energy. (Upper line equals black box temperature.)

Florida, the temperature of a black panel can drop from 70 to 25°C in about 2 min.

Condensation

Condensation arises when the sample temperature drops below the dew point temperature of the surrounding air. This causes water vapor in the air to condense on the material. The physical and chemical responses of the material caused by condensation have a far greater effect on the material than rainfall. The condensation effect can also be apparent at much deeper levels within the material. Condensation moisture has high levels of dissolved oxygen, which accentuates photodegradation by taking part in the chemical reaction.

The total amount of time a sample is wet is an extremely important factor in the determination of the degree and rate of degradation. Prolonged exposure to surface condensation will allow the absorption or permeation of a relatively high level of water and oxygen, and as the day progresses a strong pressure will be exerted by the atmosphere for water desorption. The longer the intervals of wetting and drying, the

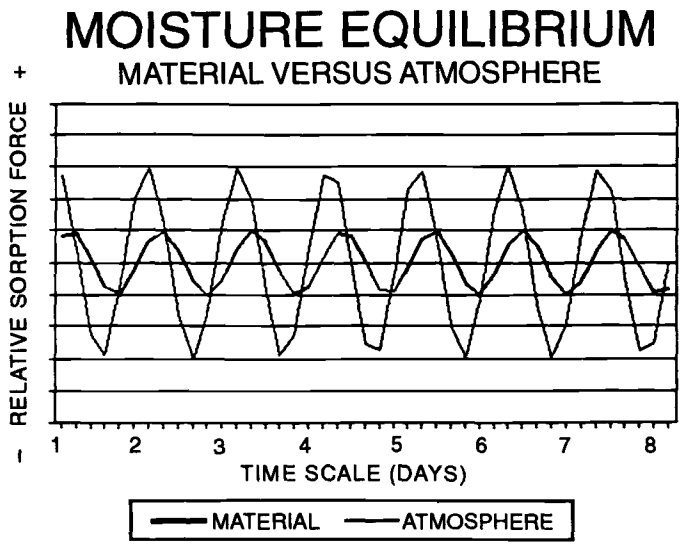

FIG. 13–Ambient versus sample moisture cycling.

deeper into the material will be the cycling effect. Water absorption and desorption rates are also a function of the diffusion coefficient of the material. The faster the rate of cycling, the more the effect remains at the surface and the less penetration is made into the bulk of the material.

The photochemical degradation mechanism is also accentuated by the presence of moisture. Rates of deterioration are greatest when the solar radiation is present in conjunction with high moisture levels. It follows, therefore, that surface breakdown effects such as chalking will occur due to rainfall, condensation, and sunlight interaction, whereas bulk substrate deterioration such as cracking is due in large part to the synergistic effects of humidity, condensation, and temperature, causing mechanical stress and release of strain in the paint film. As surface layers break down, more of the interior bulk of the material is exposed as a new surface layer.

The role of moisture in exposed material breakdown is very important, but it is also important to know the source of the moisture. The different physical (and chemical) effects produced will differ with each source. A climate such as Miami's (Fig. 14), with a range of high humidity and a high percentage of total wet time (approximately 50%), will allow moisture to play a full part in the weathering process [*11*].

Pollution

Atmospheric pollution is a significant, but lesser part of the overall weathering effect. Industrial emissions consisting of compounds that mix with water to form acid rain cause chemical reactions to occur on exposed materials. The severe long-term effect of pollution on even durable materials can be seen by the effect on ancient monuments and statues, which have withstood centuries of exposure only to succumb in recent years to atmospheric contaminants. Short-term exposure to pollution can be just as severe if the material is susceptible.

Pollution is a powerful influence on paint durability, but its effect is difficult to control and monitor. Analysis of the atmosphere will reveal the constituents of the pollution, and comparison to exposure in a clean pollution-free atmosphere will show the additional effect of the pollution on overall weathering.

Although pollutants may directly affect the paint independently of other weathering factors, most often the changes do not occur until the other influences are present. Changes in paints on exposure in industrial areas, which are seen in a relatively short time but which do not show changes in rural areas, are a clear indicator of the effect of the pollution.

Solar energy can act to change the chemical structure of the emitted waste product; for example, atmospheric SO_2 in water does not become sulfuric acid until radiated. The sulfuric acid then causes a color change due to reaction with the pigment.

Large-scale pollution such as the effect of acid rain is felt throughout most of the northeastern United States, with the greatest effect in Pennsylvania, New Jersey, and New York. Acid rain resistance can be included as part of the routine testing procedure by exposure at known polluted sites. The effect is known and is widespread.

Local pollution problems such as the smog in Los Angeles create a problem for the testing industry. Because the chemical effect of each emission is different, the weathering result of a single material may vary from city to city depending upon the industrial base.

Biodeterioration

The phenomenon of material degradation due to attack by biological organisms can take many forms. The most common form of biodeterioration of specimens exposed outdoors in Florida is mildew. The organisms that constitute mildew are fungi, which are individually microscopic but can be seen with the unaided eye when grouped in colonies or having threaded structures called hypha. The spores of the fungi attach to the surface of the material, using the constituent chemicals at the surface as a food source. All fungi are characterized by their inability to synthesize their own foods from carbon dioxide and water. They must therefore utilize an external supply of carbohydrate as their energy source. The exact chemical nature of that source will vary for each fungal species, but the more opportunistic species can use the paint directly.

As the mildew grows, surface conditions are altered. Breakdown products are formed that can act as a food source for a second fungal species, which will find the surface of the paint a favorable place to live. This succession of different organisms constitutes the microecology of the painted material's surface [*12*]. The complicated natural order that occurs in mildew attack on exposed products makes it very difficult to ascertain which species is causing the most damage.

Real-time exposure testing outdoors in conditions favorable to growth is the only way to truly test the mildew-resistance properties of any product. Single culture testing of mildewcides and mildewstats are useful as a preliminary test only.

The subtropical region of Florida is used extensively for the evaluation of fungus growth. The warm, wet climate promotes rapid growth on unprotected materials, with visible hyphae present in just a few days. A number of different exposure methods are employed to study mildew growth, the most common being a vertical north orientation. This gives a

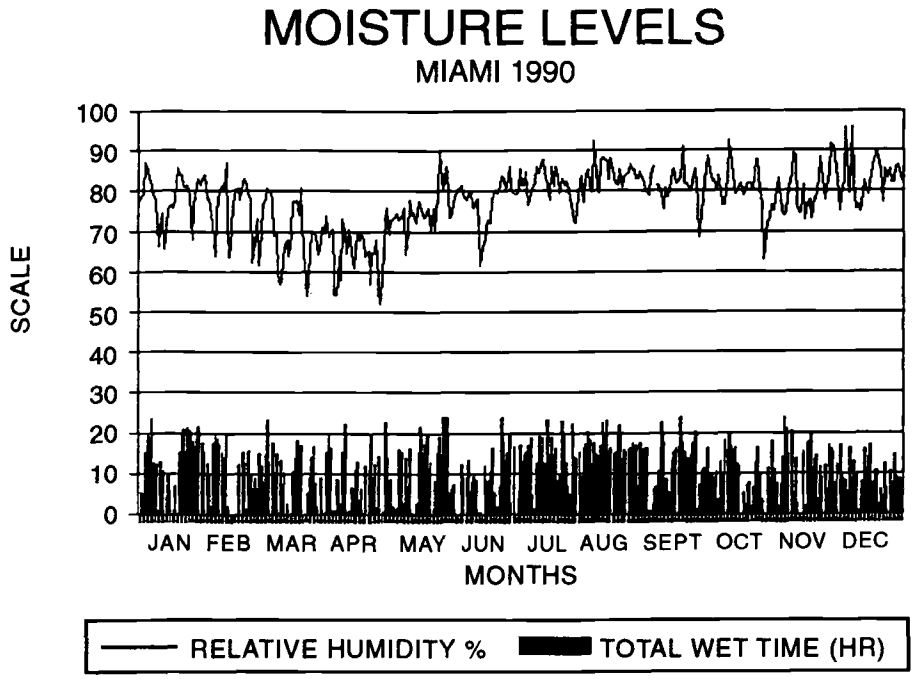

FIG. 14–Daily maximum humidity and total wet time.

shaded, damp location without the natural mildewstatic effect of solar UV radiation. A vertical south position is also used to study mildew growth as part of the total deterioration mechanism. Exposure under a roof overhang is commonly used (Fig. 15), and a tropical forest exposure is the most rigorous example of natural exposure conditions.

Mildew organisms thrive in the damp conditions found in subtropical-type climates, and growth is greatest during the summer months when rainfall and ambient relative humidities are at their highest level and temperatures are 20 to 30°C. Growth is slowed when average daily humidity drops significantly below 70%; however, during the winter, steady growth will still occur on northern exposures and in tropical forests, where moisture levels are higher and temperatures are in the optimum range.

Algae as a biodeterioration factor is different from mildew. Algae is a green plant and able to synthesize food from sunlight, carbon dioxide, and water. Its attachment to paint surfaces is not an actively attacking one as is the case with mildew. The paint film is merely supplying a substrate for the algae. By its presence on the surface, however, algae affects the microclimate and resulting deterioration may occur.

CLIMATOLOGY

Natural weather exposure testing of paints and coatings is conducted at many different sites, each with its own distinct set of influencing factors. It is the combination of the weathering factors that causes the deterioration particular to that location.

As indicated earlier, paint exposure testing facilities are located in many areas, but the subtropical area of Florida is regarded by the United States and by much of the rest of the world as the primary benchmark testing climate. This is because the exposure consists of all of the major environmental parameters in high quantity except pollution.

Each climate type has its own distinct characteristic pattern, which derives from the range of influencing parameters at that location. These can be measured and examined to determine the relative importance of each. Several important climatological types used in weathering are described below.

Climatological Types

Subtropical

The subtropical climate of southern Florida is recognized worldwide as the primary benchmark testing location. It is the climate to which all other locations are inevitably compared. It is no accident that this area is as important as it is, for it is the only true subtropical region within the United States. Due to the historical considerations discussed earlier, Florida is accepted worldwide as the standard in natural weathering. The great majority of materials will fail faster in Florida than anywhere else because the climate contains all of the major influencing parameters except pollution and in relatively high amounts (Fig. 16). The factors act together synergistically, each one increasing the effect of the other.

The high temperatures and humidity complement the photodegradation from solar radiation. The sun's energy is more potent as there is a greater relative proportion of UV to total energy. The time of total wetness is close to 50% of the total time, thereby ensuring a constant cycle of wetting and drying.

Desert

The desert of the Southwest United States (especially the Phoenix area) has also come to be regarded as a primary weathering testing site. Exposure conditions in the desert are very different than in Florida. The desert is widely used because the climate consists of clear skies and prolonged un-

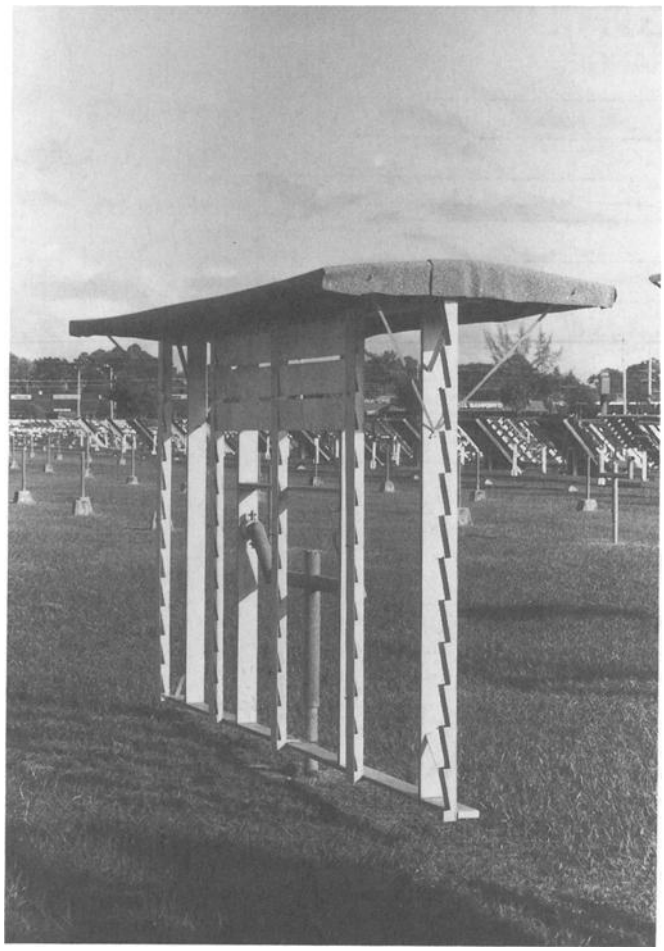

FIG. 15–Vertical exposure under roof.

interrupted solar radiation. High temperatures are produced on exposed materials, and there is a higher absolute dosage of solar UV than in Florida (Fig. 17).

For most materials, however, especially paints, the greater solar UV does not produce faster deterioration than in Florida. This is due to the lack of moisture in the exposure. Without moisture cycling, the effect of temperature and UV is much reduced. There is also no biodeterioration and no corrosion associated with desert exposure.

Extreme Cold

At the opposite end of the exposure scale from the desert is exposure testing in extreme cold weather. Low temperatures are accompanied typically by lower sunlight. International Falls, Minnesota is used as an exposure site for cold weather testing because this area frequently records the lowest temperature in the continental United States (Fig. 18). Cold weather exposure is used to test for specific failure types: cold cracking and freeze thaw deterioration. As the temperature passes through the freeze threshold, any water on the surface or in the bulk of the material forms into ice crystals. As the water freezes, its volume increases by approximately 10%, which is enough to create a substantial physical force on the paint film. This is the one environmental factor that cannot be examined during natural exposure testing in southern Florida.

Temperate with Pollution

Exposure in an industrial environment will indicate whether a paint is susceptible to atmospheric pollution. There are many sources of pollution emission into the atmosphere, and the method of administration to the paint is usually by washout during rainfall. In the United States the geographic area most affected by acid rain is the Northeast, with the next most severe area covering most of the rest of the East and the Midwest [*13*]. It is no coincidence that this is the industrial heart of the country.

The U.S. paint industry has long used Louisville, Kentucky as a typical temperate industrial exposure (Fig. 19). As a large paint manufacturing center, this area has become accepted as a location for exposure to acid rain. The temperature continental climate can be as severe as Florida, but only for a short period during the summer when the temperatures are high, humidity increases, and sunlight levels are similar to the subtropics.

Rainfall pH values below 4.5 have been recorded in some areas of Pennsylvania and New Jersey, as shown in Fig. 20. Paints and other exposed materials used in this area must be made to withstand this acid rain effect. This can be tested in Florida by artificially adding the acidic solution to the outdoor exposure test; however, outdoor exposures should be conducted in the actual polluted environment to best determine resistance.

Marine

Marine Atmosphere—Exposure to a marine atmosphere adds the corrosive influence of salt spray. Predominant test sites are located on the coasts of Florida, New Jersey, North Carolina, Texas, and California. The salt aerosols in the atmosphere settle on the exposed panel and work to enhance rusting. The closer to the surf, the greater the percentage of salt in the atmosphere. A marine atmosphere test combines the natural weathering of the site's climate with the additional natural corrosivity of the sea salt.

Marine Immersion—Exposure in seawater is used to test antifouling paints and rust-protective agents. Two exposure possibilities exist: floating immersion and fixed exposure. The floating rack positions the panels either completely or partially immersed; the level remains the same through each tide cycle. The fixed exposure in the tidal zone causes the panels to be alternately submerged and dry.

Climate Affects Exposure

Weathering deterioration is a function of the material's reaction to the influencing parameters. The two primary testing locations are both located in hot, sunny climates that produce accelerated deterioration compared to most of the rest of the United States. If different climates produce different exposure results, there is a possibility that exposure to only one set of conditions will not reveal the deterioration that may occur in another set [*14*].

Paint deterioration is determined by a number of mechanisms, each with its own threshold level for initiation. There is a level for each of the influencing factors at which the paint

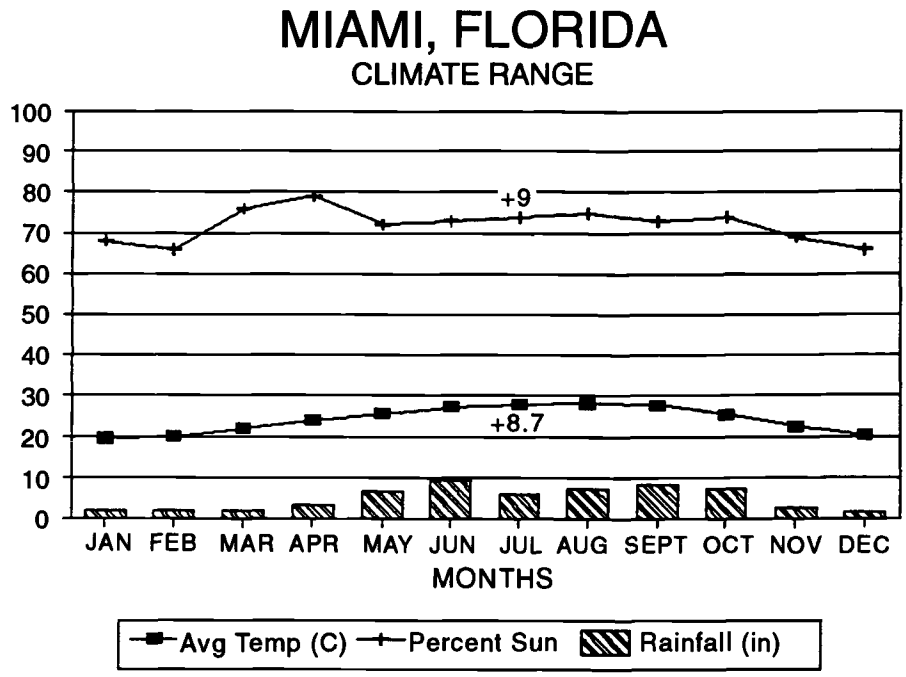

FIG. 16–Climate summary, subtropical (Miami, Florida).

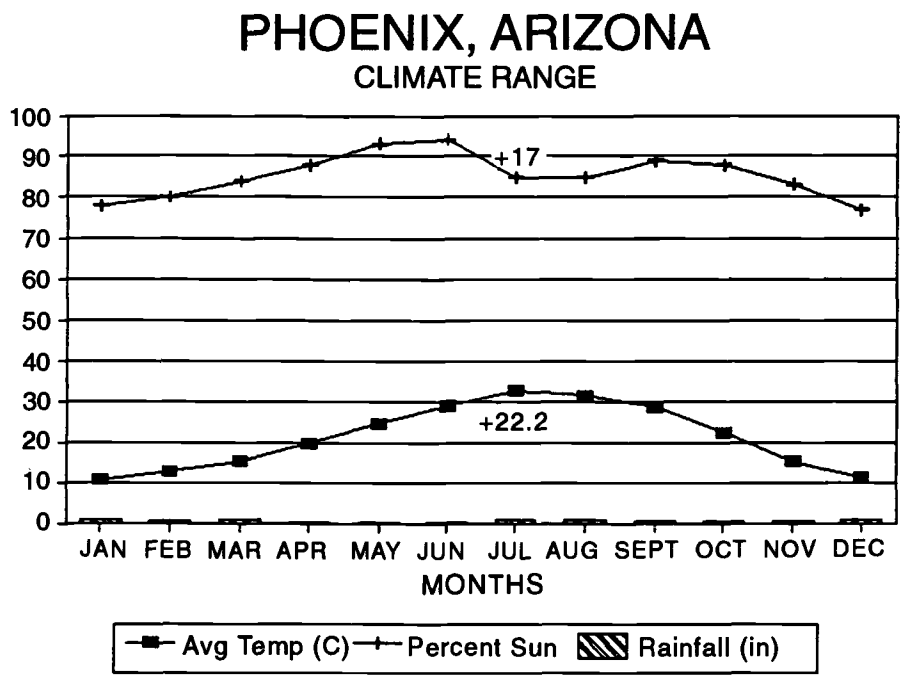

FIG. 17–Climate summary, desert (Phoenix, Arizona).

will become susceptible. When the factors interact, the overall influence is a complicated matrix that is constantly changing.

Degradation is the result of the material's response to its environment. When the environment changes, so do the changes that occur in the material. This does not always manifest as a slower or faster response, but also perhaps as a different one. Generally, however, it is practical to consider Florida as the most severe climate because it has all the influencing parameters in high abundance all year round. Other climates are missing one of the factors or are reduced in effectiveness due to the winter season.

Instrumentation

The atmospheric data required for weathering testing go above and beyond that given by the National Weather Service. The factors affecting material durability must be monitored to understand the cause and effect relationship between paint and the atmosphere. An exposure station weather re-

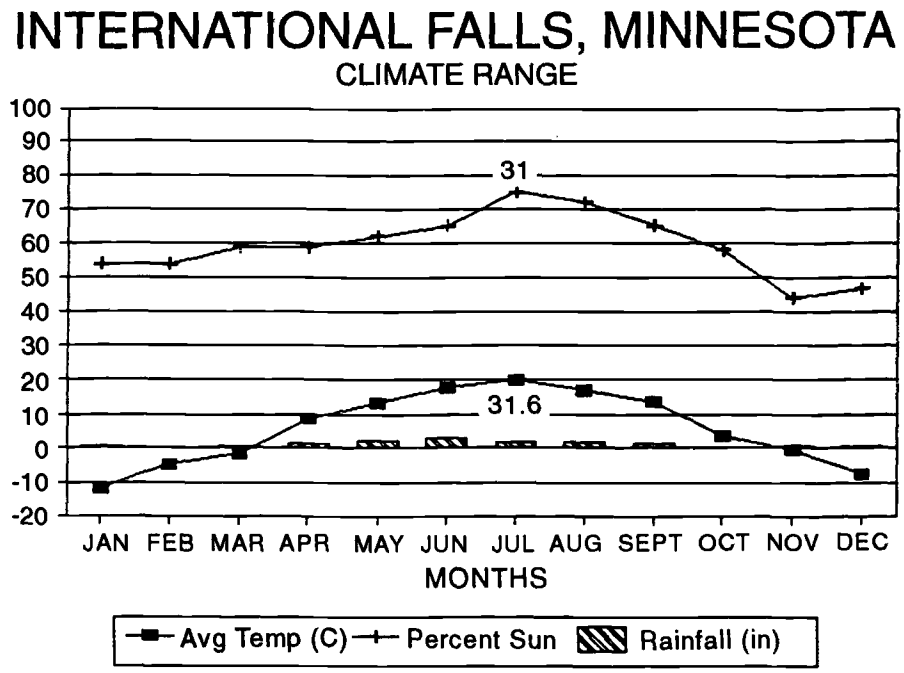

FIG. 18–Climate summary, extreme cold (International Falls, Minnesota).

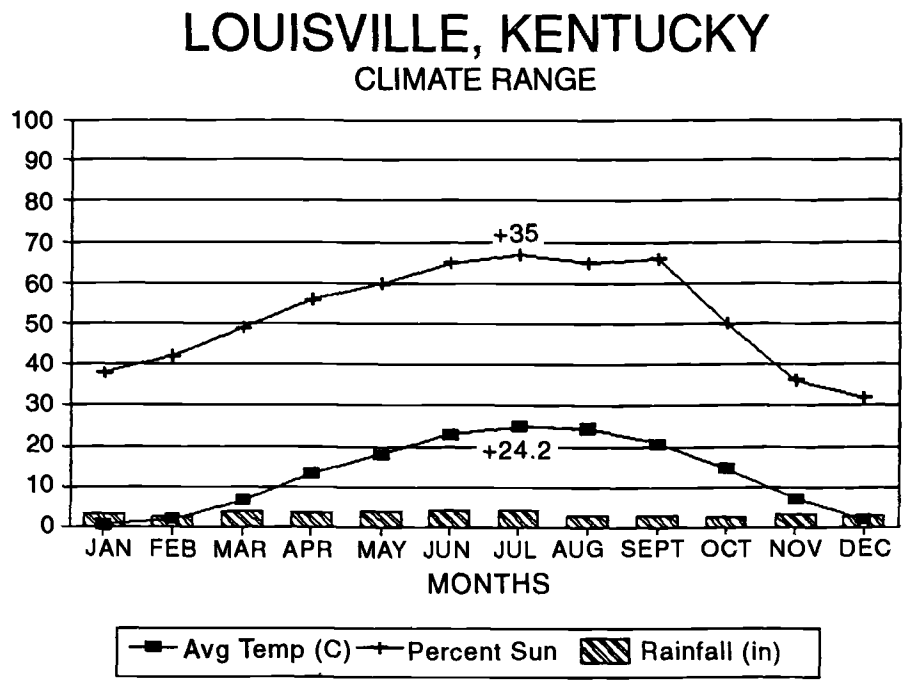

FIG. 19–Climate summary, temperate (Louisville, Kentucky).

port comprises information relevant to the exposed specimen.

The major additional items reported are the solar energy, black panel (or specimen) temperature, and total time of wetness. These are the most relevant atmospheric measurements concerning material exposure. Table 3 lists several parameters and equipment used to collect the information.

As discussed earlier, for weathering requirements, the total solar radiation is measured using a pyranometer, such as the Eppley Precision Spectral Pyranometer (PSP) (Fig. 21), which is sensitive in the range of 300 to 3000 nm. The ultraviolet is measured using a sensor that is sensitive in the range of 300 to 400 nm. The widely used Eppley Total UV Radiometer (TUVR) (Fig. 22) has a sensing range of 295 to 385 nm. These "total" sensors collect incoming radiation from all angles, having a 180° sensitive diffusion cover. This is termed *hemispherical radiation.* Total radiation measurements include both the direct beam from the sun and the diffuse energy from the atmosphere [*15*]. Direct beam radiation, excluding the diffuse sky, is measured with a pyrheliometer such as the

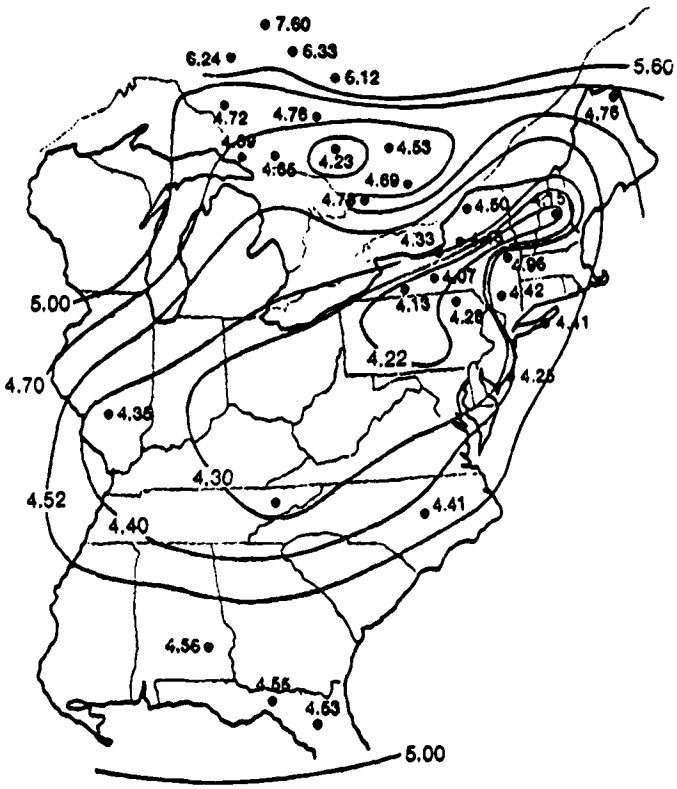

FIG. 20–Precipitation pH in northeastern United States.

TABLE 3—Weathering instruments and sensors.

Measured Parameter	Equipment Used
	Solar Energy
Total hemispherical	Pyranometer (hemispherical) PSP
Total ultraviolet	UV Radiometer (hemispherical) TUVR
Normal incidence	Pyrheliometer (6° solid angle) NIP

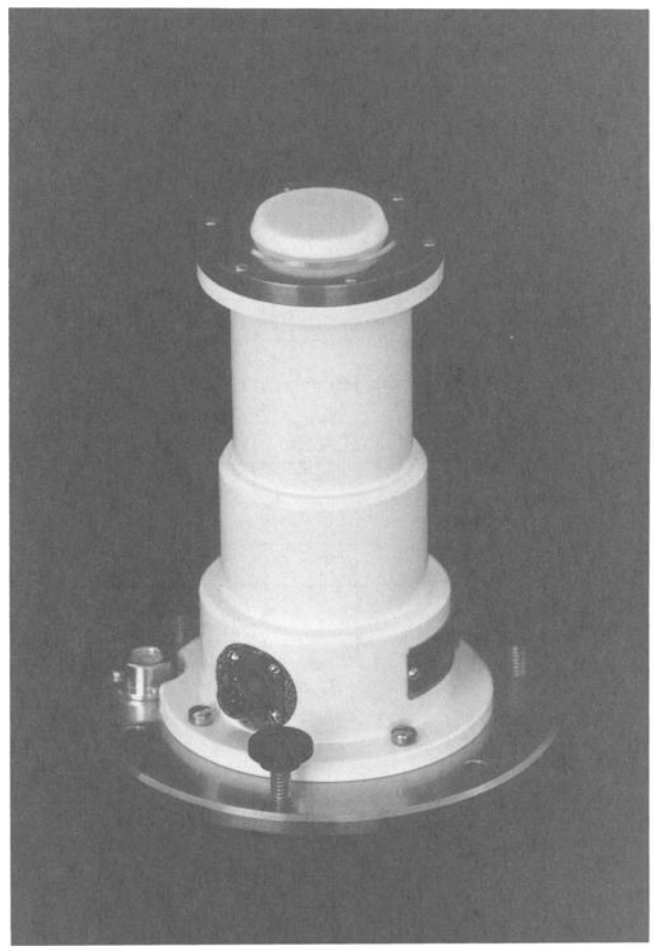

FIG. 22–Total ultraviolet radiometer (TUVR).

Eppley Normal Incidence Pyranometer (NIP). This has a 6° solid angle field of view and measures from 300 to 3000 nm. To work correctly, it must be mounted on a solar tracking device.

The intensity of the radiation is integrated with respect to time, thus allowing the amount of radiant exposure to be calculated. Values for radiant exposure are given in megajoules per square metre (MJ m^{-2}). This is the recom-

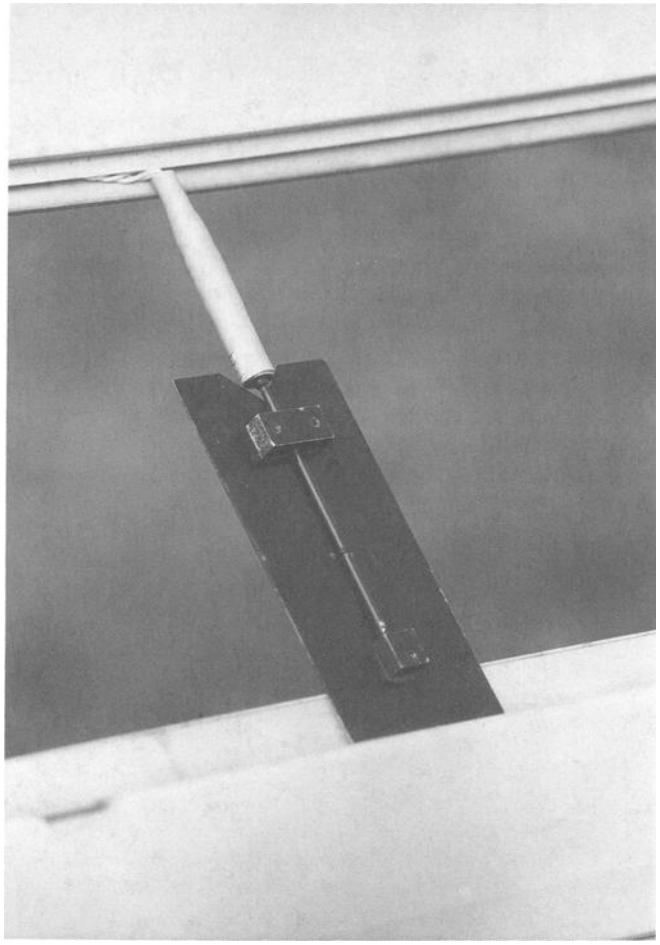

FIG. 23–Black panel thermometer.

mended SI unit; an older term used for these values is the langley, which is 1 calorie per square centimetre (1 cal cm^{-2}). To directly convert langleys to megajoules, multiply the langley amount by 0.041 84. This accounts for both the conversion from calories to joules and the change in unit area.

Black panel temperature is a measurement widely used in weathering exposures, both natural and accelerated. It is the surface temperature of a black-painted metal panel (Fig. 23) and is used to obtain a reference temperature for a paint panel exposed to a radiant energy source. Exposed materials absorb infrared energy from a light source, which causes their temperature to rise above that of the ambient air temperature. A black panel measurement is the expected maximum temperature a colored panel might achieve when exposed to a particular energy source since black absorbs all light energy. This temperature value is thus an indication of the actual exposure temperature, which is more relevant than air temperature. The black panel temperature will follow the light intensity output level of the sun.

Total time of wetness is the accumulated time an exposed paint panel has visible surface moisture [*16*]. The two sources for this are rainfall and condensation. Surface moisture can be measured by using a sensing element that requires water to complete an electrical circuit, thus operating a recording device. This will record the accumulated time for both rainfall and condensation; the time for rainfall can be removed to obtain the time due to condensation only. The sensor is described in more detail in ASTM Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing (G 84).

A rainfall duration sensor (Fig. 24) measures only the wetness time due to precipitation. The sensor is essentially the same as for total wetness measurement except that a constant heating element is incorporated so that any surface moisture will evaporate quickly, switching off the sensor very shortly after the rainfall has stopped. Keeping the tempera-

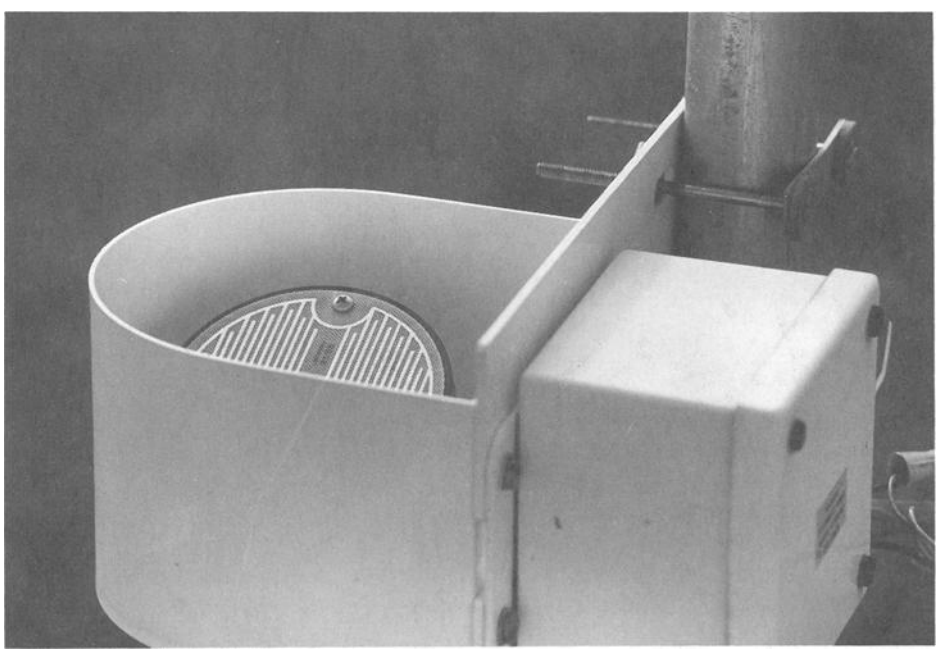

FIG. 24–Rainfall duration sensor.

ture of the sensor above the dew point will also prevent condensation from forming.

In addition to the specialized instruments detailed above, many more recognizable parameters must be measured. Ambient temperature and relative humidity can yield general information concerning the climate at the test site and the condition of the atmosphere surrounding the exposed specimen. These measurements are made following World Meteorological Organization (WMO) practices with mercury thermometers, psychrometers, or—more commonly—recording hygrothermographs in a WMO shelter (Fig. 25). Wind speed is a factor in the cooling of paint panels and is measured with an anemometer. A rain gage (Fig. 26) collects rainfall to determine the amount of precipitation. The rate of rainfall can be important; 25 mm in 30 min can be quite different from the effect of 5 mm in 2 h.

All of these data can be collected and displayed in such a manner as to characterize a weathering climate. If the influencing parameters are compared, it is possible to convey the severity of the weather with respect to the exposed materials (Fig. 27).

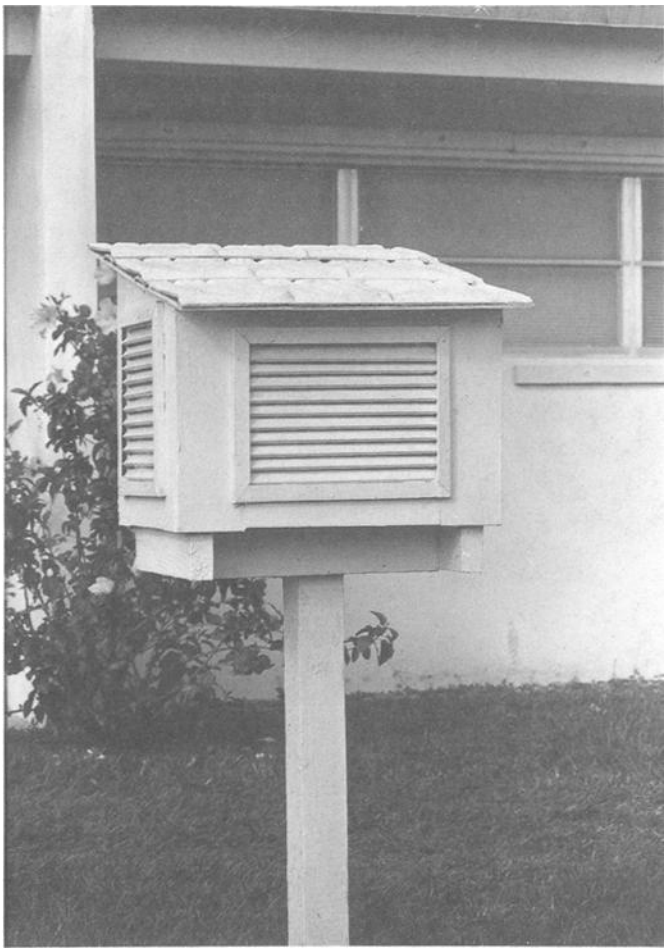

FIG. 25–WMO instrument house.

FIG. 26–Rain gage.

EXPOSURE TYPES

Exposure Frames

The most common type of exposure frame in use today is the aluminum rack designed for open (unbacked) exposures (Fig. 28). This type of rack and associated hardware should be constructed with noncorrodible material to prevent any contact corrosion effect with a specimen. Typical racks consist of a rectangular frame, adjustable hinged flaps with vinyl strips, and a clamping device to keep specimens securely fastened (Fig. 29). This type of exposure frame is very versatile in that it can be tilted to any specified angle or direction and can be adjusted to accommodate different-size specimens. Some advantages in using this type of frame are: (1) any size specimen can easily be mounted and removed, and (2) the hinged flap with vinyl strip can be adjusted to protect the top portion of the specimen so that any changes in appearance resulting from weathering can be detected.

Another type of exposure frame is known as the "black box" (Fig. 30). This insulated exposure is used mainly for recreating the conditions found on the flat surfaces of an automobile. It consists of an aluminum box painted black and open on top. Panels to be tested are placed over the open top side. If there are insufficient panels to cover the open area, black

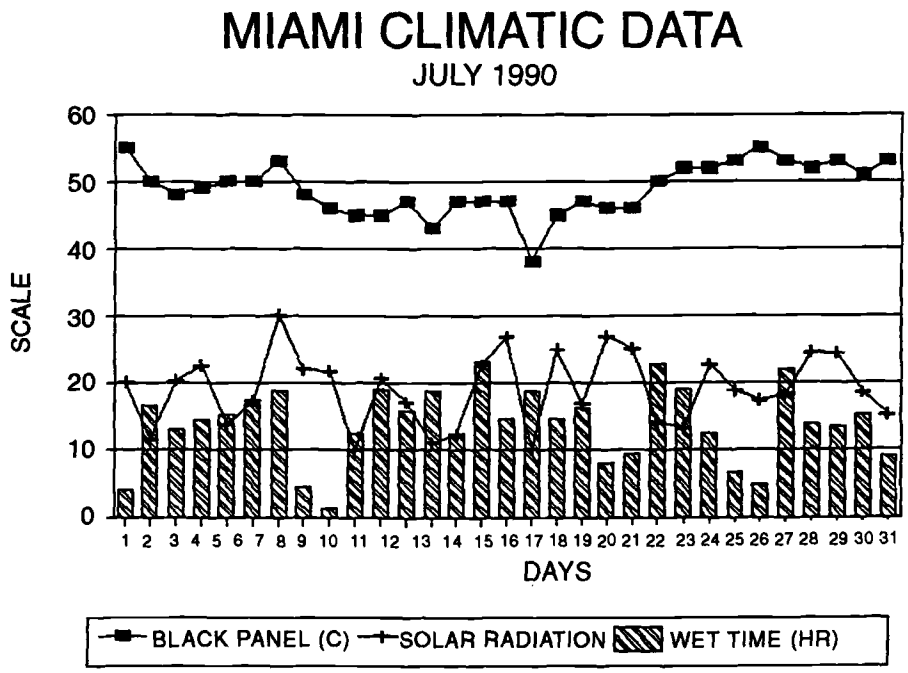

FIG. 27–Monthly weather summary, Miami, Florida.

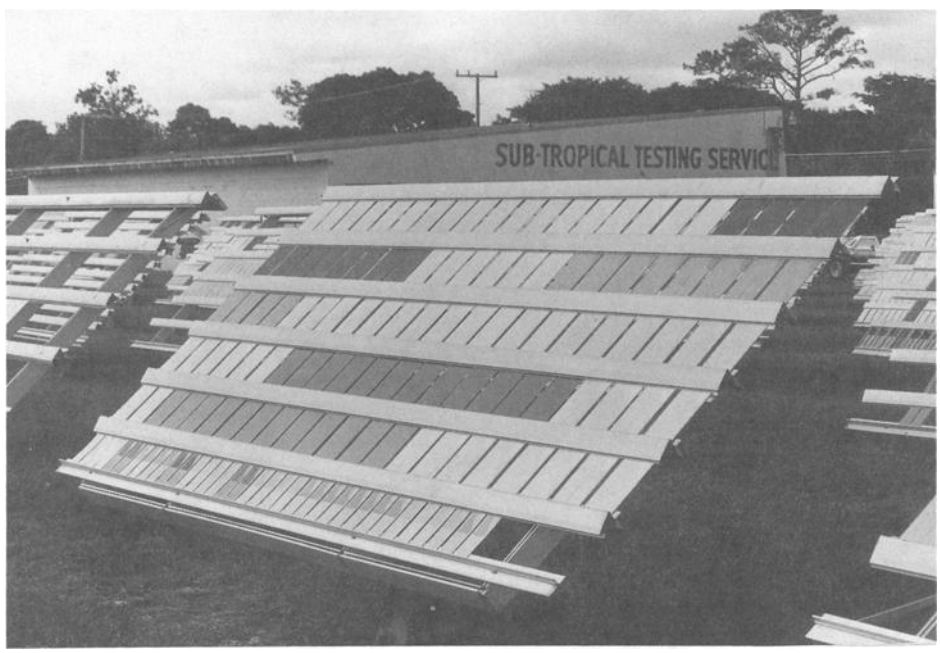

FIG. 28–Exposure rack with panels.

metal "dummy" panels must be used to completely cover the top side to maintain a high temperature during the daytime.

A third type of exposure frame in use but to a lesser degree is the solid wood rack. Like the black box, this frame also elevates sample temperature, but not to the degree of a black box. Generally, ¾-in. (19-mm) untreated plywood is used when constructing this type of rack. Depending on the condition to be simulated, the plywood can be left unpainted or painted black to further increase sample temperature. Using this type of frame is commonly referred to as "backed exposure."

Exposure Angles

The choice of exposure angle that a paint manufacturer uses for outdoor weathering is a critical decision. The angle of the specimens on exposure have a definite impact on the amount and type of degradation that can be generated. The exposure angle will affect the amount of solar radiation de-

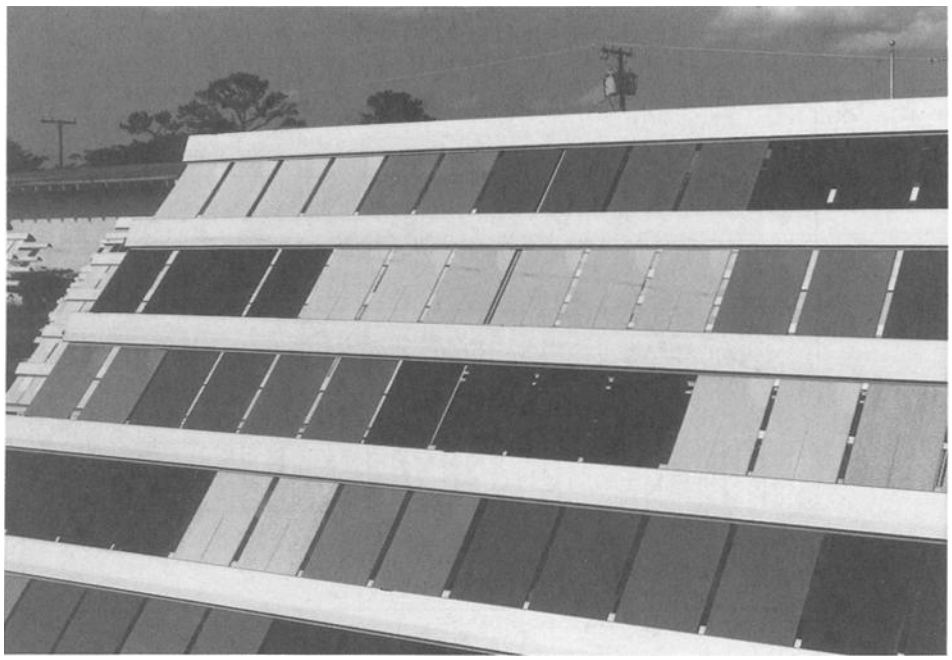

FIG. 29–Closeup of panels on exposure.

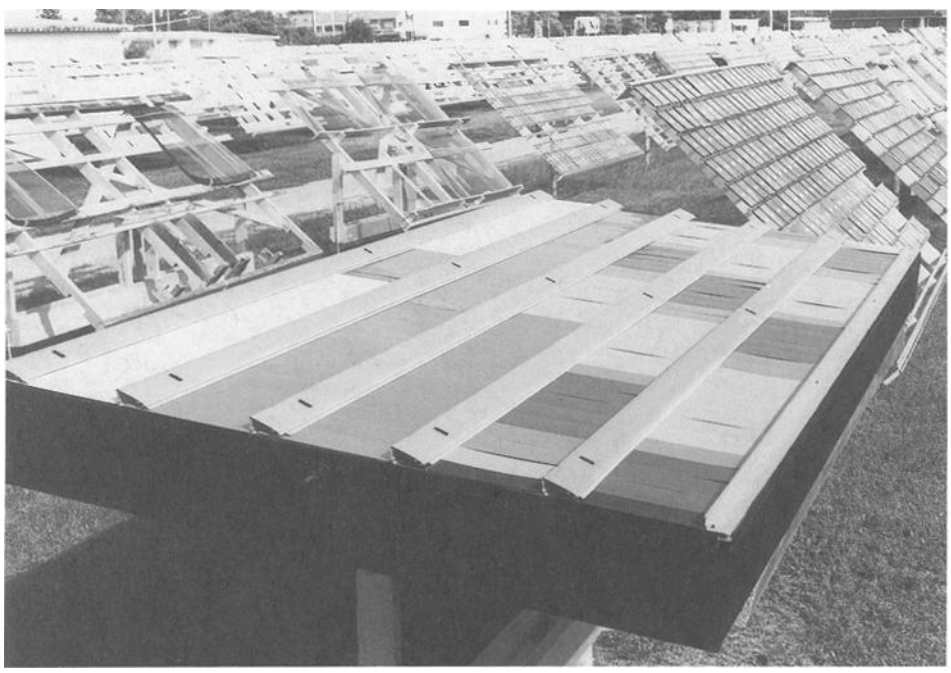

FIG. 30–Black box at 5° south.

posited on the sample, the amount of time the sample remains wet from rainfall or dew, and the temperature of the sample (Table 4). To generate meaningful test results, it is important to expose specimens at an angle similar to end use.

The basic angles of exposure that are used most commonly are as follows:

1. *45 Degrees South*—Specimens are exposed at an angle of 45° from horizontal and facing the equator (see Fig. 28). This is the most common angle used for architectural house paints and industrial coatings. This angle is also

TABLE 4—Panel exposure temperatures.

	Temperature, C			
	Maximum		Minimum	
Exposure Type	White	Black	White	Black
Open back, 45°	45	60	20	18
Solid back, 45°	50	70	19	17
Open back, 5°	48	67	20	18
Solid back, 5°	52	73	19	17
Black box, 5°	55	76	17	15
Ambient air	(32)		(20)	

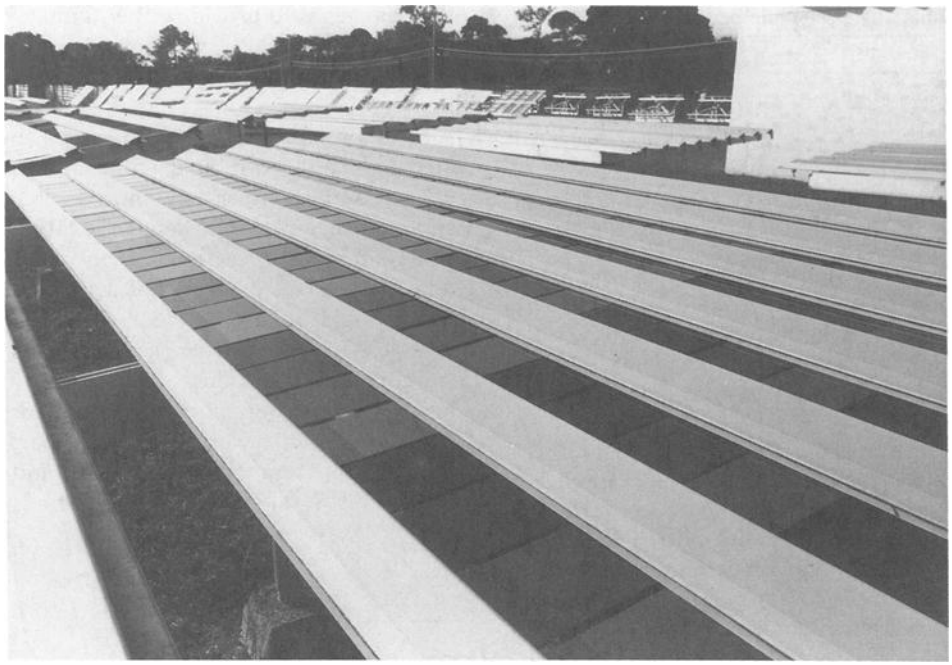

FIG. 31–Panels on exposure at 5°.

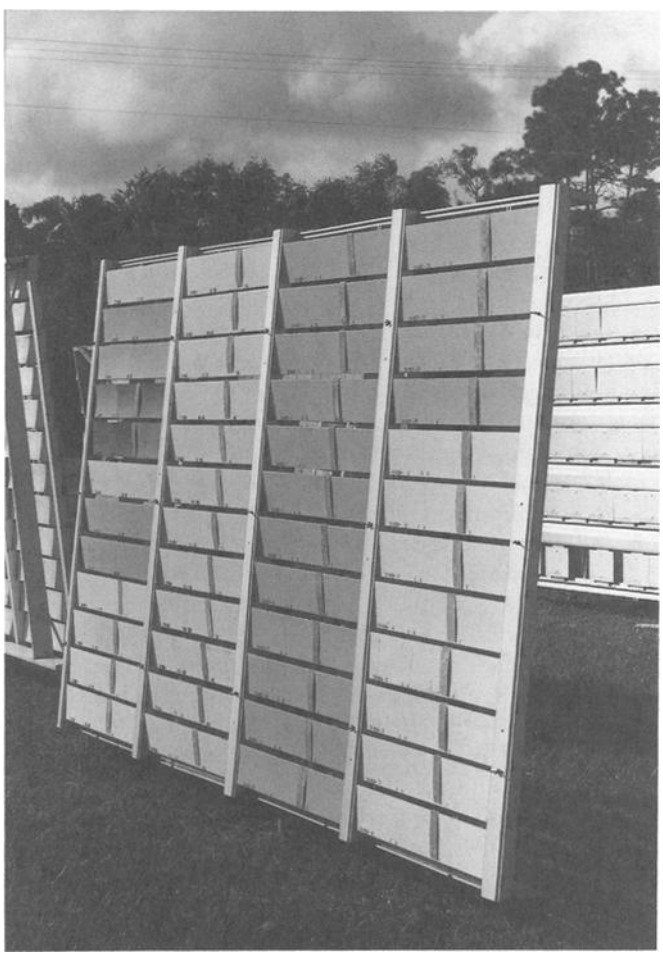

FIG. 32–Wood siding panels on exposure at 90°.

used as a compromise when end use position is unknown or variable.

2. *5 Degrees South*—Specimens are exposed at an angle of 5° from horizontal and facing the equator (Fig. 31). This angle is preferred over horizontal to avoid water ponding on the sample. When exposing in a subtropical environment, the 5° angle will increase the yearly amount of solar radiation, especially during the summer, and also the total time of wetness when compared to 45° south. This angle is also used for black box testing and for automotive finishes.
3. *90-Degree Racks*—Specimens are exposed at a right angle to the ground (Fig. 32). Exposure racks can be facing north or south depending on the end use of the coating. Generally, when testing for mildew resistance, architectural paints are exposed vertically (90°) north to maximize moisture retention.
4. *Station Latitude*—Exposure frames are tilted so that the specimens are exposed at an angle from horizontal equal to the geographic latitude of the exposure station. For the two benchmark weathering locations, Miami, Florida is at 26° latitude and Phoenix, Arizona is at 34° latitude.
5. *Variable Angle*—The angle of exposure of the specimens is changed on a seasonal basis to ensure maximum solar radiant exposure. For the Miami, Florida weathering location, the schedule calls for 5° exposure in the summer, 45° exposure in the winter, and 26° in the months of the equinox (see Table 5 for angle schedule).

Orientation

Standard exposure is for the specimen to face the equator. In the Northern Hemisphere this means that south is the predominant direction for the exposure of specimens. This is the most severe direction as it enables the sun to shine directly on the specimens for a greater portion of the day. Exposures in any other direction would only be used if any

TABLE 5—Variable angle schedule per ASTM E 782.

Month	Tilt Angle
March	Latitude angle
April–August	Latitude angle − 20°
September	Latitude angle
October–February	Latitude angle + 20°

NOTE: Latitude angle = tilt angle equal to the latitude at the exposure location.

other factor of influence was concentrated so heavily in a different direction that it took precedence over the solar influence. This may be the case where marine atmosphere exposures are used and the sample faces the shoreline rather than south.

The major exception to the south exposures is found with the testing of paints for residential use. Paint applied to wooden sidings is extremely susceptible to the effect of mildew attack, especially on the shaded side of the house, which is predominately more conducive to fungus growth. A vertical (90°) north exposure is common for painted wooden sidings. However, at times, equal mildew growth on replicate specimens has been observed by the author on vertical (90°) south exposures.

Mounting

There are several different methods for mounting specimens onto a test frame. The type of backing chosen depends more or less on the material being tested and the end use application. Generally, since most paints are applied to a wood, aluminum, or steel substrate, mounting of specimens is done on an open-backed rack. However, if a somewhat accelerated test is necessary or a specimen must be tested to a particular standard, then mounting specimens in a black box might be necessary. A different mounting technique would apply to residential siding material. In this case, mounting against a wooden backing would more closely simulate end use conditions.

Another important criterion that can have an effect on the outcome of an exposure test is the location and surrounding obstructions in the immediate area of the test site. In accordance with ASTM Practice for Atmospheric Environmental Exposure Testing of Nonmetallic Materials (G 7), the test rack is to be placed in a location so that no shadow from a neighboring obstruction shall fall on any specimen when the sun's angle of elevation is greater than 20°. Also according to ASTM G 7, the area beneath and in the vicinity of the weathering racks should be characterized by low reflectance and by ground cover typical of that climatological area. In desert areas this will be gravel, whereas in most temperate areas the ground cover will be low-cut grass.

ACCELERATED NATURAL WEATHERING

The possibility of deriving an accelerated test from outdoor exposure seems like a misnomer. There are, however, many test methods that aim to do just that. The basic idea is very simple: to artificially increase the severity of the outdoor exposure to boost degradation rates. The secondary aim of the changes is to provide either a more realistic exposure or to produce faster deterioration without the loss of any agreement in test results compared to the actual end use environment [*14*].

Outdoor exposure in Miami can be considered an accelerated test in its own right if the intended comparison is to exposure in a temperate or northern climate. All the necessary parameters are present in greater amounts. The corollary is simple: increase the severity of the influencing parameters and the rate or degree of deterioration will increase.

A straightforward outdoor test involves positioning the sample on a frame where the elements of the weather can work together to produce the deterioration. To accelerate the overall weathering process, one or more of the influencing parameters can be increased. The parameters that can be increased are temperature, wetness, and solar radiation, and there are several standard test methods designed to do just that.

Black Box

The first parameter normally modified when there is a need for acceleration is the test for specimen temperature because it is the easiest to control. There will be an increase in the rate of the forward degradation reaction as the thermal load is increased.

The simplest way to increase the temperature is to position the specimen on a solid backing of dark color with a high insulation factor (R). This method is widely used for residential sidings, roofing materials, and others. A comparison of the temperatures of black and white panels on various exposure frames on one summer day in Florida is shown in Table 4.

The black box exposure is used to test automotive finishes, and its specific purpose is to increase the temperature of the test panels to the same as the nearly horizontal surfaces of a car. This test method is described in ASTM Practice for Conducting Accelerated Outdoor Exposure Tests of Coatings (D 4141). Committee D01.27 on Accelerated Testing of Paints has conducted several studies regarding the black box [*17*], which was originally developed by General Motors. The box is made of aluminum, painted black, with the paint panels forming the top surface. The black box exposure also serves to lower the panel temperature overnight below that of the surrounding air, creating a longer condensation period.

The conditions as they affect the paint panels are a good simulation of the actual end use condition, so this test may be considered by some not as an accelerated test but as one that is realistic of the end use for that climate. If the definition of an accelerated outdoor test is one where the influencing conditions are altered over the open-backed direct weathering test, the Black Box Test is indeed an accelerated test.

A further acceleration is introduced using the Heated Black Box Test. This is a black box incorporating heating elements inside the air space. The air temperature inside the box is maintained at an artificially high level even when there is no incident solar energy.

Salt Spray

In Florida, corrosion tests are accentuated by spraying with salt water in the Scab Test. This uses the natural effects of the weather to break down the coating, then increases the corrosion at a scribe mark.

The paint panels are exposed to direct weathering at either 45 or 5° and are sprayed at regular intervals (normally twice weekly) with a 5% sodium chloride solution (Fig. 33). The spray is scheduled for times when the paint panel will be dry, thus maximizing the absorption effect.

This test has proven to be an excellent method for determining the corrosion resistance of automotive coatings. The advantage is that the results are very similar to the results of actual car corrosion determined from field studies. The simultaneous effect of sunlight and saltwater produces an overall deterioration effect rather than a single failure mode as is usually given by salt fog tests such as ASTM Test Method of Salt Spray (Fog) Testing (B 117).

Spray Rack

The stresses due to moisture vapor content into and out of the specimen are important for the overall breakdown of most materials. Moisture vapor acts as a catalyst in the photochemical breakdown process. In Arizona's desert environment with high temperature and solar radiation, exposure tests are accelerated using the spray rack, which wets the specimens on a regular basis during the day and overnight. The result produces an effect similar to Florida exposure, plus a slight speedup in the deterioration rate. This rate of increase has been seen as ranging from one to two times the rate for direct weathering in Florida.

The exposure is conducted as a solid-backed direct weathering, with the specimens sprayed daily on a regular basis during the night and/or day with distilled or deionized water. The day-time spray is normally of very short duration, intended as a harsh thermal and moisture shock to the paint surface. The nighttime spray cycles are of longer duration, intended to soak the paint thoroughly in a simulation of the overnight condensation effect. This occurs naturally very rarely in the desert of Arizona.

Both of these accelerated outdoor tests recognize the importance that wetness plays in deterioration. One important note here is that the timing of the water application is vital to produce the correct type of failure.

Follow the Sun

Increasing the level of solar radiation for an outdoor test can be done in two ways. The exposure frame can be designed to track the sun across the sky so that the specimens remain at normal incidence, which will yield greater radiant exposure. The limit for this test method is that the intensity level cannot exceed 1 Sun. A simpler method simply adjusts the tilt angle of the rack in response to the height of the sun in the sky. This "variable angle" exposure uses the schedule outlined in ASTM Practice for Exposure of Cover Materials for Solar Collectors to Natural Weathering Under Conditions Simulating Operational Mode (E 782), which is summarized in Table 5 and is based on the latitude of the exposure. The effect is to increase the solar radiation dosages up to 10% over the fixed latitude angle rack.

Fresnel Reflector Concentration

An equatorial mount using an array of mirrors to reflect sunlight back onto an exposure frame will greatly increase the incident solar enegy (Fig. 34). This is the Fresnel Reflector Concentrated Sunlight device, as specified in ASTM Practice for Performing Accelerated Outdoor Weathering of Nonme-

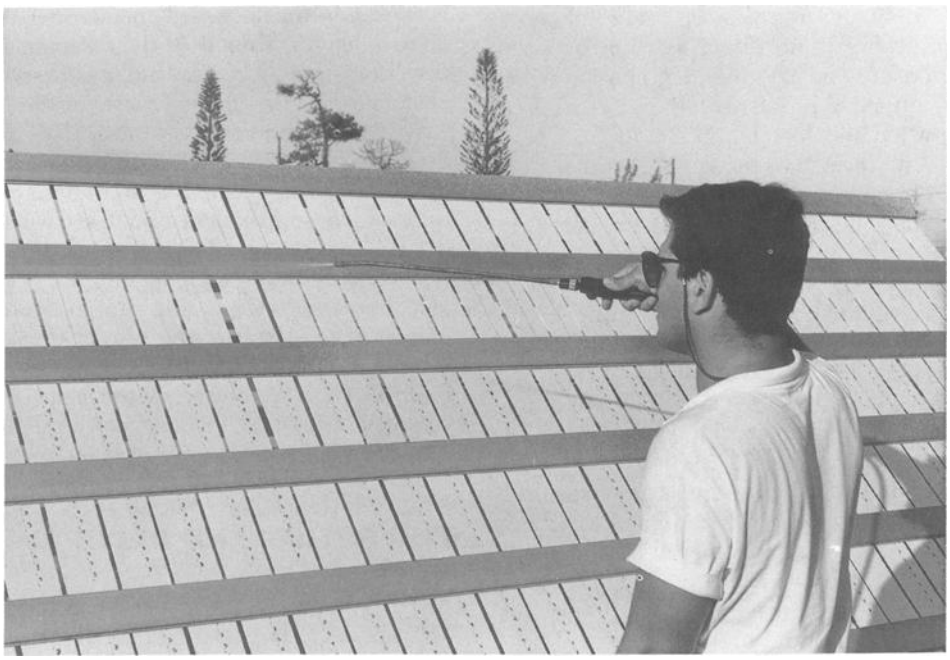

FIG. 33–Salt spray testing (Scab Test) in Florida.

FIG. 34—Fresnel reflector concentration device.

tallic Materials Using Concentrated Natural Sunlight (G 90) and when used for testing coatings per ASTM D 4141. This type of exposure is more closely related to that produced by another accelerated device, the xenon arc, than to outdoor test methods. The concentration is a factor of one for each mirror (less the efficiency of the reflector, which is about 80%), so in effect the solar irradiance on the specimen is about eight times the normal incidence tracking frame. The high intensity of the light exposure causes the sample temperature to rise also; if a water spray cycle is added, all weathering factors are increased.

The high intensity of the solar energy on the paint causes deterioration rates of 4 to 16 times the rate for non-accelerated exposure. There is no direct relation between amount of radiant exposure and extent of degradation when the irradiance level is altered. Caution must therefore be used when quoting acceleration and correlation factors from testing on this machine. With the sun as the energy source, most of the problem of matching light sources is removed. This can occur when using some laboratory-accelerated weathering devices.

The paint panels are mounted on a target board that is positioned upside down on the bottom of the air tunnel. The mirrors are arranged in a Fresnel array, whose focal point is the target board. The panels are cooled by forced air from the air tunnel, which is directed across the front and back of the panel. A set of nozzles is positioned so that water spray may be directed onto the face of the panels.

The device works optimally when there is unobstructed direct beam radiation as the machine is designed to follow the sun and reflects only the incoming energy from a small solid angle. It is important, therefore, for the machine to be aligned with the sun at all times during the day. Clouds will disrupt the optimum condition, and overcast days will prevent the Fresnel Concentrator from operating at its most efficient. As a result, the machine is normally employed in the desert, where clear skies and strong sunlight are found almost every day. It would be incorrect, however, to say that this device will not work correctly out of the desert environment; the time for accumulation of energy, however, would be greater.

The test duration for the Fresnel Concentration is determined by solar radiant exposure, normally the total ultraviolet. As the energy levels at the target board are too high for direct measurements on a permanent basis, the dosage must be calculated from direct measurements using a correction factor for the reflectance of the mirrors. The mirror material is chosen for its flat reflectance properties, thereby reflecting all wavelengths equally. If the reflectance value of the mirror material is monitored closely, it is possible to make accurate calculation of the intensity level at the specimen position.

When the irradiance is integrated, dosage levels for the Fresnel Concentration Device are eight times greater than normal incidence. One year of radiant exposure from a fixed rack can be reached in about six weeks exposure on this device.

The common thread to all outdoor accelerated (or accelerated outdoor) tests is that one or more factors have been increased to speed up the rate of the deterioration. This is usually intended to give the test a more realistic comparison to an intended end-use environment. The exception to this would be tests that increase solar intensity above naturally found levels.

INSPECTION AND REPORTING

Visual

Interim inspections of a material to chart the degradation progression throughout an exposure period will produce im-

portant information on the rate at which a sample degrades and at what time interval certain properties become noticeable. To accomplish this, visual or instrumental techniques are used to assess the severity of degradation.

When visual inspections are performed at periodic intervals, a number of variables are introduced that make it difficult to get consistent and repeatable assessments. To minimize these variables, inspection procedures must be standardized. When viewing specimens for color change or for weathering effects, it is very important to use the same light source and viewing conditions. For this reason, evaluations are conducted according to ASTM Practice for Visual Evaluation of Color Differences of Opaque Materials (D 1729). In this test method, spectral qualities are outlined for different light sources, which are to be used for various evaluations. A viewing booth will allow the most consistent readings over an extended period of time as opposed to examining changes outdoors where daylight is not always the same.

Reporting Scales

When evaluating the ability of a coating to withstand weathering effects, the changes over a period of time must be charted. To do this with consistency, reporting scales are employed to record the amount of change. In many instances it is not practical for the person most interested in the durability of a coating to see how a particular coating performs over a period of time. This is quite often the case as specimens are exposed in a different country or region of the United States in order to achieve answers in a shorter period of time. This makes it necessary to leave the inspection process up to another individual. A problem is the fact that no two people perceive a degree of change in exactly the same way. In order to minimize this problem, certain procedures are followed so that all interested parties will "see" the defect(s) the same way. This is done by using generally accepted examination procedures and the use of photographic reference standards.

The American Society for Testing and Materials (ASTM), the Federation of Societies for Coatings Technology (FSCT), and the International Standards Organization (ISO) each have examination procedures similar in quantitative descriptions. The main difference lies in the quantitative and qualitative numbering scales used. FSCT uses a scale from 10 to 0, with 10 being "perfect" or "absent of failures." ISO uses a scale from 0 to 10, with 0 representing an "unchanged" condition. Independent test labs in the United States use the ASTM/FSCT scale in their ratings unless instructed otherwise by their client. It should be noted that "perfect" is not a preferred term, and the testing labs will use the term "as received."

Failure Modes

Evaluating and recording type and degree of failure modes in a particular coating is not a difficult task if visual inspections are performed properly. Although most ratings are subjective in terms of degree of failure, an experienced and well-trained inspector consistent in his or her ratings is able to portray a good image of any degradation present. In order to do this, all relevant standards including the FSCT pictorial standards must be used when applicable. Table 6 lists the more commonly used evaluation standards for paint failure reporting. More complete descriptions of these effects can be found in other chapters of this manual.

TABLE 6—List of surface appearance standards.

Property	ASTM Method
Color change (v)	ASTM D 1729

D of I (i)	ASTM E 413

NOTE: (v) = visual; (i) = instrumental; (p) = pictorial.

Nondestructive

Nondestructive testing is aimed at inspection without the disturbance of the integrity of the specimen. This will, by the above definition, include mostly all the visual evaluations and all the instrumentally assisted optical measurements. True nondestructive testing, however, is aimed at investigating defects that cannot be seen easily with the eyes or surface scanning equipment.

Nondestructive tests aim to determine physical changes in the structure of a material that cannot be determined visually. It is particularly useful in seeing changes at the molecular level, in the bulk part of the material, or in underlying layers.

Many of the common physical tests employed to assist in evaluating the effect of weathering are in fact "destructive." The paint sample is disturbed during the measurement process, as in testing adhesion or chalking. When a destructive test is used, several disadvantages are evident: the specimen cannot continue exposure because the place where the test was conducted will affect the continuity, and a permanent record of the condition at that time is lost. These problems can be overcome by using a large number of replicates so that there will be enough virgin material for testing.

When the same sample can be studied throughout the test, it may be easier to get a much clearer picture of the sequence of events of the progression of failure mechanism. This is especially true at the earliest sign of changes in the material. If it is possible to determine the changes that occur at the molecular level during the initial stages of deterioration and follow the progression through to failure, it is possible to develop models which will assist in predicting long-term durability from short-term testing.

The range of methods included in nondestructive testing is varied, and Table 7 lists those which have been demonstrated to have an application in weathering.

Mechanical Properties

There is a major distinction that must be made between surface appearance changes in a material and intrinsic physical properties. Changes can occur on the surface without affecting the bulk of the material.

A major portion of a complete weathering program is the measurement of the physical changes produced during exposure. A result of UV degradation and associated failure modes can have a direct impact on the relationship between stress and strain of a coating and the elastic and inelastic reaction when force is applied. To have a better understanding of the true performance of a weathered specimen, it is necessary to perform tests to determine certain mechanical properties. Table 8 lists the more commonly performed mechanical tests on weathered paint panels. A more complete description of their relevance is given in other chapters of this manual.

Accelerated Weathering

by Valerie D. Sherbondy[1]

PAINTS AND COATINGS ARE USED both to protect substrates and to provide an aesthetically pleasing appearance. In an outdoor environment, both of these functions can be affected by weathering. The four major factors involved in weathering are sunlight, moisture, oxygen, and heat. Light, especially in the ultraviolet (UV) region, may lead to discoloration, premature loss of gloss, scaling, embrittlement, and chalking. Moisture may cause blistering, flaking, mildew, and early loss of adhesion. Heat may cause embrittlement, cracking, peeling, and checking. Oxygen in the atmosphere promotes oxidation of the surface of the coating, which may eventually lead to oxidation of internal layers, causing embrittlement, softening, cracking, or crazing. These elements contribute individually as well as in combination to cause coating failures.

Naturally occurring and man-made chemicals in the environment also contribute to coating degradation and could be considered a fifth element of weathering. However, the type and levels of chemicals can vary dramatically, even over short distances. Therefore, they cannot be considered as universal in character as the four factors mentioned previously. Perhaps as a consequence of this, and also partly due to tradition, chemical resistance testing is usually considered to be separate from artificial weathering. Therefore, this chapter will consider only those devices that incorporate an ultraviolet light source. Although the effects of chemicals cannot be ignored, they are discussed elsewhere in the manual.

Accelerated or artificial weathering involves the use of laboratory equipment to simulate the degradation that occurs during actual outdoor exposure [*1–3*]. Accelerated weathering is the term most often applied to artificial weathering because the elements of light, heat, and moisture are either longer in duration or more intense than the actual time and conditions encountered in outdoor exposure. This causes the coating to weather or degrade more rapidly, in a time sense, than when placed in a natural environment. However, in an attempt to accelerate the effects of natural weathering, the laboratory conditions may be overly aggressive and thus cause results that are not attained during natural weathering.

Artificial weathering devices should be designed to produce test conditions that are controllable and reproducible, so that data are reproducible on a day-to-day basis and comparable on a laboratory-to-laboratory basis. This differs from outdoor or natural weathering where there are no controls over environmental factors. Due to this variability of conditions, the results of natural weathering often are not reproducible. For example, weathering factors are different for various parts of the world and for different countries. Some locations receive more sunlight and heat, while others are cloudy and cool. There are also seasonal variations. Even for long-term testing, the data for a specimen placed outside during January would not necessarily concur with data for a duplicate specimen placed outside in July because of initial exposure effects. Even if the same location and time of year are used, the natural weathering factors change from year to year. In contrast to natural weathering, data produced under controlled laboratory conditions can be used as comparative data, assuming the same equipment, equally aged lamps, etc., even if testing was conducted during different times of the year or over several years.

In addition to reproducibility, a great advantage of accelerated weathering is that the results are available more quickly than with natural weathering, which is a phenomenon that may take years. The time saved on testing can translate into cost savings when developing new products or when choosing a new coating system for buildings, tanks, or equipment where historic data about coating performance are not available.

Even though there are many advantages to accelerated weathering, it is important to recognize that these data should be used for comparative purposes only since at this time a direct correlation to natural weathering has not been proven for any weathering device currently being used. One reason a correlation has not been developed is because data obtained through artificial weathering have been produced by subjecting the sample to unnatural conditions, and the results may or may not duplicate those found during natural weathering. If similar failure modes are experienced in an accelerated weathering device and at an outdoor test site, a direct correlation may be developed for that product. The calculated correlation would be valid only for the tested material under the stated, specific conditions, and the actual field conditions usually differ from the conditions found in a test fence area.

It should be noted that not all results obtained by accelerated weathering devices are reproducible [*3*]. Studies have concluded that even though the settings may be the same, the maintenance of the device—including light source, filters, and gauges—affect the exposure levels and thus the results of the testing. The cleaning and disposal of light filters is often subjective and a major source of variation that changes the amount of light at critical wavelengths. The intensity of the light is also dependent on the changing of, rotation of, and power supplied to the light source. These factors may speed

[1]Assistant laboratory director, KTA-Tator, Inc., 115 Technology Drive, Pittsburgh, PA 15275.

Copyright© 1995 by ASTM International

up or slow down the degradation process due to changes in both temperature and UV light exposure. Since this is known to occur, testing specifications are sometimes written to include a standard material with the test specimens or to include an actual measurement of the light during the testing. This measurement is discussed later in this chapter.

Even if the light source was not changing with time, each device has areas of more intense exposure. For this reason, most devices have recommended manual rotation procedures for the exposed specimens. These procedures should be performed at regularly spaced intervals to decrease the effects of uneven exposure. These effects would be greater on short-term tests, where the specimens would not be moved through the different stages.

Aside from the conditions of the device, the conditions surrounding the device also affect performance. Most devices require a ventilated area to maintain ambient conditions so temperature changes within the device can be maintained or obtained. For example, a relatively high ambient temperature may reduce the amount of condensation on some devices, while high amounts of ventilation may slow the temperature recovery after a water spray in other devices. It should be noted that ambient conditions are not specified by ASTM standards, although the manufacturers recommend general guidelines. Ambient conditions will vary between laboratories, adding an unknown variable that may affect the results.

ELEMENTS OF WEATHERING

There are many component factors that contribute to the weathering of a coating. The general components are light, moisture, heat, and oxygen, which are always present in various amounts. This section concentrates on these general components and on how they are simulated and intensified.

Light [4]

Sunlight is composed of light from the visible, ultraviolet, and infrared regions of the electromagnetic spectrum (Fig. 1). The damaging region of sunlight has been determined to be the ultraviolet light (UV) region, especially the shorter wavelengths ranging down to 295 nm. The portion of sunlight in the UV region is relatively small, only 5 to 7%, due to the filtering effects of the atmosphere. The UV region has been divided into three domains: UV-A, UV-B, and UV-C. The UV-A region is 315 to 400 nm, the UV-B region is 280 to 315 nm, and the UV-C region is 200 to 280 nm. Although the UV-C is the most damaging region, these wavelengths are filtered out by the atmosphere. Therefore, if light sources produced output in this region, they would cause abnormal degradation and their use should be avoided when performing accelerated weathering unless there is a possibility of UV-C exposure.

Both the UV-A and the UV-B regions cause degradation of coatings. The energy of the shorter wavelengths present in the UV-B region, ~91 to 102 kcal/mol (3.8 to 4.3 J/mol), cause more severe and rapid degradation of coatings than the wavelengths in the UV-A region. In the UV-B region, the energy levels are high enough to break carbon-nitrogen, carbon-carbon, nitrogen-hydrogen, carbon-oxygen, and carbon-hydrogen bonds in the polymeric portion of the coating. In the UV-A region, the longer wavelengths do not have sufficient energy, ~71 to 91 kcal/mol (3.0 to 3.8 J/mol), to break certain bonds, namely carbon-hydrogen. Thus, it is apparent that UV-A radiation differs from UV-B radiation in both wavelength and severity of damage.

The breaking of chemical bonds first leads to a degradation of the coating surface layers and is manifested by chalking, fading, and loss of gloss. Once the outer layers of polymer are lost, pigments are exposed. Without the protective polymeric binder, the pigments can fade and erode, causing a change in color and/or appearance.

Light has been simulated in accelerated weathering devices by mercury arcs, open and enclosed carbon arcs, fluorescent lamps, and reflection of collected sunlight. However, as the results produced by accelerated testing were compared to the results obtained from natural weathering, the light sources were modified to attempt to achieve similar results. Depending on the exact coating type and the service environment, several different specifications have been developed that indicate which light source should be used. Most of these test specifications require the use of open or "sunshine" carbon arcs, xenon arcs, and fluorescent lamps. These light sources were chosen since they were found to more closely simulate the degrading ultraviolet light range of sunlight or to rapidly produce dramatic changes in the coating.

Enclosed Carbon Arc

Originally, these lamps were used to test the light fastness of textiles. They were then combined with a water spray to be an industry-wide artificial testing device. Although mercury and carbon arcs have been in use for over 75 years, when they were used to test paint, it was discovered that they produce light that accelerates chalking and fading more than crack-

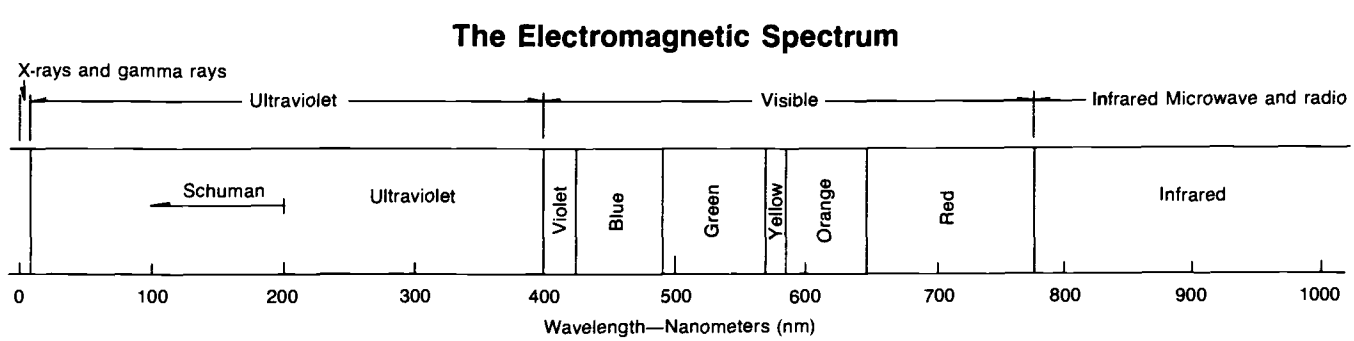

FIG. 1–The electromagnetic spectrum.

ing. The carbon arc consists of neutral solid and cored carbon electrodes. The flame portion of the lamp is enclosed in a borosilicate globe. The globe creates a semisealed atmosphere that sustains the arc and filters out UV light below 275 nm. The lamps produce two large spectral peaks that center near 350 and 380 nm, but they deliver essentially no emission below 340 nm, where the light is more severe in its degradation capabilities and more damaging to polymeric materials (Fig. 2). In addition, even the light in the visible region, 400 to 800 nm, was also low compared to sunlight, meaning that any visible color change due to the change of the pigment would require a lengthy exposure. As a result, the industry demanded a light source that provided a better simulation of natural sunlight, especially since more durable materials were being developed.

Open-Flame Carbon Arc

In response to industry demands, the open flame carbon arc or sunshine carbon arc was developed. This descendent of the carbon arc produced a spectrum closer to that of sunlight. The lamp operates in a free flow of air instead of in a globe. The lamp is composed of copper-coated electrodes and a central core of rare earth. The lamp is surrounded by a stainless-steel filter frame that also acts as an air duct. The frame holds flat, optical, heat-resistant, borosilicate glass panels that filter portions of the lower wavelength light from the spectrum. The spectrum produced by this light source is more similar to that of sunlight in the region between 310 and 370 nm (Fig. 3). However, there was still a spectral imbalance due to a large band between 370 and 450 nm, but the region between 450 and 800 nm was much closer to natural sunlight than the enclosed carbon arc lamp shown in Fig. 3. The disadvantage of this light source is the emission between 260 and 310 nm, which includes a portion of the undesirable UV-C region. Although this light source was an improvement, the industry requested the spectral distribution of the light be even closer to that of sunlight.

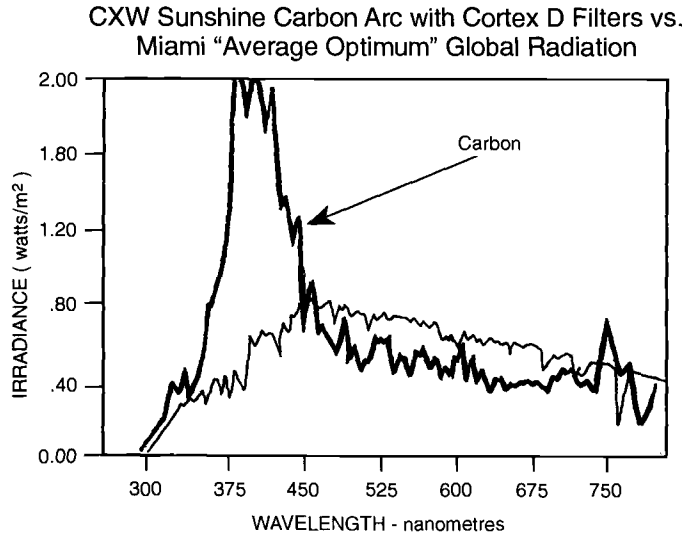

FIG. 3–Spectrum of light produced by a sunshine carbon arc. Used with permission of the Atlas Electric Devices Co.

Xenon Arc

The adoption of the xenon arc lamp for accelerated weathering devices was the next improvement in artificial weathering equipment. The xenon lamp consists of a burner tube and a light filter system. There are two types of xenon arc lamps. One type of xenon arc lamp is cooled by water circulated through the lamp housing. The cooling water also filters out the long-wavelength infrared light. The other type of xenon lamp is air cooled. Both lamp types produce a spectrum closer to sunlight when filtered and set at the correct irradiance setting. There are several filters and combinations of filters that can be used. The three common filter combinations used for artificial weathering of paint are quartz/borosilicate, borosilicate/borosilicate, and quartz/quartz. The first combination allows the UV region to extend down to 270 nm (Fig. 4). The borosilicate/borosilicate combination has a cutoff at 280 nm, which makes the spectrum closer to that of

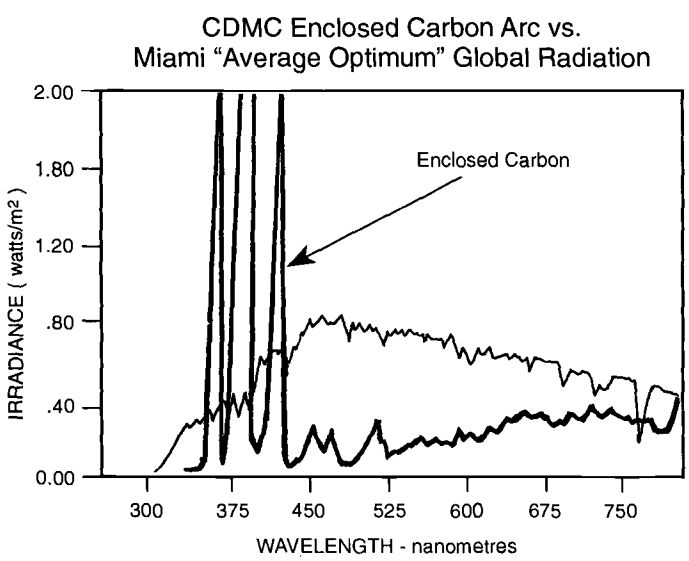

FIG. 2–Spectrum of light produced by an enclosed carbon arc. Used with permission of the Atlas Electric Devices Co.

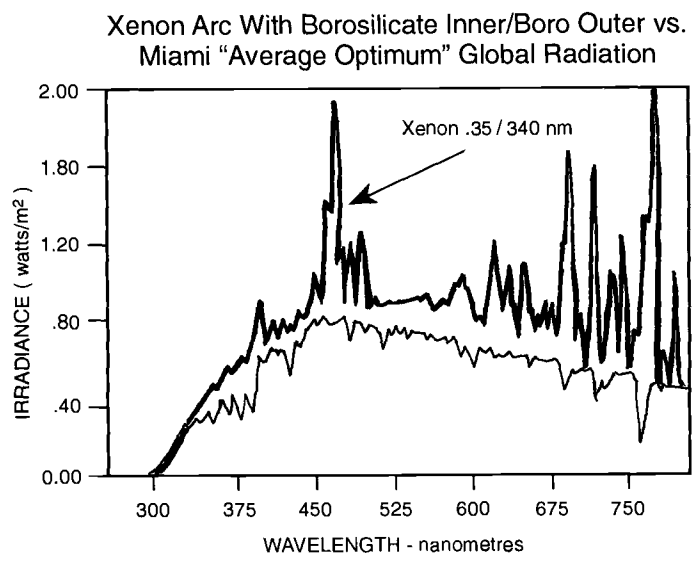

FIG. 4–Spectrum of light produced by a xenon arc. Used with permission of the Atlas Electric Devices Co.

natural sunlight, which cuts off at 295 nm. The quartz/quartz combination produces a spectrum that extends to below 250 nm, i.e., into the undesirable UV-C region, and although used to test coatings, it is the least popular of the three filter combinations.

Since the xenon arc source decays as the lamp ages, the irradiance of the light source should be monitored and can be controlled by adjusting the lamp wattage. Most new devices have a monitoring system to compensate for the decay. The most common settings are 0.35 or 0.55 W/m^2 at 340 nm. Both settings produce a spectrum with approximately the same cutoff wavelength (determined by the filter). The settings are both within the range of natural sunlight. The 0.55 W/m^2 setting is closer to summer sunlight, while the 0.35 W/m^2 setting is closer to winter sunlight. If the wattage settings are varied, the degradation rate will change.

Fluorescent UV Lamps [5,6]

The most recent development in light sources is the fluorescent UV lamp. These lamps were not developed to simulate the entire spectral range of natural sunlight. Rather, they simulate only the damaging UV region found in sunlight. Currently there are three types of fluorescent UV bulbs. The FS-40 and UVB-313 produce light with a maximum output at 313 nm (Fig. 5). The UVB-313 has a higher intensity and thus a greater weathering acceleration rate than the FS-40. The UVB-313 also has a higher, more stable output than the FS-40. Both of these lamps have outputs down to 275 nm, which is below the cutoff of natural sunlight. The third type of fluorescent lamp is the UVA-340 lamp that produces a spectrum very similar to that of natural sunlight (Fig. 6). The spectrum is made up of wavelengths in the UV-A region with a small amount of the UV-B region wavelengths. The cutoff matches that of natural sunlight. Although the results produced by the UVA-340 lamp are closer to that of sunlight, the UVB lamp is the most widely used fluorescent light source

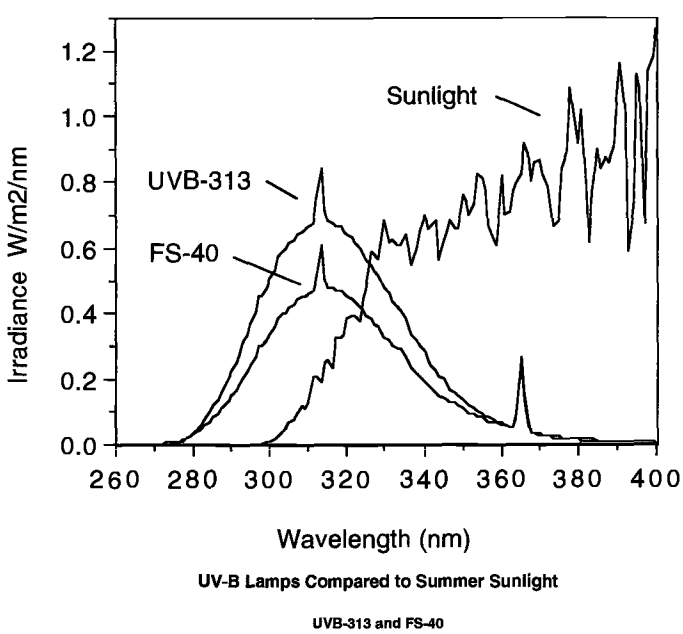

FIG. 5–UV-B lamps versus summer sunlight. Used with permission of the Q-panel Co.

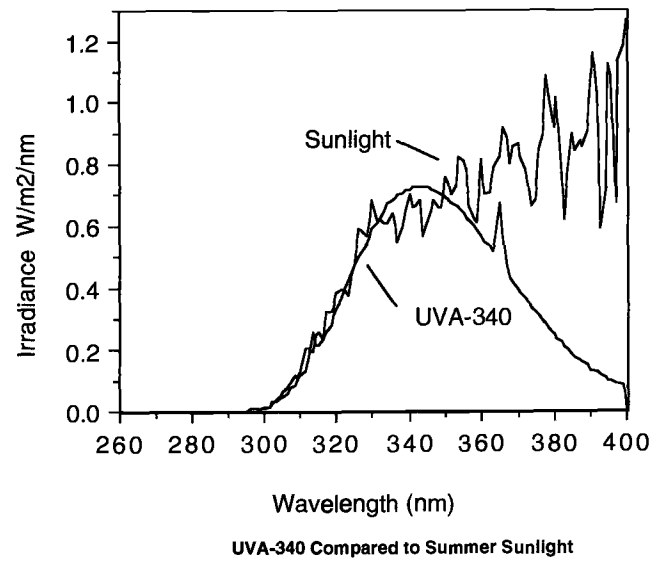

FIG. 6–UV-A 340 lamps versus summer sunlight. Used with permission of the Q-panel Co.

because of the rate at which degradation takes place. Since the cutoff of the UVA-340 lamp is higher, the degradation process takes a longer period of time than with the UVB-313 lamp, but may more closely match the degradation seen in the field. Both lamps are commonly used in the paint industry, and the choice of UVA or UVB lamp depends on the need for either speed or accuracy.

Lamp Stability

Once a light source has been selected, it is assumed that several tests run over a period of months or years can be used to evaluate the relative performance of the paints. However, this assumption is not always true. The xenon-arc source is currently the only device that always is sold with the irradiance measurement as an operating parameter and not just as an option. Even with this control, the output of the light source may vary depending on the care and maintenance of the device. The devices should be cleaned and changed as recommended to ensure the most reproducible and even spectral distribution and irradiance. The newer devices have the option of monitoring and adjusting the light output for all of the different light sources. In the future, these settings may become a required part of the report for the testing results.

There are several monitoring instruments available to measure the light output including pyranometers, radiometers, spectroradiometer, and light-sensitive materials. However, each of these devices may be used to measure different characteristics of light. Two different-colored light sources could produce the same response if a pyranometer is used to measure the light. These devices measure the amount of radiant power regardless of the spectral distribution. Even when filtered to restrict the wavelength of light being measured, it was found that the response was not sufficiently sensitive for the UV range.

Radiometers have been modified with filters to select areas of the spectral distribution. These are classified as wide band, broad band, or narrow band. The wide-band instruments

measure the light output over a range of several hundred nanometers. Broad-band instruments function over a range of 20 to 100 nm, while narrow-band instruments measure less than 20 nm. The most commercially successful radiometer measured the total ultraviolet light using a wide-band UV filter. However, when these devices were used to measure natural sunlight in comparison to the light sources, it was found that sensitivity to shorter wavelength UV was less than its peak sensitivity to visible light, which could be affected by temperature changes.

The currently used radiometer, developed for exterior monitoring, has a narrow band filter and a thermoelectrically cooled detector. This is suited for long-term use and is easily operated in the field by relatively inexperienced personnel.

For internal use and for the most accurate measurements, spectroradiometers are available. These would not withstand external use and normally require operation by skilled personnel.

In contrast to actual light measurements, there are industries, other than the paint industry, that rely on the use of light-sensitive reference materials. The reference material is placed on the cabinet at the same time as the test samples and monitored, usually for color changes, to evaluate the effectiveness of the light source. These materials must be inherently unstable to achieve the desired result. This instability should be considered when choosing a reference material. The reaction of some materials may vary widely, and the sensitivity is often a result of the total environment, so all of the other factors of exposure must remain constant. One of the major problems with using this technique in the paint industry is the short life of these materials relative to the more durable paint systems.

Even with all of the variability of light sources, proper care of the instrument can yield consistent results between laboratories. Most of these instruments have been run for many years with less monitoring and fewer quality-control procedures than are in use today, and the data have been acceptable over many years. This is due to the fact that most companies understand that the test results can only be used relative to other test results and to that end often include several competitive materials in the test protocol.

Moisture

Another important characteristic of weathering is moisture. Moisture is commonly overlooked as a significant factor of paint degradation because it is a common belief that structures are only wet when it rains, when they are splashed, and when they are immersed in fluids. Actual time-of-wetness studies have shown that samples placed outside in several different locations in the United States and Canada were wet approximately 30% of the time [7]. This averages to approximately 8 h per day. The water in a natural environment is caused by dew or condensation, rain, or melting snow or ice. The water may be absorbed or pass through the coating. If the liquid passes through and interacts or reacts with a water-soluble material, an osmotic cell may be formed. If it passes through the coating and reacts with the substrate, for example wood, the interfacial bond between coating and substrate may be destroyed or weakened.

The theory behind cyclic moisture exposure is based on the permeation of the test liquid into the coating, which may cause certain coatings to swell. During the drying cycle, reverse permeation or evaporation will occur, causing the coating to shrink, resulting in cyclic stressing of the system. The process by which degradation takes place and how fast it will occur is influenced by the permeability of the coating and the contact time required to initiate water penetration. The rate of water and chemical degradation is increased by increased temperature and ultraviolet light.

Moisture can be simulated by water spray, condensation, fog, or immersion. Depending on the device used, degradation acceleration is possible by increasing the number of wet/dry cycles or increasing the time of exposure. Since accelerated weathering devices run around the clock (and day after day for that matter), it is possible to cycle the specimen through several wet and dry periods and still meet or exceed the 8 h of average wetness found in natural weathering. Another way to accelerate the damage caused by moisture is to increase the time period of exposure to moisture. Prolonged exposure may degrade coating just as much as the stresses caused by wet/dry cycling.

Temperature

The third factor of weathering is heat or temperature. The degradation of coatings occurs more rapidly at elevated temperatures, and temperature variation can lead to expansion and contraction stresses in the coating. These stresses may be magnified by the expansion and contraction of the substrate itself, which can lead to cracking, peeling, checking, or loss of adhesion. Temperature can also accelerate the effects of other weathering factors such as light and moisture. In accelerated weathering, cyclic testing at only slightly elevated temperatures can produce accelerated results. The temperature chosen for testing should be within the expected temperature range of the service environment. Drastic increases in temperature are not necessary to produce noticeable effects and in fact should be avoided. Testing at excessive temperatures can either cause premature or unreasonable failures or even enhanced performance that would not be realized under actual use conditions. High temperatures may cause the coating to bake or cure excessively and cause it to become brittle with decreased impact resistance, or it may become more resistant to the environment than would occur if it were only air dried under ambient conditions. To prevent these occurrences, temperatures near those of actual or expected exposure should be used. The temperature should be monitored so the data have meaning relative to other test results.

Oxygen

Changing the degree of oxygen exposure of specimens by introduction of ozone or pure oxygen is possible with a few testing devices, but this modification technique is not commonly practiced. Oxygen exposure is usually inadvertently changed in artificial weathering devices. The condensation, fog, immersion, or water spray used to create moisture can introduce oxygen to the test environment and the surface of the panels. Even in natural weathering, oxidation of a coating surface usually occurs in the presence of moisture.

Oxidation involves breaking bonds within a cured coating. Either primary or secondary bonds may be affected by oxidation. Since the oxidation process is different for different chemical types (acrylic, epoxide, vinyl, etc.) of coatings, the results of oxidation can range from embrittlement to softening along with crazing, cracking, or discoloration. Oxidation usually begins as a surface phenomenon that breaks down the outer polymeric binder layers. Water can then pass through the film to the inner layers and cause further breakdown (often at an accelerated pace) of binder and additives.

Other Factors

Although light, heat, moisture, and oxygen play important roles in the deterioration process, it should be recognized that there are other factors that affect coating stability. Weather resistance is dependent on the curing or drying process, the substrate being painted, and application methods. These conditions cannot be fully simulated under controlled laboratory conditions since, as with natural weathering, these conditions are seldom the same.

In actual service, most coatings experience environmental factors that often continually change, are not reproducible, or are unforeseeable at the time of application. Examples are acid rain or other transient environmental pollutants. Chemical exposure, particularly in the vicinity of chemical plants or other heavy industrial environments, can also contribute to degradation. Testing for chemical resistance is discussed elsewhere in the manual.

ACCELERATED WEATHERING DEVICES

Carbon Arc and Xenon Arc

Carbon arc and xenon arc lamp devices are used to expose specimens to UV radiation, elevated temperature, and water spray. Carbon arc apparatus principles and operating procedures are given in ASTM Practice for Operating Light-Exposure Apparatus (Carbon Arc Type) With and Without Water for Exposure of Nonmetallic Materials (G 23), and the test conditions for paint and coatings are outlined in Practice for Conducting Tests on Paint and Related Coatings and Materials using Filtered Open-Frame Carbon-Arc Light and Water Exposure Apparatus (D 822). The basic principles and operating procedures for xenon arc devices are found in ASTM Practice for Operating Light-Exposure Apparatus (Xenon-Arc Type) With and Without Water for Exposure of Nonmetallic Materials (G 26).

There are several devices manufactured by several companies that use either carbon arc or xenon arc light sources. The basic apparatus is outfitted with one or two carbon arcs or a single xenon arc (Fig. 7). The specimen rack varies in diameter with the diameter dependent on the number or type of lamps used since different rack sizes are used to accommodate the change in irradiance from the different light sources. Samples should be mounted on the rack at a distance such that the location of each sample assures that incident irradiance does not vary by more than 5% from the average. The units usually have automatic temperature controls and may or may not have automatic humidity control. The drum

FIG. 7—Xenon arc weathering device used with permission of A.E.D. Co.

or specimen rack rotates at 1.0 rpm for both the carbon arc and water-cooled xenon arc, and at 2.0, 3.7, or 5.2 rpm for the air-cooled xenon arc to ensure uniform radiation on all samples. Water is sprayed onto the specimens as a fine mist. Exposure to light and to darkness is alternated, and the water spray is intermittent. A blower in the base of the apparatus provides a flow of air through the chamber and over the specimens. The airflow controls the temperature of the samples and removes carbon combustion products. The specimens are mounted vertically on racks above and below the center line of the radiation source. During testing, specimens should be exposed equally from the upper and lower racks.

The light source for these devices should be chosen by the chemical nature of the material to be tested since the spectra of the various light sources are different and produce different weathering results. For both the carbon arc- and the xenon arc-based devices, it is very important to monitor the levels of irradiance at a selected wavelength if the data are to be used for comparison purposes. This is required because there is a progressive decrease in radiation intensity as the lamp ages. This can be overcome by progressively increasing the lamp wattage, thereby minimizing the changes in intensity, and by monitoring the radiation output as described in ASTM G 26. The newer devices monitor and automatically adjust the wattage to keep the intensity constant.

Both carbon arc and xenon arc procedures include four test methods:

1. Continuous exposure to light and intermittent exposure to water spray.
2. Alternate exposure to light and darkness and intermittent exposure to water spray.
3. Continuous exposure to light without water spray.

4. Alternate exposure to light and darkness without water spray.

A typical cycle used for evaluating coatings with these devices is 102 min of light at 145 ± 5°F (63 ± 3°C) and 18 min of light and water spray at 60 to 63 ± 2.5°F (15.5 to 17 ± 1.5°C).

Fluorescent UV/Condensation

With fluorescent UV bulb devices as described in ASTM Practice for Operating Light- and Water-Exposure Apparatus (Fluorescent UV-Condensation Type) for Exposure of Nonmetallic Materials (G 53), specimens are cycled between exposure to UV light and condensation in a heated environment (Fig. 8).

The light source for the QUV [*8*] and UV-CON [*9*] is composed of eight fluorescent lamps that produce light in the ultraviolet range. The light source may be any of the UV fluorescent bulbs produced. The particular bulb used will determine the nature and speed of results acquired. The exterior of the specimen rack is exposed to room temperature, and the inside is exposed to heat and humidity produced by the lights and a heated water bath. The condensation is caused by the temperature differential that exists between the front and back of the mounted specimens. The exposure can be varied by changing the temperature, the length of the light, and/or the condensation segments of the cycle. A few models are also available with a spray option. The spray option can be used to simulate thermal shock or erosion by water.

The samples are mounted in brackets, which form the cabinet wall. The panels are stationary and set at an angle so condensate can run off the test surface and be replaced by fresh condensate in a continuous manner. Vents along the bottom of the chamber permit an exchange of ambient air and water vapor to prevent oxygen depletion of the condensate. The specimens are placed approximately 50 mm from the lamps. Both the lamps and the panels should be manually rotated at specified intervals to ensure even UV exposure. To maintain consistent irradiance, the fluorescent lamps are

FIG. 8—Fluorescent bulb/cyclic condensation. Used with permission of the Q-panel Co.

rotated after a specified number of hours with two of the eight being replaced. By rotating the lamps and replacing only 25% of the light source at any one time, an almost constant level of exposure is ensured.

Various test cycles can be selected. If no conditions are specified, ASTM G 53 suggests 4 h of UV light at 60°C and 4 h of dark condensation at 50°C. Test temperatures of 50, 60, and 70°C are widely used.

Fluorescent UV-Salt Fog

The Mebon Prohesion Cabinet [*10*] was originally developed as an alternative to the standard salt fog cabinet, ASTM Test Method of Salt Spray (Fog) Testing (B 117) for conducting corrosion resistance studies (Fig. 9). Recently it has been suggested for use as an accelerated weathering device when used in conjunction with a fluorescent UV condensation device [*11*].

The Prohesion Cabinet introduces a spray or fog by means of an external reservoir and a peristaltic pump operating at a flow rate of from 0.5 to 1.5 mL/h. Although a variety of solutions can be used, one consisting of 0.4% ammonium sulfate and 0.05% sodium chloride (Harrison's solution) is recommended for corrosion studies. A series of experiments with this device indicated that, at least for corrosion rate studies, this solution provided more realistic results than the warm, 5% sodium chloride solution used in salt fog cabinets [*12–14*]. The conclusion that these test results were more realistic was based on an analysis of the corrosion products. This analysis revealed that the amount of sulfur and chlorine salts on panels exposed to the particular salt solution was similar to the amount and type found on the panels that had been corroded at an outdoor location.

The fog, introduced at ambient temperature, is eliminated by forcing air through the device at 23 to 55°C. Not only does this assist in drying the panels, it also replenishes the oxygen. The wet-dry cycles can be varied from 1 to 10 h. Since the cabinet is not outfitted with a light source, it is necessary to manually move the panels from the Prohesion Cabinet to a fluorescent UV/condensation device to incorporate the element of light into the test.

UV Light-Cyclic Immersion

A proposed ASTM method entitled "Standard Practice for Conducting Cyclic Immersion/Atmospheric Exposure Tests" is currently being developed. Its intended use is for the cyclic testing of specimens, either manually or automatically, through an atmospheric environment and an immersion environment. The atmospheric environment may consist of light, heat, air, and/or chemical gases or fumes. The immersion portion of the cycle varies and is dependent on the construction material used to make the individual devices. In addition, the liquid may be heated, cooled, oxygenated, and/or filtered.

Cyclic exposure alternates wetting and drying of the samples in combination with UV light. The immersion portion of the cycle allows permeation of the test liquid into the coating. This imbibing of the test liquid may cause swelling of certain coatings and substrates that would not occur during a salt fog or condensation cycle. During the drying cycle, reverse permeation or evaporation may occur, causing the coating to shrink and cause cyclic stressing/straining of the system. Reactions during the immersion portion of the cycle are influenced by the permeability of the coating and require time to initiate. The rate of water/chemical degradation is increased by increased temperature. However, long, hot exposures may cause abnormal degradation. The atmospheric exposure after immersion may cause concentration of salts and chemicals on the surface, further increasing the rate of degradation. Care should be taken to select exposure media that approximate those expected during intended service.

FIG. 9—Mebon prohesion cabinet. Used with permission from Q-panel.

The proposed standard currently lists four different devices that meet the requirements. Description of three of the devices follows.

The first device, the Envirotest [*15*], is commonly constructed of stainless steel, but a model constructed of polyethylene is available (Fig. 10). The chamber contains a center axle with spokes for sample mounting. The lower half of the test chamber contains the immersion solution. Four fluorescent bulbs with a heating element are contained in the upper half of the chamber. The type fluorescent bulb, UVB-313, UVA-340, or FS-40, should be chosen by the nature of the specimens to be tested. The distance of the samples from the light source can be varied slightly by moving the sample mounts, but they should remain constant during the testing period.

The chamber is fitted with ports in both the atmospheric and immersion sections. The ports are used for exhausting, draining, and/or recycling liquids or gasses. These ports also allow the immersion solution to be heated, cooled, filtered, and/or oxygenated during the test without disturbing the cycle. The immersion solution may be deionized, fresh, or salt water, acid solutions, or alkali solutions.

The device allows use of a variety of UV light/immersion cycles and immersion solutions. However, a default cycle is rotation at a speed of 20 rpm, a rotation distance of 420°, a pause of 4 h, a temperature of 140°C, and an immersion solution of tap water.

The second device, the QUV/HO [*16*], is constructed of corrosion-resistant materials and encloses eight fluorescent UV lamps, a heated water pan, specimen drawers, and provisions for deionized water spray. The samples are alternately exposed to UV light, water spray, condensation, and immersion.

The immersion cycle is produced by water spray collected in the specimen drawers. The depth of immersion is controlled by the time duration of the water spray and by plugging overflow holes to a desired depth. The specimens are set at an angle to produce a shoreline effect during the immersion cycle. The drying cycle is accomplished through heat generated during the UV cycle and evaporation.

Various test conditions can be used, but the default cycle is 6 h at UV light exposure at 60°C, 2 min of water spray, 6 h of condensation at 50°C, and a maximum level of ponding water covering half of each sample. The UV light source may be any of the fluorescent bulbs and should depend on the material being tested. The spray is limited to water at this time.

The third device is the Sunchex apparatus [*17*] is constructed of corrosion-resistant material and is suitably sized for tabletop operation. An air-cooled xenon arc lamp and a horizontal specimen tray are housed in the device. When in test operation, specimens are alternatively exposed to UV light, water, immersion, and heat.

The immersion cycle is produced by a continuous water flow over the specimen for a variable amount of time. The water depth has a maximum of 0.75 in. (1.9 cm). The dry cycle is accomplished by pumping the water from the specimen tray. The UV light exposure is provided by the 1500-W lamp that is mounted approximately 21 cm above the specimen tray. Uniform radiation distribution over the samples is achieved by the use of parabolic reflectors, glass optical filters, and reflective materials on the chamber walls.

Various test conditions can be used. The light cycle is variable from 1 to 999 min, and the immersion and dark periods can be varied between 1 and 99 min. A default cycle for paint test has not been developed since this device is currently being used in the plastic, rubber, and textile industries.

Fresnel Reflector

There are three methods for accelerating natural weather exposure: black box, heated black box, and fresnel reflector. These are described in ASTM Practice for Conducting Accelerated Outdoor Exposure Tests of Coatings (D 4141). The

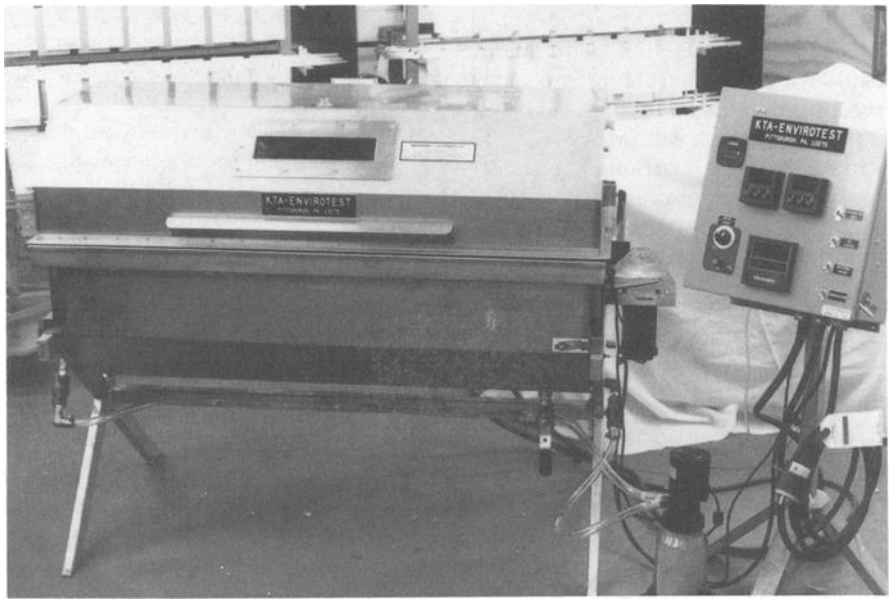

FIG. 10–Cyclic immersion/fluorescent bulb. Used with permission of KTA-Tator, Inc.

first two methods accelerate the weathering by increasing the temperature of the exposed surface and are discussed in the natural weathering section. The fresnel reflector is the only method that collects and intensifies natural sunlight to accelerate weathering. The basic principles for this method are found in ASTM Practice for Performing Accelerated Outdoor Weathering of Nonmetallic Materials Using Concentrated Natural Sunlight (G 90). It is performed in the desert region of Arizona using Sun-10, FRECKLE, EMMA, EMMAQUA, or other similar devices that involve the use of a mirror array [*6,18*]. A more detailed description of this device is presented in the chapter that deals with natural weathering.

The concentration of sunlight is achieved by collecting sunlight on ten mirrors and focusing the reflected light onto the specimen. The assembly is designed to actually follow the track of the sun as it moves through the sky. The device is equipped with a blower to regulate the surface temperature of the specimen. The maximum surface temperature that can be reached is limited to no more than 10°C above the maximum temperature normally achieved by natural weathering. The test may be performed with or without water spray. The water spray is provided by an oscillating nozzle assembly, which supplies deionized water as a fine, dense mist. The water is sprayed on the samples for set cycle times. A common cycle is 8 min of water spray per hour. Exact cycles are given in ASTM G 90.

Since this method uses natural sunlight, the spectrum produced follows that of natural sunlight but at a higher intensity level (Fig. 11). The testing can be performed for specific levels of solar exposure or for specific time periods. The quantity of light is measured by a radiometer, and it is expressed as total solar radiant exposure. The preferred method is based on solar exposure since this accounts for the natural seasonal variations of sunlight. This allows, for example, results obtained in January to be directly compared to those obtained in July.

Ultrafast Weathering

In contrast to all of the above methods, this technique of ultrafast weathering does not wait for visual changes to occur on the surface. At the present time, this method is still being evaluated to determine if there is any correlation between the information gathered using electron spin resonance (ESR) spectroscopy to monitor radical formation and natural weathering results [*2*]. The theory behind ultrafast weathering is based on the assumption that the radicals which form within the first several hours of the test will reveal the relative stability of the coating. For this testing, the process of radical formation is induced by ultraviolet radiation greater than that of sunlight. The light is filtered to remove unwanted shorter wavelengths and also focused on the sample using a cooled mirror. The sample is placed between the poles of a magnet in the microwave resonator of the spectrometer. The radical formation is plotted as a function of light-exposure time. Each paint will produce a characteristic curve. If a correlation is found to exist, the curves of different paints are then to be compared to determine which exhibits the best UV light stability. This testing could be completed over several hours instead of days, months, or years.

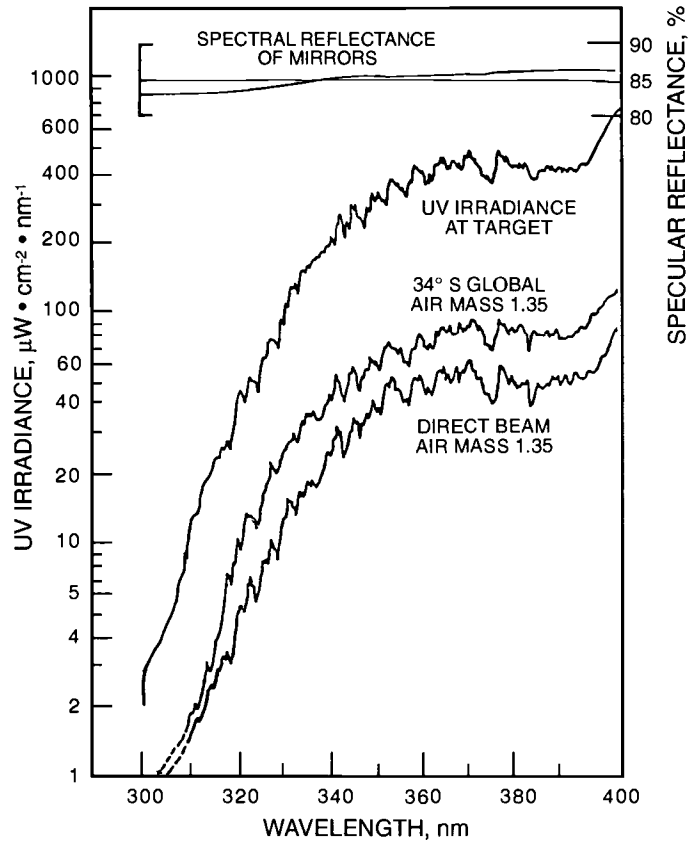

FIG. 11–Spectrum of light produced by fresnel-reflector testing devices.

Biological Deterioration of Paint Films

by David L. Campbell[1]

DESCRIPTION OF THE PROBLEM

Water-borne liquid paints can experience viscosity loss, putrefaction, gas formation, color change, and pH drift as a result of the degradation of some or all of the organic constituents [*1*]. This deterioration can be caused by bacteria or fungi-releasing enzymes in the paint or by enzymes which have been introduced into the paint through contaminated raw materials or equipment. Viscosity loss in water-borne paints can also be caused by the presence of oxidants/reductants in raw materials [*2,3*].

Micro- and macroorganisms can destroy both the decorative and protective properties of paint films. Algal and fungal growth can cause discoloration of water- and solvent-borne paint films and ultimately destroy their integrity (Figs. 1 and 2). The susceptibility of paint films to attack by microorganisms is determined in part by the chemical nature of the nonvolatile binder, the choice of pigmentation, and the pigment volume concentration. To a much greater degree, however, the susceptibility or resistance of a paint film to biological attack is determined by the presence and concentration of antimicrobial agents.

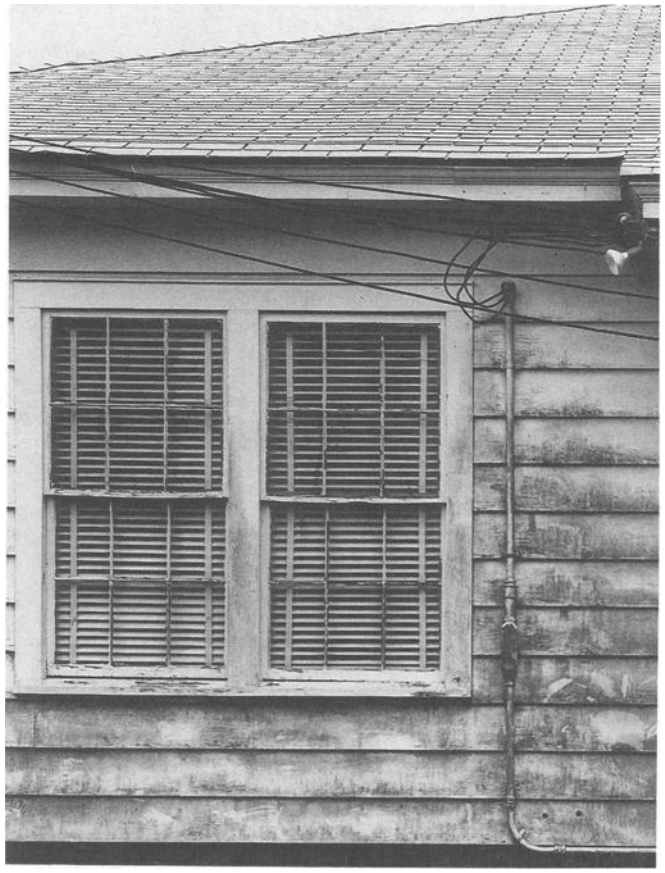

FIG. 1–Fungus discoloration of paint films. Appearance of house one year after painting shows rapid fungal discoloration of paint inadequately protected against microorganisms.

MICROORGANISMS ASSOCIATED WITH PAINT

Microorganisms associated with paint and paint films have been well established. These organisms include bacteria, fungi, and terrestrial algae.

The bacteria genera *Pseudomonas, Aerobacter, Enterobacter, Flavobacterium,* and *Bacillus* are frequently isolated from spoiled paints [*4,5*]. Of these, the *Bacillus* are unique in that, under conditions of stress such as heat, cold, or dehydration, some are able to form spores which are resistant to high temperatures and dry environments and more resistant to bactericides. Opperman and Goll [*6,7*] found anaerobic bacteria in contaminated water-borne paints and raw materials. The aerobic culture methods commonly used would not detect the presence of these bacteria, which are capable of utilizing organic paint components as nutrients.

Fungi are present on the surface of paint films in two forms. They may be present as thread-like structures technically referred to as mycelia or as clusters of spherical, usually black-colored, spores. These two different appearances of fungi have been popularly labeled the trees and fruit of fungi. In reality, they represent the two different growth forms in the life cycle of fungi. The mycelial structures are observed when the fungi are actively growing and reproducing. Spore clusters are found when conditions for growth and reproduction are less favorable. Spores are more resistant to environmental changes and antimicrobial agents than are the mycelial forms. Spores and spore clusters are frequently difficult to differentiate from soil or soot particles. Examination with a magnifying lens or microscope is frequently necessary for positive identification by even the skilled microbiologist. Photomicrographs of the two different forms of fungal growth are shown in Figs. 3 and 4.

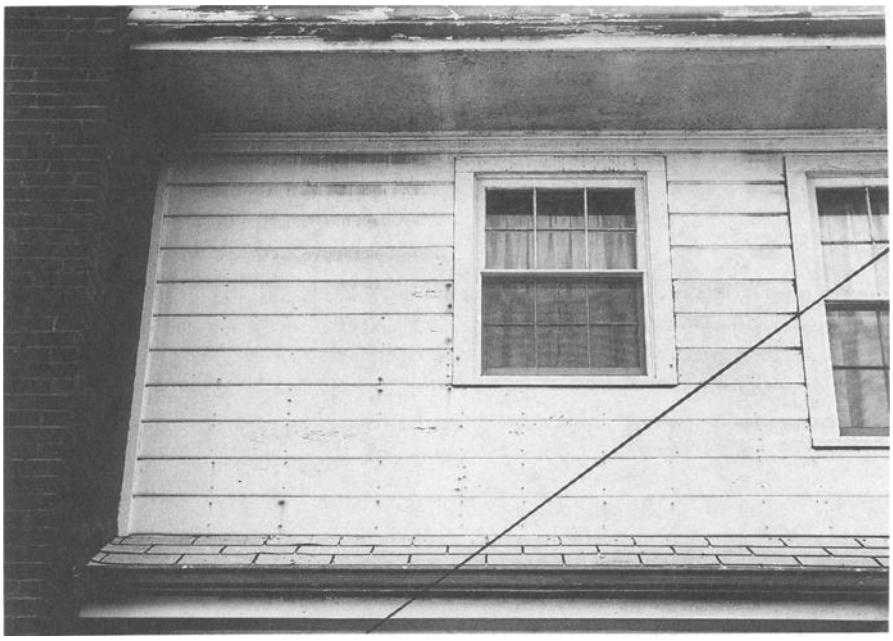

FIG. 2–Fungus disfigurement of paint films. Appearance of house three years after painting. Chalking of the paint has physically removed fungus from vertically exposed areas, but, in absence of chalking under the eaves, fungus growth has continued and showed an inadequately preserved paint.

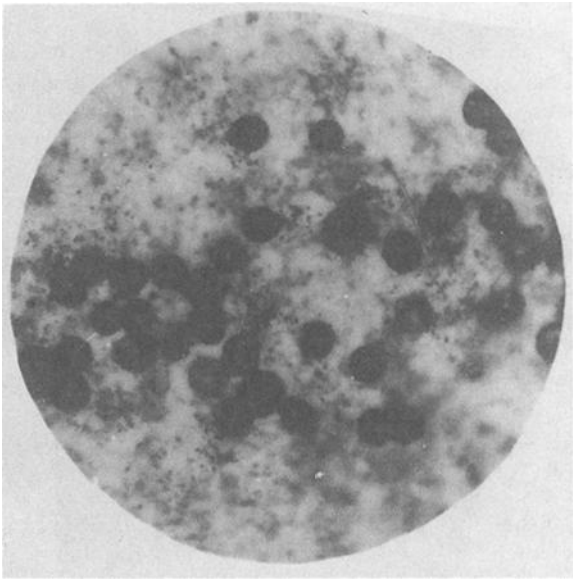

FIG. 3–Spores of fungus on a paint film. Magnification ×150.

Numerous fungi are found on and within paint films, although a few predominate. Goll and Coffey [*8*] were the first to observe and report the wide-spread growth of *Aureobasidium pullulans*. In isolation studies of oil and alkyd paint films at six wide-spread geographical locations, Rothwell [*9*] confirmed the predominance of *Aureobasidium pullulans* but noted the close resemblance of, and predominance in certain geographical areas of *Cladosporium* species (sp.). Other fungi frequently isolated include *Alternaria dianthicola* and *Phoma pigmentivora*. The same studies indicated the consistent presence of bacteria within the paint film and at the paint-wood interface. *Flavobacterium marinum* was by far the predominant bacterium isolated. Despite the differences in the chemical nature of latex emulsion binders, Drescher [*10*] isolated essentially the same microorganisms from latex emulsion paint films exposed at the same location.

The microflora of interior paint films in breweries, dairies, canneries, and other food-processing plants were reported by Krumperman [*11*] and included many fungi rarely found on exterior paint films (Fig. 5). Prominent among these are *Aspergillus* sp. and *Penicillium* sp. Found to a lesser extent were *Cladosporium* sp. and *Aureobasidium pullulans*. His investigations again indicated the frequent occurrence of the bacillus *Flavobacterium marinum*.

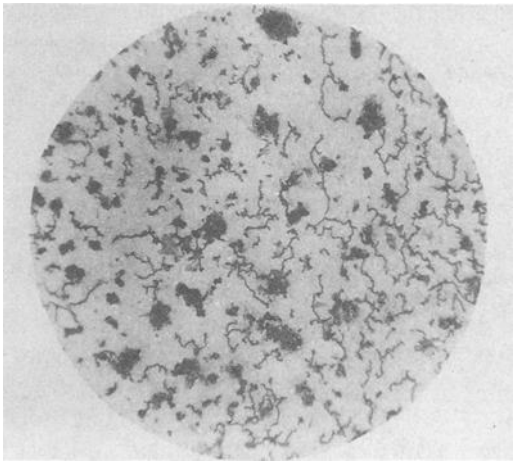

FIG. 4–Mycelia of fungus on a paint film. Magnification ×75.

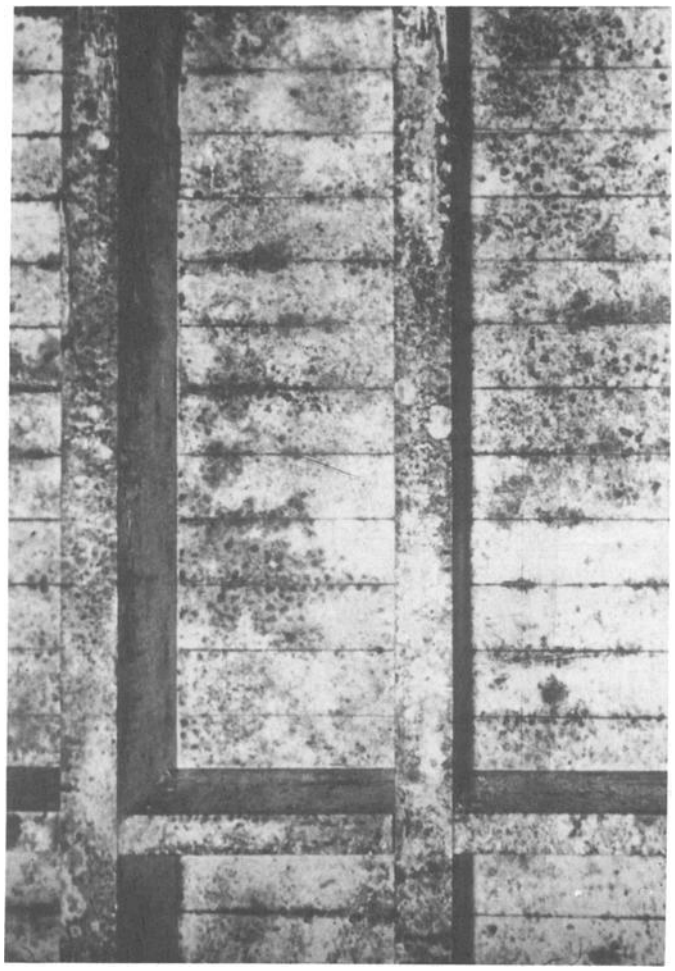

FIG. 5–Fungus disfigurement of paint films. Appearance of ceiling in a food processing plant only six months after painting. The high humidity and the nutrients supplied by food processing create an environment especially favorable to growth of fungi.

Algae, which contain chlorophyll, manufacture their own organic carbon from atmospheric CO_2 and light energy in photosynthesis. The nuisance growth of terrestrial algae on painted surfaces has been described by Skinner [*12*] and Drisko et al. [*13*]. The Cyanobacteria (blue-green algae) *Oscillotoria* sp. and *Scytonema* sp. predominate in tropical conditions. Algae may be filamentous or unicellular organisms and vary in color from green to brown to black. The green alga *Protococcus* sp. (*Pleurococcus*) is prevalent in the temperate climates (Fig. 6).

DETERMINING THE PRESENCE OF FUNGAL OR ALGAL GROWTH ON PAINT FILMS

When doubt exists as to whether the defacement is due to algae, fungi, or dirt, the surface can be examined using magnification of ×10 to ×100 to distinguish among fungal, algal, or dirt disfigurement as described in the ASTM Test Method for Evaluating Degree of Surface Disfigurement of Paint Films by Microbial (Fungal or Algal) Growth or Soil and Dirt

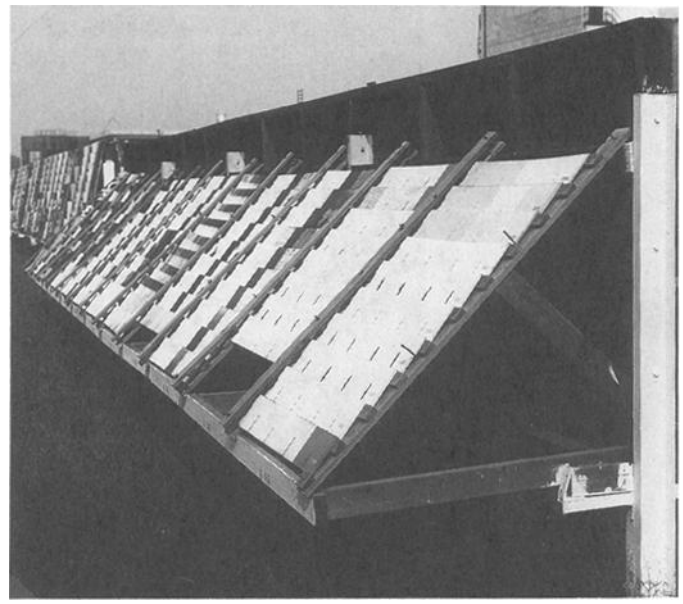

FIG. 6–Test fence exposure of paints. Specimens are placed 5° off vertical and are offset so that runoff from higher specimens does not contaminate specimens below. This arrangement allows different paint to be applied to each panel.

Accumulation (D 3274). Photographic reference standards for rating the disfigurement of paint films are illustrated in this method.

The composition of fungi and algae permits the use of chemical identification. The ASTM Guide for Determining the Presence of and Removing Microbial (Fungal or Algal) Growth on Paint and Related Coatings (D 4610) contains procedures for chemical, visual, and subculture determination of fungi and algae. The chemical procedure uses 5% aqueous sodium hypochlorite solution applied to the disfigured area of the film with bleaching as an indication of algae or fungi. The test has its limitations and thus should be interpreted with some degree of caution. Insect eggs or fecal material will bleach since both are composed of protein. The test should be limited to white or light-colored paint since on deeper-colored paint films the bleaching of fungal or algal growth may be insignificant compared to that of the paint. Moreover, a heavy chalk face interferes with the test, and areas discolored by metal may give false results. ASTM D 4610 therefore contains the visual and subculture procedures which can be used for confirmation of the chemical test results. A subculture may be made by applying a prepared petri dish containing a raised convex surface of nutrient agar culture medium directly to the surface to be sampled and exerting moderate pressure. Replace the cover and incubate for 72 h at 98°F (36.7°C). Examine the agar surface visually in accordance with ASTM D 3274. The culture medium must contain the nutrients necessary for growth of algae or fungi.

ANTIMICROBIAL AGENTS

Chemical agents used to control or prevent the deteriorating effect of microorganisms are referred to as *microbistats* if they do not kill microorganisms but prevent their reproduc-

tion and as *microbicides* if they kill microorganisms. Most of the microbistats and microbicides used in paint films effectively control fungi, algae, and bacteria by interfering with their metabolic functions.

Table 1 lists more frequently employed antimicrobial agents used in paints as bactericides, algicides, or fungicides as recommended by the manufacturers.

DETERMINING MICROBIOLOGICAL RESISTANCE OF PAINTS

The microbial resistance of paints and paint films is an important characteristic of such paints, and considerable attention has been given to developing laboratory and field tests that will predict the resistance of paints to biodeterioration. Some of the tests require the use of pure culture microorganisms. Those employed are listed in Table 2 and may be obtained from: American Type Cultures Collection, 12301 Parklawn Drive, Rockville, Maryland 20852. Many tests employ synthetic growth media. These are summarized in Table 3.

The more commonly employed tests include the following.

TABLE 1—Antimicrobial agents used in paints and paint films.

ALGICIDES
diiodomethyl-p-tolylsulfone
2-methylthio-4-tert.-butylamino-6-cyclopropylamino-s-triazine
FUNGICIDES
diiodomethyl-p-tolylsulfone
barium metaborate
2-n-octyl-4-isothiazolin-3-one
potassium dimethyldithiocarbamate
methylene bis(thiocyanate)
2-(thiocyanomethylthio) benzothiazole
2-(4-thiazolyl)benzimidazole
N-trichloromethylthio-4-cyclohexene-1,2-dicarboximide
zinc dimethyldithiocarbamate
zinc 2-mercaptobenzothiazole
3-iodo-2-propynyl butyl carbamate
tetrachloroisophthalonitrile
N-(trichloromethylthio)phthalimide
tributyltin benzoate
tributyl tin salicylate
tributyltin oxide
zinc oxide
BACTERICIDES
tributyltin oxide
tributyltin benzoate
barium metaborate
potassium dimethyldithiocarbamate
p-chloro-m-cresol
alkylamine hydrochlorides
6-acetoxy-2,4-dimethyl-1,3-dioxane
tetrahydro-3,5-dimethyl-2H-1,3,5,-thiadiazine-2-thione
2 (hydroxymethyl)amino ethanol
1,2-dibromo-2,4,-dicyanobutane
1-(3-chloroallyl)-3,5,7-triaza-1-azoniaadamantane chloride
hexahydro-1,3,5-triethyl-5-triazine
2-(hydroxymethyl)amino-2-methyl-1-propanol
4-(2-nitrobutyl)morpholine
3,4,4-trimethyloxazolidine
4,4-dimethyloxazolidine
5-chloro-2-methyl-4-isothiazolin-3-one
2-methyl-4-isothiazolin-3-one
1,2-benzisothiazolin-3-one
1,3-bis(hydroxymethyl)-5,5-dimethylhydantoin
hydroxymethyl-5,5-dimethylhydantoin

Bacterial Resistance of Liquid Paints

Resistance of emulsion paints in the container to attack by bacteria can be determined in accordance with the ASTM Test Method for Resistance of Emulsion Paints in the Container to Attack by Microorganisms (D 2574). This test predicts the package stability of water-thinned latex emulsion paints as related to bacterial growth in the paint and degradation of organic constituents.

The test consists of two parts. The paint under test is first cultured on tryptone glucose agar to determine if living bacteria are present. A negative result indicates the absence of bacteria but not necessarily resistance to attack. To determine if the test paint can withstand bacterial attack, a specimen of "spoiled" paint containing *Pseudomonas aeruginosa* is introduced into the test paint, and the latter is incubated at room temperature for a period of six weeks. At intervals of 24, 48, and 72 h and at one-week intervals for the remainder of the test period, the inoculated test paint is streaked on tryptone glucose extract agar slants. The test paint is reported to be resistant to bacterial attack if no living organisms can be recovered through six weeks of incubation. Conversely, the paint is reported to be "not resistant to bacterial attack" if living bacteria are recovered at any time during the incubation period. The principal difference between the ASTM test and previously employed tests of this type is the use of "spoiled" paint as an inoculum, rather than aqueous suspensions of bacteria removed from laboratory growth medium. By employing paint containing *P. aeruginosa*, already adapted to a paint environment, the shock of a drastic environmental change is eliminated. Repeated inoculations may be necessary to obtain a "spoiled" paint for use as an inoculum, but once prepared, it can be maintained indefinitely.

Measuring the Fungal Resistance of Paint Films

The inability to duplicate the use environments of exterior and interior paint films has made it difficult to develop suitable accelerated tests for the evaluation of their fungal resistance. Most laboratory tests have been based on the widely used agar plate method or modifications of it. Simply described, the agar plate test consists of placing a painted substrate on a bed of agar, inoculating the system with the test

organism, and observing growth during a prescribed incubation period.

Federal Test Method Standard 141

Method 6271 (Mildew Resistance) is the agar plate test most frequently referred to in specifications for paints utilized by agencies of the U.S. Government. This method employs sucrose, mineral salts, agar medium, and, in accordance with Federal specifications TT-P-19 (Paint, Acrylic Emulsion: Exterior), *Aspergillus oryzae* is the inoculating organism. The agar medium is prepared according to the recipe shown in Table 3. The pH of the medium may be adjusted to 5.5 to 6.5 with 0.1 *N* hydrochloric acid (HCl) or sodium hydroxide (NaOH). The medium is sterilized in an autoclave for 15 min at 15 lb/in.^{2} (1.034×10^5 Pa) and 121°C. Approximately 30 mL is poured into each sterile petri dish and allowed to harden.

The inoculum is prepared by adding 10 mL of sterile water containing 0.005% nontoxic wetting agent such as Tween-80 to a tubed subculture of *A. oryzae*. The mixture of spores and mycelia are removed by gently stroking the agar surface with a sterile camel's hair brush. The aqueous suspension is removed and diluted with sterile water to 100 mL.

The test paint is brushed on each side of a sheet of Whatman filter paper No. 3.0, or equivalent, and allowed to dry for 24 h. Squares of the painted filter paper, 1.25 in. (3.18 cm) on the side, and with guide lines of waterproof ink ⅛ in. (0.32 cm) from each edge, are centrally placed on the agar surface of each dish. Using a sterile pipet, 1.0 to 1.5 mL of the diluted spore-mycelial inoculum is distributed over the painted surface and surrounding agar surface. Duplicate plates should be prepared. The inoculated agar plates are incubated for seven days at 28 to 30°C and 90% relative humidity. At the end of the incubation period, the specimens are examined visually at ×1 and approximately ×18 magnification. Fungal growth on the agar surface or on the edges of the painted filter paper is ignored, and such specimens are considered to pass the test if free of growth within the guidelines.

Nuodex Method

In order to improve the accuracy of the mildew test as required by the exterior paint Federal Specification TT-P-19, Nuodex laboratories modified the test as follows: *Aureobasidium pullulans* replaced *Aspergillus oryzae* because it is the fungus most frequently isolated from exterior house paints. Malt-extract agar replaced the sucrose-mineral salts agar because, in it, *A. pullulans* exhibits growth forms typically observed on exterior paints rather than yeast-like forms that it exhibits when grown on the sucrose-mineral salts agar.

Hutchinson Method

The Hutchinson Method [*14*] is similar to the Federal Method 6271, but employs glass string rather than filter paper as the paint substrate, a liquid broth culture media containing no carbon source and a mixed suspension of *Aspergillus niger, Aspergillus flavus,* and *Penicillium funiculosum.*

ASTM Test Method for Resistance to Growth of Mold on the Surface of Interior Coatings in an Environmental Chamber (D 3273)

This test is used to evaluate the resistance of interior paint films to fungus attack and reportedly provides more accurate results by virtue of removing the artificial aspects of the previously described laboratory method. Test paints are applied to either white pine or gypsum board panels measuring 3 in. (7.0 cm) by 4 in. (10.2 cm) by 0.5 in. (1.3 cm). Two coats of paint are applied to both sides and all edges of the panels at a spreading rate of 450 ft/gal (11.1 m/L) per coat. The specimens are then conditioned at 75°F (24°C) and 50% relative humidity for four days after application of the last coat before being placed in the test chamber. The chamber may be any cabinet capable of maintaining a relative humidity of 95 to 100% and a temperature of 90°F (32°C) and large enough to accommodate specimens, a water bath, and a soil bed that serves as an inoculum source. The soil bed is constructed of a stainless steel or plastic tray with a monel mesh bottom (16 mesh). The soil employed is a good quality, green-

house grade potting soil containing 25% peat moss. The pH of the soil is maintained between 5.5 and 7.6. The soil is inoculated with spore and mycelium suspensions of *Aureobasidium pullulans, Aspergillus niger,* and *Penicillium* sp. prepared from 10 to 14-day-old agar slants. At least 14 days should be allowed for the fungi to sporulate prior to beginning any tests.

Panels can be placed in the cabinet at any angle desired. Inoculation of the paints is accomplished naturally by airborne spores. To maintain a continuous inoculation, a small fan (1/250 HP operating at 300 rpm) is mounted on a wall of the cabinet just above the level of the soil bed and directed over the surface of the soil. By virtue of the mesh tray bottom just above the water bath, the soil remains moist to ensure maximum growth of the fungi. The test panels are rated for fungal growth over a four-week period. When operating properly, unpainted wood panels or paints containing no antimicrobial agent should develop a 4 to 6 mold growth rating within two to three weeks. The advantage of the environmental chamber method is its close duplication of use conditions.

Zabel Test

The Zabel Test [*15*] was developed to overcome the difficulty in achieving the growth of *Auseobasidium pullulans* in the ASTM environmental chamber. The procedure involves five major steps: (1) the preparation and treatment of partially painted wood specimens; (2) the preparation of stain chambers; (3) sterilization of the specimens and assembly in the stain chambers; (4) inoculation of the painted wood and incubation; and (5) disfigurement evaluation.

Specimen Preparation and Treatment

Flat strips of veneer (7.5 cm long, 3.0 cm wide, and 0.5 cm thick) are cut from the sapwood of southern yellow pine. The strips are heat sterilized for 20 min at 121°C, cooled, and then painted by brushing one heavy coat on the upper half of one surface. After the paint has set and hardened (two to three days), the strips are soaked in distilled water for 15 min, placed individually in Petri plates supported on small glass rods (or placed individually in large glass tubes and cotton stoppered) and surface sterilized by steaming for 15 min in an autoclave at 100 to 101°C. The painted specimens are then ready for introduction to the stain chambers.

Stain Chambers

The stain chambers are screw cap 16-oz French square bottles. These are vertically positioned, and 20 g of vermiculite are added.

The agar medium is prepared according to the formula shown in Table 3. A micronutrient solution is prepared as follows: $Fe(NO_3)3.9H_2O$, 723.5 mg; $ZnSO_4{\cdot}7H_2O$, 439.8 mg; and $MnSO_4{\cdot}4H_2O$, 203.0 mg; dissolved in 600 mL of double distilled water, cleared of precipitate with H_2SO_4 (CP grade), and made to a final volume of 1 L. The micronutrient solution is added to the nutrient media in amounts of 2 mL per liter. The micronutrient-enriched nutrient media is then poured into the vermiculite-containing stain chambers (100 mL per chamber). A small square of filter paper is placed on the surface to minimize vermiculite displacement during the pouring, then removed.

Sterilization and Specimen Assembly

The chambers are autoclaved for 40 min at 121°C, stored at room temperature for 24 h and cooled, then reautoclaved for 15 min at 121°C. After chamber cooling, the painted strips are inserted aseptically. The strips are positioned with the painted surface up at about a 15° angle from the vertical and center inserted until the bottom of the painted zone is about 0.5 cm above the vermiculite surface.

Inoculation and Incubation

Spore suspensions of *A. pullulans* (ATCC strain 16624) are prepared by growing the fungus for 14 days at 28°C on malt extract agar (25 g of malt extract and 15 g of agar per liter) plates. Discs (5 mm in diameter) of mycelium are cut from the pigmented margin of the colony and transferred individually into tubes containing 10 mL of sterile distilled water. The tubes are then agitated vigorously for 5 s on a vortex stirrer, forming a uniform suspension of spores and mycelial fragments.

The spore suspension is then aseptically pippetted on the top (5 mL amounts per strip) of the painted zone on the specimens and distributed so it runs uniformly down the painted surface. The spore suspensions should be used within 1 h of preparation. The stain chambers are then incubated at 28°C for 30 days. Darkness is maintained except lighting for occasional observation.

Disfigurement Evaluation

Blue stain development in the wood and fungus growth on the paint are observed and recorded weekly.

Field Exposure Tests

Because of the many different angles of exposure and degree of protection of paint films on houses, buildings, and industrial plants, the only absolutely accurate field exposure test to measure the fungal and/or algal resistance of paint films is the application of the paint on these structures. This is not economically feasible, and thus it has been the practice to apply and expose paints on panels affixed to test racks, providing various angles of exposures (Figs. 6, 7, and 8). See ASTM Practice for Determining by Exterior Exposure Tests Susceptibility of Paint Films to Microbiological Attack (D 3456).

To ensure accurate measurements of fungal or algal resistance, at least duplicate test panels should be mounted so that painted surfaces are exposed both totally to sun and rain and protected from exposure as occurs on the underside of panels exposed at a 45° angle. Paints exposed to the atmosphere should be examined regularly during the period in which the paint shows no chalking, since chalking of paint films frequently physically removes fungus growth from the surface.

Insect-Resistant Paints

While insects do not pose a deteriorative threat to paints or paint films, their attachment to paints following application and prior to the hardening of the paint film presents a serious decorative problem in many geographical areas. Thus, insect-resistant paints are requested continuously, and tests measuring this property are needed. The best-known test for measuring insect resistance of paints is that devised by Westgate

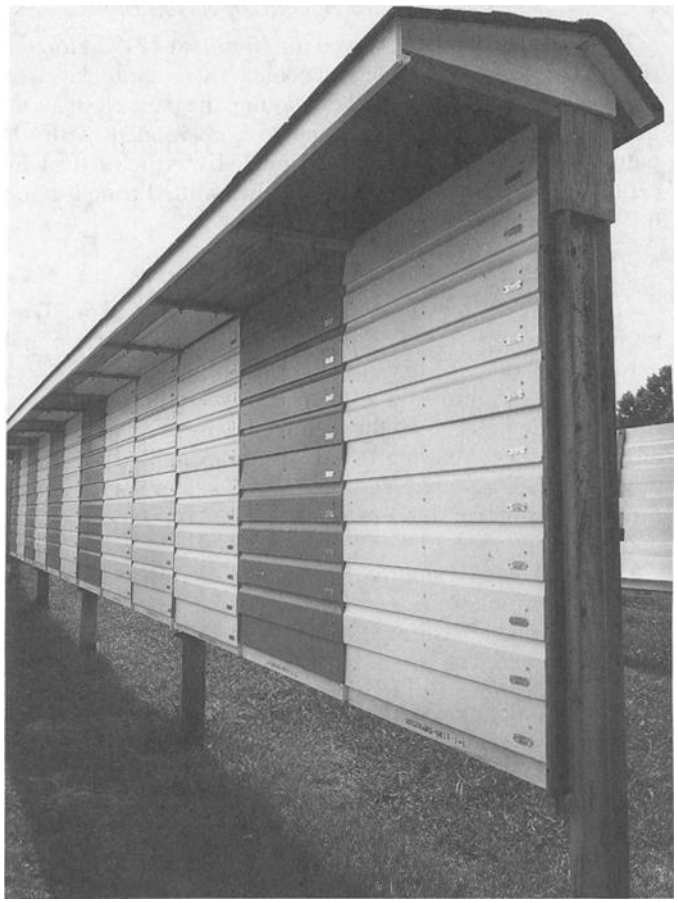

FIG. 7–Test fence exposure of paints. Overhanging eave duplicates house construction and allows evaluation of fungus resistance in both protected and unprotected areas. Because the overlapping siding permits runoff, only one paint system should be used in any vertical area. Compare with Fig. 6.

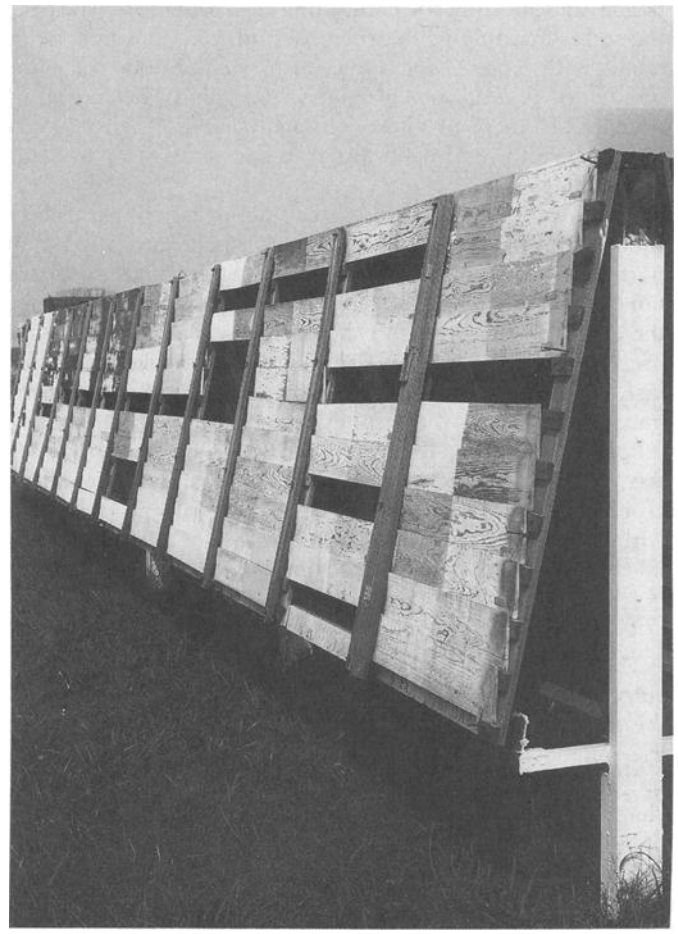

FIG. 8–Test fence exposure of paints. Specimens are placed at an angle of 45° to accelerate weathering comparable to that on roofs, window sills, and other similarly oriented areas. Because of early chalking of paint so exposed, such arrangements are not suitable for evaluation of fungus resistance. However, the underside of 45° exposure provides excellent conditions for evaluating fungus resistance in protected environments.

and Bolton [*16*]. The essential feature of this laboratory method is a lethal chamber from a hiding power sheet, 11½ in. (28.6 cm) by 17½ in. (44.5 cm). The treated paint is applied at a definite spreading rate by means by a doctor blade. The amount, in milligrams, of insecticide per square foot of dry film equals

$$45.4\,WNI/A$$

where

W = weight, pounds, per gallon of paint,
N = percentage of nonvolatile matter,
I = percentage of active ingredient in the nonvolatile portion of the paint, and
A = area, square feet per gallon of paint. Convert to square meters per liter by multiplying by a factor of 0.025.

The sheet bearing the dried film is rolled up to the diameter of a Petri dish and fastened in place with tape. This tube, when capped on both ends with Petri dishes, forms a lethal chamber that may be handled, observed, and stored with ease. It may also be taken apart and given a variety of treatments between tests.

The test insects, for example, the common housefly *Musca domestica*, may be reared from eggs in the laboratory or they may be obtained in the pupal stage from biological supply houses. The flies are transferred most easily from the rearing cage to the lethal chamber by allowing them to fly upwards toward a light. The rearing cage is placed on its back. On the door is placed a sheet of pressed wood containing a hole in which the capped test roll is inserted. A light is arranged above the test roll. The sliding glass door is now pulled out, and the flies stream upward into the test roll. The lower end of the roll is closed with a second Petri dish after the specimen of flies (50 to 100) has been transferred. The flies may be kept under observation during the entire period of contact, which may be terminated within 30 s by blowing the flies into a recovery cage supplied with food. After 24 h have elapsed, the dead and living flies are counted, and the percentage mortality is calculated.

The method has been used to study many of the variables that influence the action of insecticides in paints. Although some insecticide-treated paints show pronounced and prolonged lethal action, the same results may be obtained with

sprays which deposit residues on the paints at a much lower rate of application.

Chemical Resistance

by Alan H. Brandau[1]

THE ABILITY OF A COATING TO RESIST chemical deterioration or staining is an essential element in its evaluation. What follows is a review of established test procedures with various levels of complexity and equipment sophistication that provide a standardized tool for evaluating potential flaws such as discoloration, softening, swelling, adhesion loss, gloss reduction, etc. These tests provide a common ground for crucial communication of performance properties between the manufacturer and end user of a coating. Since these tests are to be representative of actual exposure conditions, it is vital that the tests approximate, as closely as possible, genuine conditions in the field [*1*].

STAINING

Staining tests provide a thorough method of determining the ability of a coating to resist staining from household chemicals, chemical reagents, and other materials common in today's environment. The tests generally expose the coating surface to a spot of the reagent on the coating surface or by immersion of a coated test panel in the reagent for a specified period with timed check points.

Staining from Household Chemicals

Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes, ASTM D 1308, encompasses the evaluation of discoloration, change in gloss, blistering, softening, swelling, loss of adhesion, or other phenomena resulting from a variety of household chemicals. Materials or chemicals suggested as reagents include:

- Distilled water, hot and cold
- Ethyl alcohol, 50% by volume
- Vinegar, 3% acetic acid
- Alkali solution
- Acid solution
- Soap and detergent solutions
- Lighter fluid
- Fruit cut
- Oils and fats
- Condiments
- Beverages
- Lubricating oils and greases

Other materials can also be used as specified by customer or seller. The procedure utilizes open and watch glass covered spot tests with the reagent at ambient temperature as well as immersion tests in the reagent.

Staining in the Transportation Industry

ASTM D 1308, mentioned above, is supplemented by ASTM D 1540, Test Method for Effect of Chemical Agents on Organic Finishes Used in the Transportation Industry. Materials or chemicals suggested as reagents include:

- Glycol-based antifreeze up to 100%
- Acid, alkali, and salt solutions
- Soap and synthetic detergent solutions
- Lubricating oils and greases
- Polish abrasives, creams, and waxes
- Road oils and tars
- Rubber, elastomers, plastics, tapes
- Gasoline
- Water
- Hydraulic fluids
- Alcohol windshield washing solutions

As with ASTM D 1308, discoloration, change in gloss, blistering, softening, swelling, loss of adhesion, or other phenomena are examined after testing. With some reagents, exposure to sunlight or UV light for a specified time is required. Elevated temperature is also used to more closely simulate surface conditions in hot, sunny climates. Gasoline resistance tests combine dripping of fuel at ten drops per minute at a 20° angle with a UV lamp trained on the surface at a 90° angle. Adequate ventilation and safe handling of the dispensing and collecting vessels are essential to safety when working with gasoline. The staining potential of solid materials requires close contact and heat exposure before evaluation.

Staining Resistance of Furniture Finishes

Staining resistance of furniture finishes is covered as part of ASTM D 2571 (Test Methods for Heat-Shrinkable Tubing for Electrical Use), 11.0, Resistance to Oils, Greases, Cosmetics, and Other Household Chemicals. This procedure is concerned with materials such as cosmetics, alcohol, boiling water, and coffee.

Boiling water and hot coffee, prepared by various methods, are poured on a horizontal panel surface and allowed to dry, and the surface is examined for graying, spotting, softening, staining or other film deterioration. Cosmetics are applied to

[1]Vice president, Marketing, Consolidated Research, Inc., 200 E. Evergreen Ave., Mount Prospect, IL 60056.

Copyright© 1995 by ASTM International

the coating surface and placed in a 50°C oven overnight and examined for discoloration or film failure. Fifty percent alcohol or 100 proof vodka is trapped on the coating surface with a watch glass for at least 6 h, allowed to evaporate, and then observed for whitening or spotting that cannot be removed with light polishing with a dry cotton pad.

SOLVENT/FUEL RESISTANCE

ASTM D 2792, Test Method for Solvent and Fuel Resistance of Traffic Paint, relates a method of evaluating the resistance of a coating to solvent and fuel that causes blistering, wrinkling, loss of adhesion, and loss of hardness. The coating is applied to tin panels and air dried for 90 h. Half the panel is immersed in the test liquid, and the vessel is covered for a period of 4 to 18 h as may be specified by the customer. The panels are then removed and examined for defects. The panels are allowed to dry for another 24 h and reexamined for film defects and softening as compared to the unimmersed portion of the control panel.

If subtle differences between coatings are important such as comparative research and development efforts, then the panels can be examined more often without drying at intervals such as 1, 2, 4, 6, 24, and 48 h.

Battelle Chemical Resistance Cell

Several advantages over other immersion methods are claimed for this cell [2], which was developed in the course of research sponsored by Steel Shipping Container Institute, Inc. at Battelle Memorial Institute:

- Panels may be flat or indented
- Edge effects area voided
- Simultaneous testing in liquid and vapor
- Wider range of temperature

The cell consists of a Pyrex glass tube, open at both ends, held horizontally between coated test panels (Fig. 1). A convenient glass tube size is 2 in. (5.08 cm) in diameter and 3 in. (0.762 cm) in length with the ends ground flat. Gaskets are used between tube and panels to give a liquid-tight seal. The frame has screw adjustments for tightening the assembly. A sponge rubber pad behind one panel evens the pressure. A glass ring is used to surround the dimple when an indented panel is under test. The cell is filled through a hole in the middle of the tube. In use, the cell is half filled and stoppered tightly.

Bratt Conductivity Cell for Chemical Resistance

This cell [3], shown in Fig. 2, was designed to use conductivity of a film during chemical resistance tests as a measure of its chemical resistance. The cell proper is a 2-oz vial from which the bottom has been removed, in effect becoming a short piece of glass tubing. The cell is formed by the base plate and an additional plate with a hole that fits over the top of the vial and rests on the shoulder.

During a test, a potential of 15 V is applied to the cell. The metal substrate serves as the positive electrode. The external resistance is selected to produce a voltage drop of about 14 V across the cell.

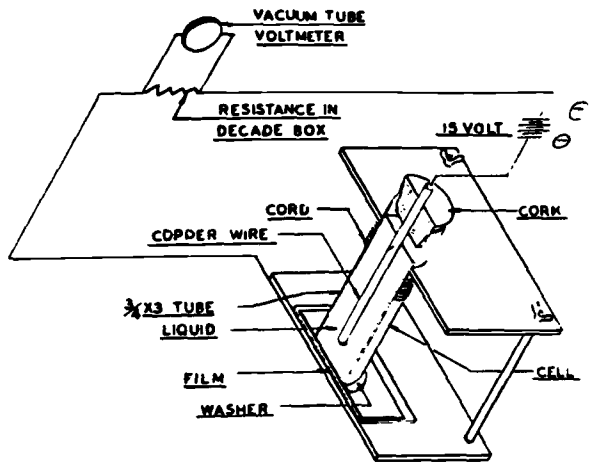

FIG. 2–Bratt conductivity cell. (Courtesy of S. G. Wilson.)

Gearhart-Ball Solvent Resistance

Gearhart-Ball [4] solvent resistance tests utilize free coating films. The cup test employs fastening the free film over the top of a beaker or dish (Fig. 3). Approximately 20 mL of

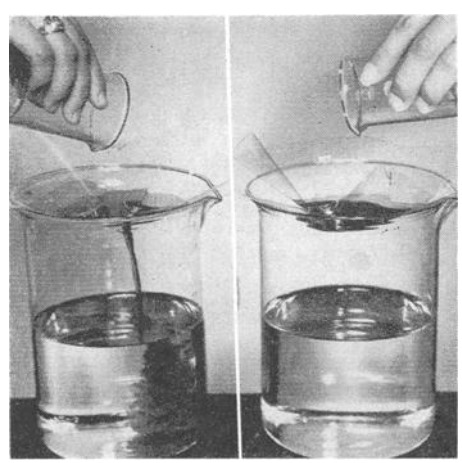

FIG. 3–Cup test for solvent resistance. (Courtesy of F. M. Ball.)

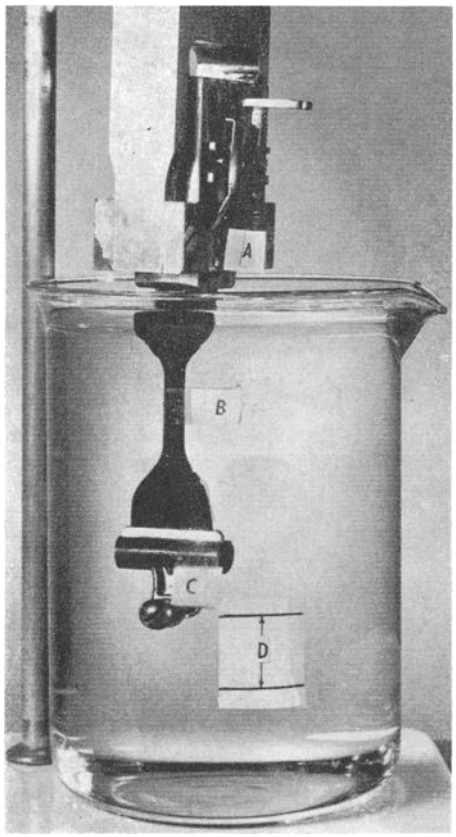

FIG. 4—Distensibility test for solvent resistance. (Courtesy of F. M. Ball.) A = specimen clamp; B = tensile specimen strip; C = alligator clip and weight; D = one inch distance marking.

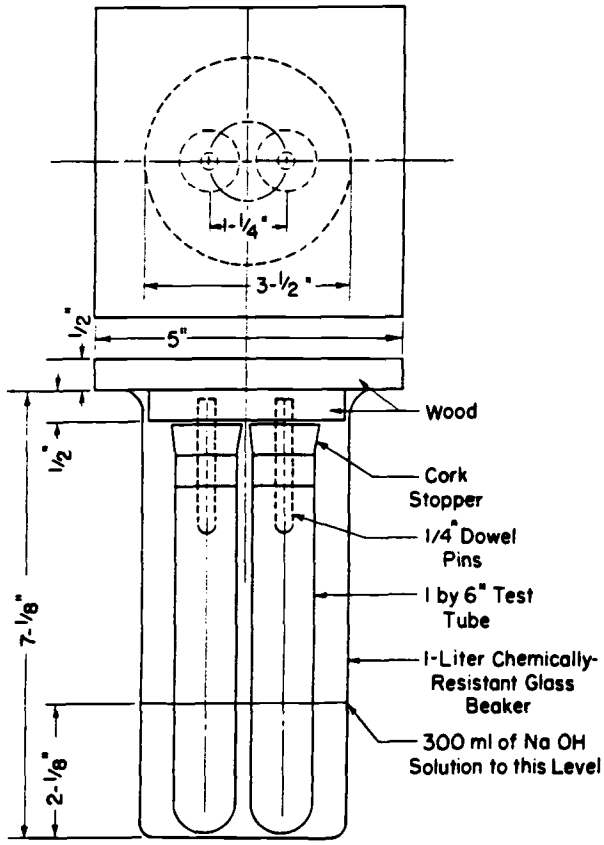

FIG. 5—Apparatus for alkali resistance test.

solvent is poured over the film, and the length of time required to puncture the film is noted. This test would be considered a crude screening test. More precise data can be derived from the distensibility test where a tensile strength strip (see ASTM D 2370.8) is clamped with either a tensile tester jaw or an alligator clip on the upper end, and the bottom end is clamped with an alligator clip with a 12-g weight and immersed in a clear beaker containing the solvent reagent (Fig. 4). The beaker is immediately marked with the initial length, and the time required to elongate the strip one inch is recorded.

Solvent Rub Resistance

Although solvent resistance can be evaluated using ASTM D 1308, many use or adapt a solvent rubbing technique with a gauze cloth soaked in a solvent (MEK is common) and rubbing with the thumb back and forth in 2-in. (5.08-cm) strokes. This procedure, ASTM D 4752, Test Method for Measuring MEK Resistance of Ethyl Silicate (Inorganic) Zinc-Rich Primers by Solvent Rub, is imprecise because the person's strength and the size of the thumb is variable. Nevertheless, it provides a quick relative test without having to wait for exposure results. The MEK resistance of some two-component ethyl silicate zinc-rich primers has been shown to correlate well with the cure of the primer as determined by diffuse reflectance infrared spectroscopy.[2]

ACID RESISTANCE

Acid resistance is determined by exposing a coated panel to freshly prepared mortar as well as a hydrochloric acid solution and is fully described in ASTM D 3260, Test Method for Resistance to Acid and Mortar of Factory-Applied Clear Coatings on Extruded Aluminum Products. The acid resistance test is performed by first sealing the edges of a specially coated panel with a paraffin and beeswax mixture and then

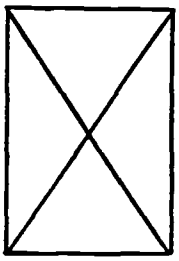

FIG. 6—Q panel is scored with an "x" to expose bare substrate.

FIG. 7–Diagram of salt-spray (fog) cabinet.

immersing the panel in a 10 vol% solution of 31.6% solution of HCl at ambient temperature for 6 h, followed by rinsing, drying, and examination for blistering, peeling, lifting, crazing, flaking, or discoloration. Mortar resistance is performed by applying a fresh mortar patty, prepared to a specified formula, to both sides of the specially coated panel and then placing in a high relative humidity cabinet for seven days. The mortar is then carefully removed and the panel wiped off with a damp cloth followed by examination as with the acid test.

ALKALI AND DETERGENT RESISTANCE

ASTM D 1308, Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes, is also recommended for evaluating alkali and detergent resistance. It is a simple common sense technique that can be used for many materials or chemicals that can stain or discolor a coating. The choice of testing materials should be related to the coatings end use. As previously mentioned, ASTM D 1308 describes techniques for either immersing the coated substrate in the reagent, putting a small amount of the material on the coated surface and covering with a small watch glass, or just leaving the material on the surface uncovered. The coating is then checked for staining after a period of time or at 1, 2, 4, 6, 24, and 48-h intervals.

For detergent resistance of appliance finishes, a solution of a specified detergent containing a high percentage of sodium phosphate is applied and the temperature maintained at 165°F (73.8°C) for the duration of exposure, usually 250 to 500 h. The test panel is submerged at least six inches into the solution. This is a more severe test than a spot test, but it is more representative of actual service conditions. Examination is done after rinsing and blotting the panel and looking for any manifestation of coating failure.

ASTM D 1647, Test Method for Resistance of Dried Films of Varnishes to Water and Alkali, describes an alkali resistance immersion test using coated test tubes. The use of test tubes coated by dipping into the coating prevents the reagent from creeping under the edge of a flow-on film. As many as 20 tubes are prepared for this test, allowing examination after 1 to 8, 16, and 24 h (Fig. 5). The exposed specimens are rinsed with water and allowed to dry for 30 min before examining for whitening, blistering, or removal of the film.

WATER AND MOISTURE RESISTANCE

There are a number of types of chambers such as moisture chambers, salt fog cabinets, and other accelerated weathering equipment that tests coating moisture resistance as well as other resistance criteria. This type chamber is useful for spot checking accelerated long-term environmental durability. But to be practical, all that is needed to test moisture or water resistance is to partially immerse a coated sample in a glass beaker containing water. The water is maintained at 100°F (37.7°C) for an extended period of time, and the panels are periodically checked for discoloration, whitening, or blistering of the film. The test results are compared to a specification or a standard sample run concurrently. The procedure for this test is ASTM D 870, Standard Practice for Testing Water Resistance of Coatings Using Water Immersion.

SALT FOG TEST

Salt fog resistance is important for marine, automobile, and aircraft coatings and any other exterior coating exposed to salt spray by being near the ocean or exposed to salted road conditions. The severe corrosion caused by salt is well known. The test requires a salt fog cabinet and coated panels. The coating is scored to the bare substrate with a X shape (Fig. 6). The edges are sealed with a weather-proof tape, and the panel is placed in the cabinet for a specified period of time. The metal panels are exposed to the settling fog of an atomized neutral (pH 6.5 to 7.2) sodium chloride solution consisting of 5 parts by weight sodium chloride and 95 parts distilled or deionized water. The sample is then periodically checked to see if the rusted exposed metal has propagated under the coating causing coating failure. As with water resistance, the results are compared to a standard or a specification.

A typical salt spray cabinet as shown in Fig. 7 incorporates a basic chamber, an air saturator tower, a salt solution reservoir, atomizing nozzles, specimen supports, a heater, and controls for maintaining specified temperature. Such chambers are available commercially from several suppliers. The testing procedure, ASTM B 117, Test Method of Salt Spray (Fog) Testing, describes this method in more detail.

Testing Coatings for Heat Resistance and Flame Retardance

56

by Wayne Ellis[1]

HEAT RESISTANCE

WHEN ORGANIC COATINGS are exposed to elevated temperatures, the initial effect is usually softening, followed by hardening, embrittlement, and degradation. The rate of response and the extent of degradation depend on coating composition, temperature, and length of exposure. There is a distinction in the terminology used to define the resistance of coatings to such changes. Below 400°F (200°C), the property is called "thermal resistance," while above that temperature the property is identified as "heat resistance." Both thermal and heat resistance relate not to occasional heating, but to resistance to change from exposure to a constant heat influence over months or years. Special organic coatings can be formulated to provide thermal resistance, such as those designed to protect steel surfaces exposed to elevated temperature during service life. The upper temperature limit for most organic coatings is in the range of 400°F (200°C). In general, inorganic coatings exhibit better heat resistance than organic coatings. A special group of products are thermal protection coatings, including ablative coatings to protect space vehicles during atmospheric re-entry and intumescent coatings that protect wood or other cellulosic surfaces exposed to fire.

Evaluation of heat resistance is carried out on coated specimens exposed to selected temperatures representative of service conditions and later subjected to other exposure conditions to determine susceptibility to loss of protective function.

ASTM Method D 2485

Typical of this kind of testing is ASTM Test Methods for Evaluating Coatings for High-Temperature Service (D 2485). This method provides an accelerated means of determining performance when coatings are exposed to high temperatures. In Method A, for interior service coatings, coated steel panels are heated for 24 h in a muffle furnace at a selected temperature. One panel is plunged immediately into water for thermal shock, while another is cooled and then subjected to a bend test. In Method B, for exterior service coatings, coated steel panels are heated in a muffle furnace at increasing steps of temperature from 400 to 800°F (205 to 425°C). One panel is subjected to salt spray for 24 h, while another is exposed outdoors for twelve months. When test exposures are completed, the panels are examined and evaluated for film degradation including rust formation, blistering, loss of adhesion, dulling, and chalking.

ASTM Method D 1211

Another test method involving temperature exposure is ASTM Test Method for Temperature-Change Resistance of Clear Nitrocellulose Lacquer Films Applied to Wood (D 1211). A common failure of clear films applied to wood is cracking or checking that may occur over a period of time, either with the grain or at an angle to the grain. This "cold check" test is designed to accelerate the occurrence of checks or cracks by cycling at the temperatures of exposure. In this procedure, which constitutes a single cycle, lacquer-coated wood panels are first subjected to a temperature of 120 ± 5°F (48.9 ± 2.8°C) for 1 h, followed by exposure at −5 ± 2°F (−21 ± 1°C) for 1 h, and then a return to room temperature for 30 min. The number of cycles used is a decision by the testing agency.

FLAME RETARDANCE

Terminology

The technical terminology relating to flame retardance must be understood. The general concept concerned is *burning characteristics*. (With one exception [*1*], these standard definitions are found in ASTM Terminology of Fire Standards (E 176). Several interrelated terms are:

- *fire performance test*—A procedure that measures the response of a material, product, or assembly to heat or flame under controlled conditions. A fire performance test allows the quantitative description of one or more fire performance characteristics for the specific fire and other parameters of the test.
- *fire resistance*—The property of a material or an assemblage to withstand fire or to provide protection from it.
- *fire retardancy*—In paint, this is the ability of a paint to retard the spread of flame over a coated substrate, usually at the sacrifice of the paint film.
- *fire-retardant coating*—A fluid-applied surface covering on a combustible material that delays ignition and combustion of the material when the coating is exposed to fire.
- *flame resistance*—The ability to withstand flame impingement or give protection from it.
- *flame-retardant coating*—A fluid-applied surface covering on a combustible material which delays ignition and re-

[1]Deceased, formerly of Harleysville, PA.

Copyright© 1995 by ASTM International

duces flame spread when the covering is exposed to flame impingement.

- *flame-spread index*—A number or classification indicating a comparative measure derived from observations made during the progress of the boundary of a zone of flame under defined test conditions.
- *surface flame spread*—The propagation of a flame away from the source of ignition across the surface of a liquid or a solid.

Rationale for Test Selection

Note the conceptual difference in the definitions between fire-retardant and flame-retardant coating. Testing coatings for burning characteristics may be carried out to compare the response to flame exposure of different specimens or to evaluate the performance under fire conditions. In the former mode, small-scale testing is appropriate. But, while small-scale testing may be useful in preliminary evaluations in the latter mode, large-scale testing is essential if test results are to be used as a measure of performance in fires in buildings or other structures. Small-scale tests are categorized as flame-test standards. Large-scale tests are categorized as fire-test-response standards. Only the latter are appropriate in fire risk assessments. The scale of test is indicated in each of the following test method descriptions.

Tests for Combustibility

ASTM Method E 136

ASTM Test Method for Behavior of Materials in a Vertical Tube Furnace at 750°C (E 136) is a small-scale method designed to identify materials that do not aid combustion or add appreciable heat to an ambient fire. This method is not intended to apply to laminated or coated materials; however, it is useful in evaluating material believed not to be combustible.

Figure 1 shows a cross section of the vertical tube furnace. The specimen, nominally 1.5 in. (38 mm) wide by 1.5 in. (38 mm) thick in cross section with thermocouples attached, is inserted in a furnace controlled at 1382 ± 10°F (750 ± 5.5°C) and held there until temperatures at the specimen thermocouples are at furnace temperature. The standard contains an instructive commentary section describing the rationale for the test, its limitations, and usefulness of the test results. This test method presently does not contain a precision and bias statement.

ASTM Method D 2863

ASTM Test Method for Measuring the Minimum Oxygen Concentration to Support Candle-like Combustion of Plastics (Oxygen Index) (D 2863) is a small-scale method that measures the minimum concentration of oxygen in a flowing mixture of oxygen and nitrogen that will just support flaming combustion. Figure 2 shows the typical equipment layout. Film or thin-sheet test specimens are nominally 2.0 in (52

mm) wide and 5.5 in. (140 mm) long. The minimum oxygen concentration is measured under equilibrium conditions of candle-like burning. The equilibrium is established by the relation between the heat generated from the combustion of the specimen and the heat lost to the surroundings as measured by one or the other of two arbitrary criteria, namely, a time of burning or a length of specimen burned. This point is approached from both sides of the critical oxygen concentration to establish the oxygen index.

While this method is useful for comparing resistance to combustion of organic materials, correlation with burning characteristics under actual use conditions is not implied. *Precision*: In a testing program in which 18 laboratories checked the same five materials, the standard deviation was 0.4 for materials with an oxygen index below 21% and 0.7 to 1.4 for materials with an oxygen index above 21%. Table 1 contains results from another test series. *Bias*: There are no recognized standards on which to base an estimate of bias.

ASTM Method D 1360

ASTM Test Method for Fire Retardancy of Paints (Cabinet Method) D 1360 is a small-scale test method. This procedure measures the relative fire-retardant properties of coatings by determining the weight loss and char index of coated wood panels exposed to flaming ethyl alcohol. It is useful for comparing the burning behavior of coating materials under specified conditions; however, the test results do not always correlate with large-scale spread-of-flame tests, such as ASTM Test Method for Surface Burning Characteristics of Building Materials (E 84). D 1360 is a measure of combustibility, through weight loss, rather than a measure of flame-spread index value. The precision of this method is yet to be determined.

Tests for Flame Spread

ASTM Method D 3806

ASTM Test Method for Small-Scale Evaluation of Fire-Retardant Paints (2-ft Tunnel Method) (D 3806) determines the protection afforded to a substrate by a coating by evaluating the flame spread over the coated surface when the specimen is ignited under controlled conditions in a small tunnel. Figure 3 shows the layout of the 2-ft (610 mm) tunnel apparatus. The test panels are wood, ¼ by 3⅞ by 23⅞ in. (6 by 100 by 605 mm). The tunnel apparatus is calibrated with a zero-flame-spread panel and with another reference panel coated with a paint rated for flame spread by the method of ASTM E 84. A standard gas flame is applied to the lower end of the inclined test panel, and the progress of the flame front upward is observed, measured, and recorded at 15-s intervals. The test results establish a basis for comparing surface-burning characteristics of different coatings without specific consideration of all the end-use parameters that might affect surface-burning characteristics under actual fire conditions.

TABLE 1—Precision results.

Type	Laboratory-To-Laboratory Standard Deviation	Within Laboratory Standard Deviation
B	0.5 to 1.1	Below 0.2
C	0.4 to 1.5	0.1 to 0.3 (est.)
D	0.5 to 1.4	Below 0.6

The method is useful in laboratory comparison of intumescent paint formulations, but large-scale testing by Method E 84 is desirable for correlation with real fire conditions. *Precision*: Table 2 indicates the repeatability of this method. The standard deviation shown relates to the maximum difference that would be expected between duplicate specimens. The degree of repeatability is dependent on the level of flame-spread ratings.

ASTM Method E 162

ASTM Test Method for Surface Flammability of Materials Using a Radiant Heat Energy Source (E 162) is a small-scale procedure, intended for research and development purposes, for measuring the surface spread of flame under exposure to a radiant heat source. Figure 4 shows details of the test equipment. The specimen, which is representative of the material or assembly being evaluated, has dimensions of 6 by 18 in. (150 by 460 mm) by the sheet thickness. It is placed at a downward angle of 30° from the vertical, facing a gas-fired porous refractory heat-radiating surface, 12 by 18 in. (300 by 460 mm), operating at 1238°F (670°C). The rate at which flames travel along the surface depends on the physical and thermal properties of the specimen. The orientation of the specimen is such that ignition is forced near its upper edge and the flame front progresses downward. The time of arrival of the flame front at each of 3-in. (76-mm) marks on the specimen holder is recorded, and observations are made for flashing, dripping, and any other behavior characteristics that appear to be of interest. The maximum temperature rise as indicated by thermocouples in the stack is recorded. The test is completed when the flame front has progressed to the 15-in. (380-mm) mark or after an exposure of 15 min, whichever occurs first, provided the maximum temperature of the stack thermocouples is reached.

A flame-spread index, I_s, is calculated as the product of the flame-spread factor, F_s, and the heat evolution factor, Q. F_s is calculated from a plot of

$$I_s = F_s Q$$

with vertical distance as a function of flame-arrival time at each horizontal mark. The Q factor is calculated from the equation $Q = CT/\beta$, where C is an arbitrary constant, T is the observed maximum stack-thermocouple temperature difference between the temperature-time curve for the specimen and that for a similar curve of a calibration specimen, and β is the mean stack thermocouple rise for unit heat input of a calibration burner. The flame-spread indices determined by this method may be compared with those determined in ASTM Method E 84, although correlation is not necessarily obtained. A precision and bias statement for this method is being developed by ASTM Committee E-5 on Fire Standards.

ASTM Method E 84

ASTM Test Method for Surface Burning Characteristics of Building Materials (E 84) is also called the 25-ft (7.6-m) tunnel test, or the Steiner tunnel test, or the NFPA 255 test. A large-scale test, E 84 is applicable to exposed finishes on ceilings or walls. The test is conducted with the material in a horizontal position with the exposed surface facing downward. The purpose of the test is to determine the relative

burning behavior of the specimen by observing flame spread. The test exposes a nominal 24-ft (7.32-m)-long by 20-in. (508-mm)-wide specimen to a controlled air flow and flaming fire exposure adjusted to spread the flame along the entire length of a reference material (select-grade red oak) in 5.5 min. A photoelectric cell is placed at the vent end to detect and record smoke emission. Figure 5 shows details of the test furnace and the specimen placement.

The specimen is exposed to the standard flame conditions for 10 min or less if the specimen is completely consumed in the fire area and no further progressive burning is evident and if the photoelectric cell reading has returned to the baseline. The flame-spread index (FSI) is determined by calculation from the plotted time-distance curve in relationship to the area under a similar curve for the reference material, select grade red oak. Arbitrarily, red oak is assigned a flame-spread index of 100 and the inorganic reinforced-cement board an FSI rating of zero. The precision and bias of this method has yet to be determined.

Several studies have been conducted to examine the relationship of the flame-spread index (FSI) test results obtained for materials with their behavior in large-scale fire-growth

experiments and with the fire-test response of other laboratory methods. Reports of other comparisons with large-scale experiments can be found in the references to this chapter. Comparisons have also been made between Test Methods E 84, E 162, and D 3894 [*1*].

ASTM Method D 3894

ASTM Test Method for Evaluation of Fire Response of Rigid Cellular Plastics Using a Small Corner Configuration (D 3894) is intended for evaluation of cellular plastics; however, this large-scale test is useful for characterization of the burning behavior of coatings applied to representative substrates. It simulates configurations of two adjacent walls or two adjacent walls and ceiling. It is useful in predicting performance of such materials in a Factory Mutual Laboratories full-scale corner wall test.[2] Figure 6 shows the corner construction of the D 3894 setup. The test configuration provides a critical surface geometry affording a combined heat flux that includes the conductive, convective, and radiative responses of any specific burning material.

The specimen consists of a corner, supported by an outside frame, made from panels each measuring 610 by 1220 by *T* mm (2 by 4 ft by *T* in.), *T* being the thickness of the test panel, and a ceiling section of similar composition measuring 1220 by 1220 by *T* mm (4 by 4 ft by *T* in.). A standard burner is used for ignition. Visual observations are made, and a record of flame-travel distance from the test corner junction outward on the horizontal plane is made at the start of the test and at least every 15 s for the test duration. The test is terminated after 20 min or sooner if the flame becomes uncontrollable. *Precision*: Tables 3 and 4 are based on a round robin involving five materials tested by five laboratories. *Bias*: There are no recognized standards by which to estimate bias of this test method.

[2]For details contact Factory Mutual Research Corp., P.O. Box 09102, Norwood, MA 02062.

Full-Scale Compartment Fire Tests

ASTM Method E 603

At present there is no ASTM standard test method for conducting full-scale room fire tests, although there is considerable experimental activity. ASTM Guide for Room Fire Experiments (E 603) describes full-scale compartment fire experiments designed to evaluate the fire characteristics of materials, products, or systems under actual fire conditions. E 603 is intended as a guide for design of experiments and for the interpretation of the results. The guide may be used to establish laboratory conditions that simulate a given set of fire conditions as realistically as possible.

[d] $l_R = 2.83\ v_R$.

Analysis of data from room fire experiments can serve two purposes: (1) to relate the severity of the room fire experiment to the laboratory-measured fire properties, which establishes empirical relationships that validate the strengths and the weaknesses of the various fire test methods now being used or proposed to control the materials to be used in the rooms; and (2) to evaluate materials and products for acceptability, particularly those materials for which there are no adequate material property tests. This standard contains a detailed rationale for full-scale compartment fire tests. It should be consulted in detail.

Testing Intumescent, Fire-Retardant, and Ablative Coatings

These special-purpose coatings are intended to protect substrates from damage by fire exposure. Intumescent coatings are designed for cellulosic substrates, as fire-retardant coatings for structural steel substrates, and as ablative coatings for the exterior of re-entry space vehicles. See the reference section for more specific references.

Intumescent coatings applied to wood panels are tested for flame-spread index by ASTM E 84. Evaluation of fire-retardant coatings for the protection of structural steel is conducted according to ASTM E 119.

ASTM Method E 119

ASTM Method for Fire Tests of Building Construction and Materials (E 119) is a large-scale fire endurance test applicable to assemblies of masonry units and to composite assemblies of structural materials for buildings, including load-bearing walls and other walls, partitions, columns, girders, beams, slabs, and composite beam and slab assemblies for floors and roofs. It is also applicable to other assemblies and structural units that constitute permanent and integral parts of a finished building.

E 119 is the principal method for evaluating structural integrity of building assemblies under actual fire conditions. It is the method designated in building codes and fire codes to rate structural integrity in fire exposure. The test exposes a full-scale specimen within a standard furnace to a standard fire that is controlled to achieve specified temperatures throughout a prescribed time period. The test measures heat transmission and measurement of load-carrying ability of the specimen during the test exposure. Figure 7 is the time-temperature relationship used in controlling the test. Precision and bias of the method are not stated. Method E 119 has been in wide and continuous use since 1917 for fire rating building assemblies. It has wide acceptance.

There are no standard test methods for ablative coatings. NASA SP 5014 [2] describes the general topic. Thermogravimetric analysis is useful in understanding the effect of high temperature on inorganic as well as organic coatings.

ASTM Method E 1131

ASTM Test Method for Compositional Analysis by Thermogravimetry (E 1131) provides a general technique incorporating thermogravimetry to determine amounts of volatile matter, combustible material, and ash content of compounds. It is applicable, using either an inert or a reactive gas environment, to solids and liquids in the temperature range from room temperature to 1830°F (1000°C). The test method is an empirical technique using thermogravimetry in which the mass of a substance, heated at a controlled rate in an appropriate environment, is recorded as a function of time or temperature.

Historical Methods

The heat and fire test methods described are those most used today in characterizing coatings. Historically, a variety of other bench-scale screening tests have been used, but they are no longer in vogue as they do not relate to actual service

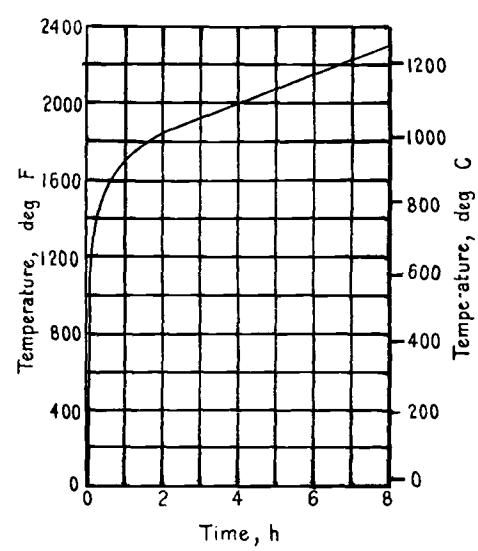

FIG. 7—Time-temperature relationship used for test control.

conditions. Details of the following historical tests may be found in ASTM STP 500 [*3*]: Schulz fire-retardant tester, NJZ box test, stick and wick test, vertical match test, crib test, fire-tube test, SS-A-118 acoustical tile test, Schlyter test, and the 8-ft tunnel test.

Water-Resistance Testing of Coatings

*by Wayne Ellis**

OTHER CHAPTERS IN THIS MANUAL cover the influence of water on the formulation and durability of organic coatings. Recent ASTM publications about the moisture effects in building materials are listed in the Bibliography at the end of this chapter. These publications describe moisture problems and solutions involving coatings and their uses. Although this chapter is intended to describe only the principal testing and evaluation of water resistance, some general remarks may be helpful in understanding the test conditions.

EFFECTS ON COATINGS OF EXPOSURE TO WATER AND WATER VAPOR

The adhesion of coatings to substrates is strongly influenced by the absorption of water and by the permeability of the coating to water vapor. The mechanism of this influence proceeds as follows:[1]

1. Absorption of water molecules in the coating film.
2. Inclusion of water in the interface between film and substrate.
3. Blister formation.
4. Corrosion/erosion of the substrate.
5. Flaking or peeling of the film.

Although there is no fixed relationship between water absorption and water vapor permeability, generally the higher the water absorption the more permeable the film is to water vapor. Normally the permeability measurements are made on freshly applied films. It should be noted that with progressive aging and weathering, films become more cross-linked, and in the case of water-sensitive binders, the water-soluble additives are washed out by exposure to rain and dew. Hence such films will show decreasing permeability with time.

Water resistance is defined by ASTM as "measured ability to retard both penetration and wetting by water in liquid form".[2] Nearly always it is a required property for coatings. Water resistance generally is measured on specimens of coatings applied to nominally impermeable substrates such as metal, wood, or masonry. (Water vapor permeability, on the other hand, is evaluated on free films.) Water resistance may be evaluated as part of other test regimes, such as exposure testing, water repellency, corrosion, chemical resistance, salt-fog resistance, and cycling tests such as humidity-cycling and light-and-water-exposure testing.

TRADITIONAL TEST METHODS

Spot tests and immersion tests of coatings applied to substrates traditionally have been used as "quick and dirty" techniques to compare specimens. Criteria for evaluation include softening, blistering, solvation, color change, loss of adhesion, and rusting or other deterioration of the substrate. These observations should lead to further and more comprehensive testing related to intended conditions of product use. Such testing may include exposure to controlled condensation, 100% relative humidity, or water fog to evaluate moisture blistering resistance. Even more intensive testing may involve washability and scrub resistance.

SPECIMEN PREPARATION

Careful preparation of coated specimens is essential to assure a proper and meaningful relationship to field exposure and to avoid false test results. The substrate composition and surface preparation, specimen preparation, and the number of specimens should be agreed upon between involved parties prior to testing. Applicable methods for the preparation of test panels are given in ASTM Methods D 609,[3] D 1734,[4] and Practices D 1730.[5] Test Methods D 823[6] cover application techniques for the production of uniform films.

IMMERSION TESTING

ASTM Practice for Testing Water Resistance of Coatings Using Water Immersion (D 870) describes basic principles

and operating procedures for testing water resistance of coatings by the partial or complete immersion of coated specimens in distilled or demineralized water at ambient or elevated temperatures. Coated specimens are partly or wholly immersed in water in a container that is resistant to corrosion. The exposure conditions are varied by selecting the temperature of the water and the duration of the test.

Failure may be caused by a number of factors, including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation. Any effects such as color change, blistering, loss of adhesion, softening, or embrittlement are observed and reported. These test results typically are a pass or fail determination, but the degree of failure also may be measured.

WATER FOG TESTING

ASTM Practice for Testing Water Resistance of Coatings Using Water Fog Apparatus (D 1735) covers the basic principles and operating procedures for testing water resistance of coatings in an apparatus similar to that used for salt spray testing.[7] The apparatus required consists of a fog chamber (Fig. 1), a water reservoir, a supply of suitably conditioned compressed air, one or more atomizing nozzles, specimen supports, provision for heating the chamber, and necessary means of control. Coated specimens are placed in an enclosed chamber where a water fog surrounds them. The temperature of the chamber is usually maintained at 100°F (38°C). The exposure condition is varied by selecting the duration of the test.

Failure in water fog tests may be caused by a number of factors, including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation. Any effects such as softening (measured by pencil hardness), color change, gloss change, blisters, loss of adhesion, embrittlement, and rusting or corrosion of substrate are observed and reported.

100% RELATIVE HUMIDITY TESTING

Practice for Testing Water Resistance of Coatings in 100% Relative Humidity (D 2247) covers the basic principles and operating procedures for testing water resistance of coatings by exposing coated specimens in an atmosphere maintained at 100% relative humidity so that condensation forms on the

specimens. The apparatus (Fig. 2) consists of a test chamber, a heated water tank, and suitable controls. Heated water vapor is generated at the bottom of the chamber, causing saturation of the air immediately above the water tank. As the saturated mixture rises, it cools below the dew point temperature, causing condensation on the specimens suspended above. Condensation is uncontrolled. (For testing at 100% RH with controlled condensation, see ASTM D 4585, described below.)

Effects of exposure at 100% relative humidity may be color change, blistering, loss of adhesion, softening, or embrittlement. Any such effects are observed and reported. They may be caused by a number of factors including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation.

CONTROLLED CONDENSATION TESTING

Practice for Testing Water Resistance of Coatings Using Controlled Condensation (D 4585) differs from D 2247 in that the coated specimens are mounted with the uncoated face exposed to room temperature air. The apparatus (Figs. 3 and 4) consists of a test chamber in which the specimens form the roof of a chamber that is fitted with suitable water supply and controls.

Water vapor is generated by heating a pan of water at the bottom of the test chamber. The specimens form the roof or walls of the test chamber so that the back sides of the specimens are exposed to the cooling effects of room temperature air. The resulting heat transfer causes water vapor to condense on the coated specimens as liquid water saturated with

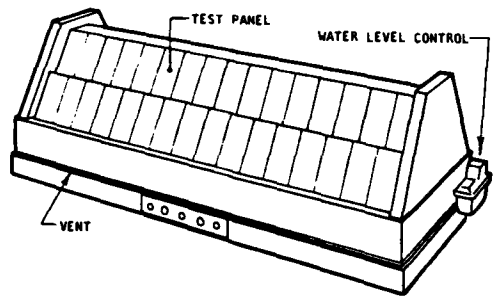

FIG. 3–Controlled condensation apparatus (Fig. 1 of ASTM D 4585).

air. The temperature and amount of condensate forming on the specimens are controlled by the test temperature and room temperature.

The specimens are inclined so that the condensate runs off the test surface by gravity and is replaced by fresh condensate in a continuous process during the condensate cycle. Exposure conditions are varied by selecting the temperature of the test, the duration of the test, and periodic drying of the specimens. Failure may be caused by a number of factors including a deficiency in the coating itself, contamination of the substrate, or inadequate surface preparation. Any effects such as color change, blistering, loss of adhesion, softening, or embrittlement are observed and reported.

CYCLE TESTING

Test Method for Finishes on Primed Metallic Substrates for Humidity-Thermal Cycle Cracking (D 2246) covers an accel-

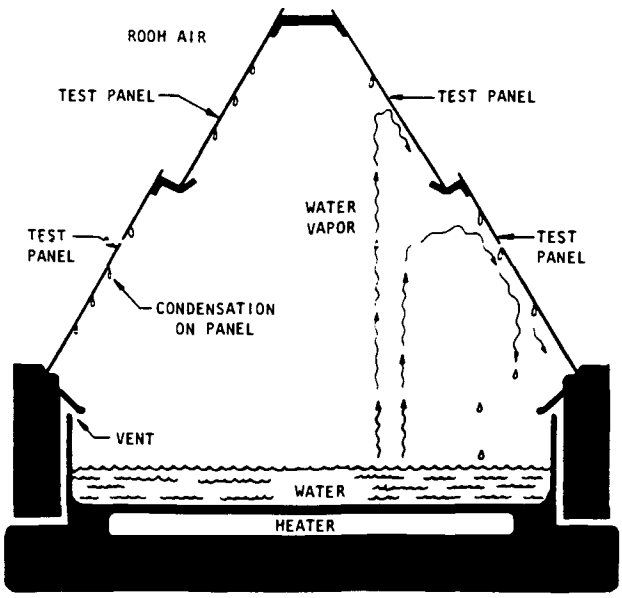

FIG. 4–Apparatus and cross section (Fig. 2 of ASTM D 4585).

erated means for determining the tendency of an organic coating to fail by cracking when exposed to humidity-thermal cycling. It is evaluated by alternate exposure of prepared specimens in a cabinet maintained at 100°F (38°C) and 100% relative humidity (with continuous condensation on the specimens), then in a cold box at −10°F (−23°C), allowing only a maximum of 30 s for transfer. Specimens are rated (using a grid overlay) by counting the number of grid squares within which one or more cracks is visible. Evaluation before and after exposure may be done for checking (D 660[8]), for cracking (D 661[9]), for erosion (D 662[10]), and sometimes for water beading (D 2921[11]).

ASTM Test Method for Humid-Dry Cycling for Coatings on Wood and Wood Products (D 3459) is a procedure for evaluation of coatings designed for use on interior wood and wood products by exposure alternately to low and high humidity at an elevated temperature. Test panels having a minimum area of 12 by 12 in. (300 by 300 mm) are exposed in 48-h cycles in exposure chambers maintained at 97 ± 2% relative humidity and 122 ± 3.5°F (50 ± 2°C); the other chamber maintained at 50 ± 5% relative humidity and 73.5 ± 3.5°F (23 ± 2°C). At each change of conditions during cycling, the panels are inspected under strong light for possible damage or change, which may be in the base material or in the coating.

Testing for the effect of water exposure combined with other exposures is not described in this chapter. Such testing includes light-and-water exposure apparatus using carbon-arc ultraviolet,[12] Xenon-arc,[13] and fluorescent UV.[14]

Part 13: Specific Product Testing

Aerospace and Aircraft Coatings

58

by Charles R. Hegedus,[1] Stephen J. Spadafora,[2] David F. Pulley,[2] Anthony T. Eng,[2] and Donald J. Hirst[2]

ORGANIC COATINGS ARE PRIMARILY applied to aircraft for environmental protection and appearance. Reference *1* concludes, "The rate controlling parameter for the corrosion of aircraft alloys, excluding the mechanical damage factor, is the degradation time of the protective coating system." This clearly indicates the importance of the coating system's durability and its ability to control corrosion and erosion. Relative to appearance, commercial aircraft benefit from the aesthetic characteristics of the coating system, while military aircraft rely on camouflage properties to minimize enemy detection and tracking during mission operations.

To meet operational requirements, aircraft coating systems traditionally consist of a primer and a topcoat. Primers inhibit corrosion of the substrate and enhance adhesion of subsequent topcoats, while topcoats are applied for appearance and to enhance overall durability of the coating system. Self-priming topcoats, which perform as both primer and topcoat in a single coating, have recently been introduced [*2,3*]. In addition, specialty coatings are strategically applied to perform various functions such as protection against rain erosion, chafing, immersion in fuel, and high temperature. References *4* through *6* provide more detail on the formulation and properties of aircraft coatings.

A number of factors affect the performance of aircraft coatings, including the substrate material, the aircraft's operational environment, and flight conditions. Aircraft structures and skins are manufactured from numerous metallic alloys and polymeric composites with a variety of pre-paint treatments, thus complicating the adhesion and corrosion inhibition characteristics of the coating system. Environmental conditions also can vary dramatically (arctic, tropical, marine, industrial, desert, etc.). Skin temperatures during flight can range from −54 to 177°C (−65 to 350°F) while ground conditions may be relatively benign or highly corrosive. Aircraft type and mission also play important roles in coating system performance. A commuter aircraft that hops from island to island in the tropics sees frequent pressurization and depressurization along with high temperature, humidity, and salt water. In contrast, a military tactical aircraft may fly far fewer hours but will experience extreme structural loads during flight conditions. These flight conditions place environmental and mechanical stresses on the aircraft coating system. Therefore, selection of appropriate test and evaluation procedures is an essential component for determining acceptable coatings for aircraft application.

VISCOSITY

The viscosity of aircraft coating components, component mixtures, and raw materials is valuable to the formulator, manufacturer, and applicator for assessment of rheological characteristics. These characteristics affect paint application properties such as atomization, leveling, sagging, and brushability.

Cup Methods (Cup Viscometers)

In aircraft coating specifications and at application sites, Zahn and Ford cup viscometers are used for admixed paints because they are inexpensive, easy to use and maintain, and produce practical quantitative data. Although the stand-mounted, standard Ford cup is more accurate due to its stability, deeper capillary orifice, and larger volume, the dip-type Zahn cup is preferred since it is easiest to use and maintain. Zahn and Ford viscometers are described in ASTM Test Method for Viscosity by Dip-Type Viscosity Cups (D 4212) and ASTM Test Method for Viscosity of Paints, Varnishes, and Lacquers by Ford Viscosity Cups (D 1200), respectively.

Brookfield and Stormer Methods

Brookfield and Stormer viscometers are rotation-type viscometers described in ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D 2196) and ASTM Test Method for Consistency of Paints Using the Stormer Viscometer (D 562), respectively. The Brookfield viscometer, which measures absolute viscosities in centipoises (cP) using a rotating spindle, is particularly effective in determining viscosities of non-Newtonian fluids due to its ability to measure shear stress (that is, torque of rotating spindle) at various speeds and shear rates. Since the cup viscometers described above offer relative simplicity and ease of use, the Brookfield viscometer is not used at application sites. However, it is frequently used as a research tool to characterize the viscosities of polymeric resin materials and dispersions.

The Stormer or Krebs-Stormer viscometer uses a rotating paddle to measure relative viscosity expressed in Krebs units.

Copyright© 1995 by ASTM International

It is designed to provide controlled, uniform, and relative data based on a paddle-stirring motion. This type of viscometer is rarely used in the laboratory or required in current specifications due to the ease of use and maintenance of cup methods and to the accuracy of the Brookfield method.

DENSITY

Wet coating density measurements provide a check on the theoretical density value and on the uniformity of the manufactured product. Determination of density by any convenient or suitable method in this Manual is acceptable; however, a weight-per-gallon cup is normally used due to the ease of use of this instrument.

FINENESS OF GRIND AND COARSE PARTICLES

Fineness of grind and presence of coarse particles are determined to assess the quality and uniformity of the pigment dispersion and coating finish. In order to produce a high gloss coating of good appearance, a paint should be free of coarse particles. However, the extremely low gloss requirements of some aircraft camouflage paints require relatively large particle sizes. Fineness of grind is determined by ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems (D 1210), commonly referred to as the Hegman scale. The coarse particle content is determined by the weight retained on a 325-mesh sieve as specified in ASTM Test Methods for Coarse Particles in Pigments, Pastes, and Paints (D 185).

SOLIDS AND VOLATILE CONCENTRATION/ CONTENT

General

Several analysis techniques are used to determine the total solids, pigment concentration, and volatile concentration of aircraft coatings. This information can be used as a check on the coating composition when compared to the theoretical value as determined from the formulation. It can also be used to determine the quality of an as-received product and its potential surface coverage per volume of paint. In addition, restrictions on the volatile organic compounds (VOC) content of coatings increase the importance of determining the volatile concentration, and methods to determine this value are continuously being developed and refined. The following methods are currently used to determine these compositional properties for aircraft coatings.

Total Solids Content

The total solids content of a coating, often referred to as its nonvolatile content, is a measure of the combined polymer and pigment content in a paint. It is typically represented as the weight fraction or percentage of these "solid" components relative to the as-received "wet" coating. For aircraft coatings, this is determined by subtracting the volatile fraction of the coating from the total to determine the nonvolatile content. The method specified in ASTM Test Method for Volatile Content of Coatings (D 2369) is used. A method that provides a volumetric assessment is ASTM Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D 2697).

Pigment Concentration

Three methods are available to determine the pigment weight concentration within a coating: ASTM Test Method for Determination of Pigment Content of Solvent-Type Paints by High Speed Centrifuging (D 2698); ASTM Practice for Separation of Vehicle from Solvent-Reducible Paints (D 2372); and Federal Standard 141 Method 4021, Pigment Content (Ordinary Centrifuge). These methods use the fact that pigment particles, generally being more dense than the vehicle, will settle under centrifugal force. One distinction between these methods is the variation in rinsing solvent(s) used to separate the polymer from the pigment. Although each method utilizes a different solvent blend, it is common to deviate from the specified method by using solvents which are appropriate for the specific paint under analysis. All three methods result in a quantitative determination of pigment weight concentration in the paint; however, the latter two methods lend themselves to chemical analysis of the pigment sample after this determination.

Volatile Concentration

ASTM D 2369 is a standard experimental method to determine the total volatile content of a coating. In contrast, ASTM Practice for Volatile Organic Compound (VOC) Content of Paints and Related Coatings (D 3960), offers a method of calculating the VOC using the nonvolatile content, the water content (if any), and the density of the coating. These latter values are predetermined using referenced ASTM methods, and they are subsequently used in the calculations to determine VOC of the paint. It should be noted that in solvent-borne coatings the VOC is the volatile content; however, water-borne coatings obviously have a nonorganic volatile component which must be taken into account when performing these calculations. The VOC is typically recorded in units of grams of organic volatiles per liter of paint with pounds per gallon used as an alternate.

Chemical Analysis

A variety of methods are used to analyze the chemical composition of aircraft coatings and their components. The specific technique which is selected is determined by the material being analyzed and the level of quantitative or qualitative data required. Some of the more common techniques to analyze polymer and solvent systems are gas chromatography, infrared and ultraviolet spectroscopy, and nuclear magnetic resonance (NMR). Atomic absorption and X-ray spectroscopy are common techniques for determining the chemistry of inorganic pigments. Table 1 provides some of the common ASTM methods used to analyze aircraft coatings.

TABLE 1—Analytical methods for aircraft paint components.

Compound	ASTM Method
Ketones	D 2804: Test Method for Purity of Methyl Ethyl Ketone by Gas Chromatography
Isocyanate	D 3432: Test Method for Unreacted Toluene Diisocyanates in Urethane Prepolymers and Coating Solutions by Gas Chromatography
Water	D 4017: Test Method for Water in Paints and Paint Material by Karl Fischer Method
Lead, Cadmium, and Cobalt	D 3335: Test Method for Low Concentrations of Lead, Cadmium, and Cobalt in Paint by Atomic Absorption Spectroscopy
Chromium	D 3718: Test Method for Low Concentrations of Chromium in Paint by Atomic Absorption Spectroscopy

Because of growing concerns over potentially toxic materials, restrictions are being placed on the lead and chromium content of many aircraft paints. These restrictions are in direct conflict with corrosion control requirements since chromate salts, such as strontium chromate, barium chromate, and zinc chromate, have been shown to be excellent corrosion inhibitors for many metals. Therefore, many specifications require analysis for these pigments to ensure either their presence or their absence. Specific methods to determine lead and chromate content are listed in Table 1.

STORAGE STABILITY

General

The effects of long-term storage on aircraft coating performance are a major concern. Long durations of time and extreme temperatures can have drastic effects on the chemical and physical nature of paints, causing them to have different properties than when they were originally manufactured. Since many aircraft manufacturing, rework, and maintenance activities have paint storage facilities which have only moderate environmental controls, determining the effects of these conditions is necessary. Of primary importance are chemical stability and pigment dispersion. These properties are assessed in the laboratory following long-term and accelerated storage conditions.

Long-Term Evaluation

Methods typically used for determination of stability of aircraft coatings are specified in ASTM Test Method for Package Stability of Paint (D 1849), and Federal Test Method Standard (FTMS) 141 method 3022.1, Storage Stability (Filled Container). In these methods, the packaged coating is allowed to sit undisturbed at ambient conditions for an appropriate period of time. (One year is typical for aircraft coatings.) At that time, the coating is reevaluated to compare its physical and optical properties with those originally found for the as-manufactured material. Other methods may be used to evaluate specific aspects of the material at that time, such as FTMS 141 method 3011.2, Condition in Container, method 3021.1, Skinning, or method 4208, Evaluating Degree of Settling of Paint. In most cases, it is essential that: (1) the paint be free from skinning, (2) the pigment has not reagglomerated or formed a compacted cake at the bottom of the container and it can be easily redispersed to form a consistent mixture, and (3) the applied coating has properties similar to when it was manufactured.

Accelerated Conditions

To speed the evaluation of a coating's behavior under storage conditions, methods have been devised to accelerate this behavior by subjecting the coating to extreme conditions. One common example is specified in FTMS 141 method 3019.1, Storage Stability at Thermal Extremes, which subjects the coating to 49°C (120°F) or −12°C (10°F) for 168 h, depending on the type of storage suspected. Methods involving cyclic exposure to high and low temperatures have also been used. With the development of high-performance waterborne coatings for aerospace applications, one major concern is the freeze-thaw stability of these coatings. ASTM Test Method for Freeze-Thaw Resistance of Water-Borne Paints (D 2243) is used to evaluate coating consistency and performance after 17 h at −18°C (0°F).

Another technique for predicting storage stability of coatings is by evaluating the settling properties of pigments under accelerated conditions. Aircraft coating specifications rarely contain this type of evaluation; however, centrifugation is often used as a research tool to evaluate the tendency of various pigments to settle and compact in specific vehicles. The centrifugal force and the duration are selected on a case by case basis to ascertain differences between systems.

FLASH POINT

General

The flash point of a coating is the minimum fluid temperature at which the solvent vapors are ignited by a spark or flame. It can be predicted roughly as the weighted average of the individual flash points for each of the solvents in a coating formulation. The closed-cup technique is generally preferred since container breakage during shipment and storage often leads to flammable vapors being trapped in a confined space. Naturally, these flash points tend to be lower than the corresponding open-cup values.

Pensky-Martens

The Pensky-Martens test is a closed-cup method that can be conducted on an admixed coating or on one of the separate components in the liquid (uncured) state. The material may be refrigerated to bring it to a temperature below the expected flash point. It is then placed in a closed metal cup, heated slowly while stirring, and periodically exposed to a pilot flame through a shutter mechanism. A thermometer immersed in the fluid measures the coating temperature. The flash point is the minimum temperature at which the solvent vapors ignite,

yielding a large flame that propagates over the surface of the fluid. The procedure is covered in ASTM Test Methods for Flash Point by Pensky-Martens Closed Tester (D 93), Method A for clear coatings and Method B for pigmented coatings.

Setaflash

The Setaflash test uses an enclosed apparatus with automatic controls to determine the flash point. It is easier to operate than the Pensky-Martens tester and utilizes an electric heater for efficient heat transfer and greater accuracy. ASTM Test Methods for Flash Point of Liquids by Setaflash-Closed-Cup Apparatus (D 3278), Method B describes the test procedure.

Tag

The Tag tester is similar to Pensky-Martens, except that the cup is placed in a bath containing a mixture of water and ethylene glycol. Only coatings with no suspended solids (such as, fillers) can be evaluated. ASTM Test Method for Flash Point by Tag Closed Tester (D 56) is the applicable test method.

POT LIFE

Pot life is the length of time in which the flow properties (such as, viscosity) of catalyzed paints will not change within an acceptable range for application. Acceptable coating conditions can vary from no change up to gellation. Pot life requirements in the aerospace industry tend to be controlled by production limitations. Since a normal production work shift is 8 h, many paints have been required to have a pot life spanning this period. More recently, restrictions on the volatile organic content compounds (VOC) of paints have resulted in high solids coatings which tend to inherently possess higher viscosity and shorter pot life (2 to 6 h). Pot life of aircraft coatings is usually determined by measuring viscosity as a function of time after mixing the paint for application. Substantial increases in viscosity are an indication that the pot life is nearly expended.

It should be noted that the issue of pot life can be circumvented via the use of plural-component spray equipment, which is becoming more common in the production painting of aircraft. This equipment stores the various components of a multi-component paint separately and then mixes those components at the desired ratio immediately before or at the spray gun. This equipment not only negates pot life as a factor but also minimizes the amount of catalyzed multi-component paint that is wasted due to unused material. The only drawback is that this equipment is most effectively and efficiently used when large volumes of paint (5 gal or more) are used as opposed to small quantities (1 gal or less), which are typical of touchup maintenance operations.

DRYING TIME

ASTM Test Method for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature (D 1640) defines drying times of paint films. As many as eight stages of the paint drying process are recognized by coatings authorities. Determination of a particular set of drying properties is important for aerospace coatings due to the strict time and processing constraints placed on production and maintenance painting facilities. No particular drying time parameters are universal throughout the aircraft industry. Each paint facility has acceptable limits for these drying properties depending on their function, schedule, and climatic conditions. For example, set-to-touch time may be more important to a small parts shop where components are handled shortly after painting. In contrast, dry-hard times may be paramount at a production facility for painting entire aircraft that must be flown shortly after painting.

Set-to-Touch

A film is set-to-touch when it clings weakly to the finger under gentle pressure but none of the film transfers to the finger. This property indicates that the painted piece can be handled gently, but excessive contact will diminish the quality of the coating. This property may be considered important to shops painting small aircraft components which must be moved from the application area.

Tack-Free

Basically, tack is the tenacity of the film to cling to foreign objects. This component of drying is not considered of major importance in production painting; however, it may be used to ascertain the overall drying characteristics of a coating.

Dry-to-Recoat

This stage of drying is considered to be the most important for painting of aircraft because it is one of the major factors controlling the production rate. Dry-to-recoat is the time at which a second coat, or specified overcoat (such as, topcoat), can be applied without developing irregularities in the coating system, such as lifting, blistering, or loss of adhesion. If overcoated prior to the recoat time, these defects can be caused by a number of factors, one of which is the trapping of solvent in the original coat.

Dry-Hard

The most common technique is to squeeze or pinch the coated surface with the thumb and forefinger with maximum pressure. The dry-hard time is when this procedure can be performed without leaving a permanent mark on the coating surface. This drying stage is also important in production painting of aircraft since painting is usually the last stage of maintenance and the aircraft can be flown after the coating is dry-hard.

FILM THICKNESS

Aircraft coatings are developed and manufactured to be applied within acceptable thickness limits. Coatings which are applied outside of these limits will not exhibit their opti-

mum performance properties. For example, thin coatings may not have the required tensile and shear strength, making them susceptible to cracking and chipping, especially around fastener heads and at panel seams. In contrast, coatings which are too thick may lack flexibility and can exhibit excessive internal stresses. Another important consideration is the excessive weight that coatings add to an aircraft, causing additional fuel consumption. Therefore, coating thickness is diligently controlled and measurements are performed in both the wet and dry states.

Wet coating films are checked for thickness during aircraft application processes using various wet film thickness gages according to ASTM Test Method for Measurement of Wet Film Thickness of Organic Coatings (D 1212). A tooth gage is commonly used in the aerospace industry since it is simple to use, inexpensive, and can be used to obtain good approximations of dry film thickness. These approximations are made by multiplying the wet film thickness by the coating volume percent solids.

The thickness of cured aircraft coatings can be determined either destructively or nondestructively. Destructive methods involve the chipping or cutting of dry films from a substrate and subsequent measurement of the coating thickness with a gage. This approach is typically not taken for aircraft coatings since the coating-substrate bond must be destroyed. Nondestructive techniques include micrometer, eddy current, magnetic induction, and a magneto-resistor/thermistor system. These are the most desirable methods of dry film thickness determination used in the aerospace industry, both in the field and in the laboratory due to their accuracy and ease of use. One problem encountered is that aircraft are constructed of a number of types of materials. Therefore, the method used to determine coating thickness may depend on the substrate material, especially if a nondestructive method is used.

OPTICAL PROPERTIES

General

The appearance of an applied coating is determined by a number of optical properties (color, gloss, opacity, etc.). In the commercial aerospace industry, where public opinion is a consideration, these optical properties can strongly affect the initial impression of the aircraft and are considered to be important with respect to customer recognition. The optical properties of coating systems for military aircraft affect the detectability of these aircraft and thus effect their survivability in potentially threatening scenarios. In both the commercial and military sectors, optical properties are specified with strict tolerances and are closely monitored with instrumentation as well as with the naked eye.

Color

The colors used on commercial aircraft tend to be strong and vibrant for recognition and attraction. The colors of military aircraft coatings are empirically selected in order to achieve either theater-specific (desert, forest, arctic, etc.) or multi-theater (world-wide) camouflage paint scheme requirements. In either case, paint color is considered to be important. In addition, color change is often used to assess the effects of environmental exposure (weathering, immersion in fluids, etc.) on aircraft coatings. Means of characterizing aircraft coating colors range from qualitative visual assessment to quantitative measurements with instruments, the latter providing the obvious advantage of consistent, numerical results. For the latter, ASTM Test Method for Calculation of Color Differences from Instrumentally Measured Color Coordinates (D 2244) is followed, resulting in a color description in either the XYZ or Lab color coordinates. Color differences, as qualified by a delta E value, are determined by using these color coordinates as described elsewhere in this manual to determine delta E.

One additional note must be made with respect to color measurement of aircraft coatings. Colorimeters and spectrophotometers can both be used to quantitatively measure color. Colorimeters use a specified light source with defined radiation wavelengths and intensities, typically resulting in a direct output of XYZ and/or Lab color coordinates. Spectrophotometers measure light reflected from the coating surface over an entire wavelength region. (In the case of color characterization, this is the visible region of the spectrum.) Of the two, colorimeters are less expensive and easier to use. However, colorimeters do not account for metamerism. Metamerism is a phenomenon that occurs when an object appears to be different colors under different light sources. This effect is observed with some coatings for military aircraft, which use unconventional pigments to obtain camouflage properties. In order to confirm that two colors are the same, their total reflectance over the entire visible spectrum must match. These data are obtained using a spectrophotometer. In addition, spectrophotometers are frequently used for military aircraft coatings to determine their reflectance characteristics outside of the visible region, most commonly the infrared and ultraviolet regions.

Opacity (Contrast Ratio)

Opacity or hiding power is the ability of a coating to mask the underlying substrate. Opacity of aircraft coatings is usually quantified by its contrast ratio according to ASTM Test Method for Hiding Power of Paints by Reflectometry (D 2805). In this method, the coating is applied over white and black substrates. (Contrast ratio or Leneta charts are typically used.) A colorimeter is used to measure the coating's luminous reflectance (Y) on the black and white surfaces. Contrast ratio is then determined by:

$$\text{Contrast ratio} = Y(\text{black})/Y(\text{white})$$

Contrast ratio is a function of coating dry film thickness. The method must define the coating thickness at which the contrast ratio is determined; 2.0 mils is common for aircraft topcoats. Applying a coating to a precise thickness is difficult and may require several attempts. An alternative approach is to determine the contrast ratio at several coating thicknesses and subsequently fit the data to a quadratic equation. This equation can then be used to determine the contrast ratio at the desired coating thickness.

Reflectance and Gloss

Incident light which is reflected from a surface has two components, specular and diffuse. Specular reflectance or gloss represents light that has been reflected off a surface when the angle of incidence equals the angle of viewing. Diffuse reflectance is light reflected in all directions other than specular. Specular reflectance data are usually obtained via glossmeters whereas diffuse reflectance data are obtained by the use of goniophotometers.

Gloss of aircraft coatings is measured by instruments that have been standardized to either 60° or 85° incident angles according to ASTM Test Method for Specular Gloss (D 523). Commercial aircraft coatings have high gloss and are usually characterized at 60°. In contrast, many military aircraft are painted with low gloss coatings for camouflage purposes. In addition to gloss analysis at 60°, military coatings are also analyzed at 85° in order to minimize glare at grazing angles.

Directional reflectance represents the optical data that are obtained from analyzing reflected diffuse light. This type of data are normally obtained via goniophotometric equipment. Several methods describe procedures for these measurements, including ASTM Test Method for Directional Reflectance Factor, 45 deg, 0 deg, of Opaque Specimens by Broad-Band Filter Reflectometry (E 1347) and Practice for Goniophotometry of Objects and Materials (E 167). The use of diffuse reflectance of aircraft coatings is typically limited to those for tactical military functions which require camouflage properties.

ADHESION

General

For aircraft coatings to provide maximum protection against degradation, they must firmly adhere to their substrate. Because of the complex nature of adhesion, various techniques have been devised to determine the adhesive characteristics of coatings. Since a coating's adhesion to its substrate can be significantly affected by environmental conditions, these tests are often performed after exposure to accelerated conditions such as immersion in water at elevated temperature. Common adhesion tests used to evaluate aircraft coatings are tape and scrape tests. Other techniques, such as mechanical peel, tensile, and shear tests, are used less frequently.

Tape Tests

Adhesion tape tests are described in ASTM Test Methods for Measuring Adhesion by Tape Test (D 3359). These are the easiest and most versatile of the adhesion tests because they can be conducted in both laboratory and field environments. Tape tests are performed by cutting through the applied coating, into the substrate. A variety of scribe patterns can be used. One common pattern (described in the "A" method of D 3359), which is used to evaluate aircraft coatings, is two scribes forming an "X." An alternative pattern (described in the "B" method of D 3359), is formed by scribing eleven parallel lines through the coating, followed by a second set of eleven lines which are perpendicular to the first set. These scribe lines create a matrix of 100 squares. Adhesive tape is firmly applied over the scribe area and is subsequently removed with a quick upward motion. Coating adhesion is then characterized using standard ratings for the amount of coating removed according to the ASTM method.

As mentioned above, the coated specimens can be subjected to a specific environment prior to testing adhesion characteristics. This practice is most commonly performed with the tape tests. A typical exposure for aerospace coatings is a 24-h immersion in water at 21°C (70°F). More severe exposures are becoming common as coating technology advances. One example is immersion in water at 65°C (150°F) for seven days. Immediately upon removal from the water, the coating is scribed and tested.

Scrape Adhesion Test

The scrape adhesion test is described in ASTM Test Method for Adhesion of Organic Coatings by Scrape Adhesion (D 2197). Scrape adhesion is used to characterize the adhesive and shear strength properties at the primer-substrate interface. The instrument used for this test is the Gardner Labs Scrape Adhesion Test Apparatus (Model SG-1605). The specimen for this test has an area which is uncoated with the substrate exposed. The test is performed by guiding a weighted stylus at a 45° angle to the specimen along the exposed substrate into the coating system. The scrape adhesion value is recorded as the heaviest weight used without shearing the coating from the substrate. Typical scrape adhesion values for aerospace primers fall into the 3 to 5-kg range.

The scrape adhesion test is also used to determine the intercoat adhesion between a topcoat and a primer. When testing this property, a specimen with a section of primer exposed is used and the stylus is guided across the primer into the topcoat. Typical scrape adhesion values for aerospace topcoats also fall into the range of 3 to 5 kg. This test can also be performed after exposure to severe environmental conditions.

Peel and Tensile Tests

Peel test methods are rarely used for aircraft coatings. Instead, a modified version of an adhesive peel test is occasionally used. In this test, two thin metal strips are bonded together using the coating as the adhesive. One end of the specimen is left unbonded, and the metal strips at this end are separated to form a "T." They are subsequently pulled apart in a tensile machine, and the force needed to pull the two strips apart is recorded as the adhesive peel strength of the coating. The type of failure (adhesive or cohesive) is also recorded. An adhesive failure indicates that the coating strength exceeds that of the coating-substrate adhesive strength.

The most common tensile adhesion test used on aerospace coatings is a tensile pull-off test, also referred to as a button test. In this test, a flat head paten is bonded to the surface of the coating with an adhesive. A tensile force is then applied to the paten perpendicular to the coating surface until the paten is removed. The location at which the paten is removed from the surface must be carefully examined. In many cases, the adhesive which bonds the paten to the coating will fail or the coating may fail cohesively. In these cases, it can only be

stated that the adhesive strength of the coating exceeds the tensile strength recorded. Only if the coating fails adhesively is the recorded tensile strength that of the coating-substrate adhesion.

FLEXIBILITY

General

Flexibility is an important property for aerospace coatings, particularly at low temperatures (−51°C), which is common for aircraft cruising at high altitudes. Cracking of coatings at skin joints and around fastener heads can lead to corrosion of exposed areas. Corrosion inhibiting epoxy primers used on aircraft tend to be brittle and exhibit poor flexibility, whereas the urethane topcoats are generally more flexible, especially at low temperatures. Sealant materials and elastomeric primers occasionally are used to improve the overall flexibility of the paint system.

Mandrel Bend

The flexibility of high-performance coatings is commonly characterized by the mandrel bend test method outlined in ASTM Test Methods for Mandrel Bend Test of Attached Organic Coatings (D 522). This test is normally conducted at low temperatures such as −51°C and is performed by bending a painted specimen 180° around mandrels of various diameters with the coating aligned away from the mandrel. After allowing the specimen to return to room temperature, the coating is examined for cracking along the bend. The smallest (most severe) mandrel diameter which the coating can withstand without cracking is recorded. One standard military specification requirement for this test on low gloss coatings is a 2-in. mandrel bend while more flexible coatings can withstand mandrel bends of ⅛ to ¼ in. at low temperatures without cracking.

Impact Tests

The most universal test for measuring impact flexibility of aerospace coatings is Method 6226 (G.E. Impact) of Federal Test Method Standard 141B. The test apparatus consists of a solid steel cylinder weighing 1.69 kg (3.7 lb) which has spherical knobs protruding from the end. These knobs are designed such that the coating system is subjected to elongations of 0.5, 1, 2, 5, 10, 20, 40, and 60%. The impact is accomplished by allowing the steel cylinder to fall freely from a height of 1.05 m (42 in.) through a hollow cylinder guide, striking the reverse uncoated side of the specimen. The imprints formed from the knobs are examined, and the impact elongation is recorded as the highest deformation without cracking of the coating. A standard requirement for this test on aircraft top coats is 20% elongation.

Another commonly used test is the Gardner impact test specified in ASTM Test Method for Resistance of Organic Coatings to the Effects of Rapid Deformation (Impact) (D 2794). This test is performed in a similar fashion to the G.E. impact test described above; however, the weighted cylinder has a rounded end and is dropped from various heights. The weight of the impact cylinder and the highest height that causes no cracking or disbondment of the coating are used to calculate an impact strength, usually in inch-pounds. This test can be performed directly on the coated side of the panel or, like the GE impact test, on the reverse, uncoated side.

Tensile (Elongation) and Fatigue Tests

For aerospace coatings, free films of the coating generally 5 mils thick or greater are prepared and tested for tensile characteristics. Epoxy primers have relatively high tensile strengths (>2500 psi) but very poor elongations (<10%), whereas flexible primers can have elongations exceeding 100%. It should be noted that the rate of deformation has a significant effect on mechanical properties, including tensile, and this must be clearly specified as part of the testing procedure. For this reason, elongations obtained from impact tests cannot usually be directly correlated with those from tension tests.

Fatigue tests are not usually performed to study coating performance. However, fatigue testing of coated specimens with fasteners has been performed to study cracking of aircraft paints around fastener heads. In these studies, increased flexibility of the coating generally leads to less cracking and better overall performance. Isolated studies [*8*] have been reported in which coatings were used as a variable in fatigue testing of metal test fixtures. In these studies, a series of specimens were exposed to a corrosive environment to induce corrosion fatigue. In these cases, flexibility and corrosion inhibition are essential characteristics of the coating.

WEAR RESISTANCE

General

Aircraft coating systems can experience wear due to a number of causes and mechanisms. The most obvious of these is abrasion at leading edges of wings, antennas, and radomes caused by impingement of rain, sleet, dirt, and other debris. Since these leading edges are critical to flight dynamics, special wear-resistant coatings are often applied to these areas to protect the underlying substrate from damage. Another form of wear can be caused from the movement of adjacent parts such as flaps and stabilizers. In addition, internal parts such as bearings may be coated to prevent excessive wear. Since all of these types of wear cause different mechanisms of coating degradation, a number of varying tests are performed to simulate in-service conditions. For example, coatings which protect against rain erosion do not usually protect well against erosion from sand. Specifications for aircraft coatings (other than those for rain erosion) typically do not contain wear tests; however, development and selection of new aerospace coatings often require that characterization of wear properties be performed. Therefore, careful evaluation of wear mechanisms and selection of suitable evaluation methods is essential for these types of coatings.

Rain Erosion

There are a number of facilities throughout the United States which have built equipment to evaluate rain erosion. Some of these facilities are discussed in Refs *9* and *10*. In general, coatings are applied to a small specimen which is subsequently secured to a test fixture arm. The test is performed by spinning this arm in a chamber with falling water droplets that impinge upon the coated surface. Parameters of the test include:

1. Substrate material, thickness, and geometry.
2. Coating type and thickness.
3. Water droplet size and falling rate.
4. Testing arm speed (specimen-water droplet impact).

Although attempts to correlate data from various test rigs have been unsuccessful at obtaining quantitative relationships, trends in coating performance have been observed. These trends generally agree with rain erosion performance on aircraft.

Air Blast

Techniques that are used to evaluate erosion from sand, dirt, and other foreign debris typically involve an air blast to impinge particles on to the coating surface. A common method is ASTM Test Method for Abrasion Resistance of Organic Coatings by Air Blast Abrasive (D 658). This method uses 75-μm silicon carbide particles flowing at a rate of 45 g/min with an air supply pressure of 13 kPa. The method is often modified to evaluate effects of other particles and air pressures. The results can be reported as the weight of debris necessary to abrade a unit film thickness or as the weight loss of coating per weight of abrasive used.

Taber Abraser

ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (D 4060) is a frequently used test throughout the coatings industry because it is well defined and relatively easy to perform. As such, it is often used for aircraft coatings to assess their wear characteristics. Care must be taken in interpreting Taber abraser results since reproducibility of data from lab to lab is not consistent.

HARDNESS AND MAR RESISTANCE

Pencil Hardness

The most frequently used test for hardness of aircraft coatings is the pencil hardness test, ASTM Test Method for Film Hardness by Pencil Test (D 3363). Briefly stated, it is performed by guiding pencils of various hardness across a coating surface to determine the hardest pencil that will not scratch or mar the coating. The test is used on aircraft coatings for several reasons, including:

1. To assess coating cure and cure rate.
2. To evaluate the coating's ultimate hardness.
3. To evaluate damage caused by weathering and operational fluids (such as, by comparing coating hardness before and after exposure).

Shore Hardness

The Shore hardness test (ASTM Test Method for Rubber Property-Durometer Hardness (D 2240)) is inappropriate for thin coatings (thickness <6.4 mm or 0.25 in.). However, for thicker coatings such as sealants, ablative, and intumescent materials it can be used to evaluate hardness, cure, and environmental effects.

Arco Microknife

Although the microknife test was originally designed to evaluate adhesive strength of coatings, it has been used to determine hardness. This can be performed by placing a specified weight on the diamond stylus and determining the number of scratch cycles required to cut through the coating. It can also be performed by determining the weight needed to get through the coating with a specified number of cycles.

Mar Resistance

Mar resistance is not usually considered a critical property for aircraft coatings. One method is the balance beam test that uses the scrape adhesion apparatus described in ASTM Test Methods for Adhesion of Organic Coatings by Scrape Adhesion (D 2197). The method determines the weight required to mar a coating surface with a stylus.

CORROSION INHIBITION

Salt Spray

Corrosion resistance is an important property for aerospace coatings, and numerous tests have been developed to evaluate the corrosion preventive properties of coatings, ranging from simple exposure studies to sophisticated electrochemical analysis.

Salt spray tests are commonly used as accelerated corrosion resistance tests for coatings. The two primary methods used for aircraft coating systems are the 5% NaCl neutral salt spray test covered by ASTM Test Method of Salt Spray (Fog) Testing (B 117) and the acidified SO_2/salt spray test covered by ASTM Practice for Modified Salt Spray (Fog) Testing (G 85). Specimens coated with an aircraft finishing system are usually scribed with an "X" through the coating into the substrate and then exposed for various times (usually 1000 to 3000 h for ASTM B 117 and 48 to 1000 h for ASTM G 85). Exposure periods for coatings vary for different substrate materials and can be selected either as a specified duration or as the point where significant differences in finishing system performance are observed. After exposure, the panels are inspected for corrosion in the scribe area and blistering or uplifting of the coating across the specimen. Subsequently, the coatings can be carefully removed from the surface without disturbing the underlying substrate by using a chemical stripper, and the specimen surface can be examined for evidence of corrosion.

Standard aircraft epoxy primer/polyurethane topcoat systems perform well on aluminum substrates in the neutral test, normally exhibiting no significant corrosion products in the scribe or any blistering of the coating after 1000 h. These

materials may last up to 3000 h without any evidence of corrosion. The SO_2/salt spray environment simulates stack gases such as those found in industrial areas and on diesel-powered aircraft carriers. It is an extremely aggressive environment, and aircraft systems exposed to this environment tend to fail at much shorter times than in the neutral test. A system exhibiting no significant corrosion products or blistering after 500 h is normally considered acceptable in this acidified environment.

Because numerous materials are used in the construction of aircraft, the contact of dissimilar materials is common. When this occurs, the potential for galvanic corrosion is high if the two dissimilar materials are not insulated from each other. In many cases, organic coatings are applied to provide this insulation. Therefore, it is becoming common to assess the ability of aircraft coatings to inhibit galvanic corrosion by painting and exposing specimens containing dissimilar materials. One example is a graphite-epoxy composite coupled to aluminum.

Immersion Studies

Total immersion corrosion tests can be severe depending on the immersion solution, duration, and exposure temperature. Again, blistering or uplifting of the coating or corrosion of the underlying substrate constitutes failure in this test. Although this type of evaluation is not typically performed on aircraft paints, coatings requiring a high degree of impermeability, like those used in or around aircraft bilge areas, galley, lavatories, and other areas where water can be entrapped, would be evaluated with this type of test.

Filiform Corrosion

Filiform corrosion occurs on painted aluminum, steel, and magnesium in a high-humidity and elevated temperature environment containing oxygen and chloride ions. Filiform initiates at points where the coating ruptures (commonly around fastener patterns or panel seams) and propagates as filaments under the coating. If unchecked, damage of the coating system can allow other corrosion mechanisms such as stress corrosion cracking, exfoliation, and crevice corrosion to ensue. Typical filiform corrosion tests involve exposing coated specimens to hydrogen chloride vapors and then placing them into a high-humidity (85 to 95% RH) and elevated temperature (85 to 140°F) environment for a specified duration such as 1000 h. It should be noted that this type of corrosion is prominent on pure aluminum. For this reason, the test is performed on aluminum clad specimens in lieu of aluminum alloy.

Electrochemical Analysis

Reference *11* provides a thorough review of electrochemical methods used to evaluate the performance of corrosion protective coatings. Of these methods, electrochemical impedance spectroscopy (EIS) is one of the most promising techniques because it provides both qualitative and quantitative information about the corrosion resistance properties of the coatings and the substrates to which they are applied. In addition, EIS can give insight on the nature of their interfacial adhesion. References *12* and *13* provide detailed descriptions of EIS and its application for analyzing organic coating/metal substrate systems. EIS measurements can be made using equipment like EG&G Princeton Applied Research Corp. (PARC) Model M388 Impedance System. Test cells consist of a glass o-ring joint clamped onto a coated metal specimen [*12*]. Electrolytes used for specimen exposure can range from distilled water to neutral or low pH salt solutions.

For an EIS experiment, the test cell described above is filled with the selected electrolyte solution. A reference electrode (such as, Calomel) and a counter electrode (such as, platinum or graphite) are immersed in the cell with the metal substrate serving as the working electrode. The EIS cell is allowed to reach equilibrium as indicated by its open circuit potential or steady-state rest potential. Small excitation amplitudes, usually in the 5 to 10-mV range, are introduced to the system, and the response signal is measured. These data can be correlated to an electrical circuit consisting of resistors and capacitors. The information from this electrical circuit is a model depicting the electrochemical reactions occurring in the coating-substrate system. Because of the detailed quantitative information that is obtained from EIS analysis, it's use as a tool to research high-performance aircraft coatings is growing. In many cases, attempts are made to correlate EIS data with results from other corrosion studies such as salt spray. This approach provides a detailed assessment of coating integrity, durability, and corrosion inhibition.

WEATHERING AND ENVIRONMENTAL EXPOSURE

Outdoor Exposure

Outdoor exposure tests are normally conducted over periods of one year or more. In an effort to produce timely results, these tests are not frequently performed on aircraft coatings. However, one common specification for an aerospace topcoat, MIL-C-83286, does require a one year exposure of coated panels on an outdoor test rack in Florida. It is specified that the panels must be at a 45° angle and facing south. After this exposure period, the coating is evaluated for changes in color, gloss, and flexibility.

The U.S. Navy has instituted a program to evaluate the exterior durability of coatings in its operational environment by placing exposure racks on aircraft carriers and other ships. Results of these exposures have resulted in identification of successful aircraft coatings. Details of this effort are provided in Ref *14*.

Accelerated Weathering

The components of outdoor natural weathering which have the most significant effects on coatings and other materials are ultraviolet radiation and water (humidity, condensation, rain, etc.). It has been proposed that these conditions can be simulated and that the resulting effects can be accelerated by subjecting coatings and other materials to high-intensity light (including ultraviolet wavelengths) and water.

The most common accelerated weathering methods used for aircraft coatings are the xenon-arc Weatherometer and

the QUV accelerated weathering tester. The former method is described in ASTM Practice for Operating Light-Exposure Apparatus (Xenon-Arc Type) with and Without Water for Exposure of Nonmetallic Materials (G 26). Again, there are a number of test variables which have significant effects on coating performance, and various laboratories have adopted slightly different procedures and parameters. Since there are no precise correlations between natural weathering and any of the accelerated methods for aircraft coatings, it is especially important that the test variables are well defined. One common approach that is used in military and federal specifications (MIL-C-85285, Coating, Polyurethane, High Solids and TT-P-2756, Polyurethane Coating: Self-Priming Topcoat, Low VOC) follows ASTM G 26, Type BF as a guideline. The exposure is performed in a 6000-W, xenon arc weatherometer with a continuous cycle consisting of 102 min of high-intensity light only and 18 min of light and water spray. The conditions in the chamber are as follows:

1. Black body temperature	60°C (140°F)
2. Relative humidity	50%
3. Intensity of the arc wavelength	0.55 W per m^2 at 340 nm

The exposure period is 500 h, and the coating is subsequently evaluated for changes in gloss, color, and flexibility.

The second common method for accelerated weathering is described in ASTM Practice for Operating Light- and Water-Exposure Apparatus (Fluorescent UV-Condensation Type) for Exposure of Nonmetallic Materials (G 53). In this case, specimens are subjected to periods of ultraviolet light and condensation, respectively. During the condensation period, the coating surface is exposed to 100% relative humidity at elevated temperature, while the back side of the specimen is exposed to cooler air, thus producing water condensate on the coating. Exposure parameters include UV intensity, duration of exposure to each condition, and temperature of the chamber and condensate.

Humidity

Since high temperature and humidity can cause coating disbondment and substrate corrosion, extreme humidity exposure is often performed on aircraft coatings to evaluate their resistance to such environments. Again, exposure parameters vary and must be clearly specified for reproducibility and interpretation of results. ASTM Practice for Testing Water Resistance of Coatings in 100% Relative Humidity (D 2247) is usually followed. The chamber conditions are 49°C (120°F) and 100% relative humidity with constant condensation on the coated panels. A typical exposure period can range from 30 to 90 days.

FLUID RESISTANCE

Aircraft coatings are frequently subjected to aggressive operational and environmental fluids. Several examples are hydraulic fluids, engine oils, fuel, deicing solutions, and cleaners. In order to assess the resistance of aircraft coatings to these fluids, a number of exposure tests are performed. The exposure can range from a simple wiping action to long-term immersion. The temperature of the exposure is also a critical variable. Following exposure, the specimen is usually evaluated for degradation of the coating (discoloration, softening, blistering, etc.) and substrate (corrosion).

Water Resistance

Resistance to water is usually performed by total immersion. The severity of the exposure can range from 24 h at ambient temperatures to seven days at 65°C (150°F). Since water can play a significant role in coating disbondment [*15*], adhesion tests are frequently performed immediately upon removal of the coated specimen from water immersion.

Another technique is to measure the water absorption (uptake) of a coating as a function of immersion time. This is performed by simply weighing the coated panel (or free film) as a function of immersion time. Water up-take values for high-performance aircraft coatings can range up to 20%.

A third technique to characterize the effects of water on a coating is to determine its water vapor transmission rate (WVTR). WVTR is a measure of the rate at which water will permeate through a coating. ASTM Test Method for Water Vapor Transmission of Organic Coating Films (D 1653) describes two methods to determine WVTR. In Method "A," a free film of the coating is sealed to the open mouth of a cup containing distilled water. In Method "B," the free film is sealed to a cup containing desiccant. These fixtures are exposed to controlled environments (temperature and humidity), and they are weighed periodically to determine the rate of water vapor diffusion through the coating. Aircraft coatings must exhibit low WVTRs to maintain their adhesion and corrosion inhibition.

Organic Solvent Resistance

Resistance to organic solvents is usually performed by rubbing a coated panel with a cloth dampened with a specified solvent. Since toluene and methyl ethyl ketone (MEK) are both harsh and have been frequently used in the aerospace industry, they are common solvents. After rubbing the surface, the coating is inspected for color change, dissolution, or any abnormality which may have been caused by the solvent. The cloth can also be inspected for residue which may be apparent by a color change.

Hydraulic Fluids and Engine Oils

Hydraulic fluids and engine oils are frequently used at elevated temperatures, and therefore their attack on aircraft coatings can be accelerated and more severe. Table 2 describes typical immersion tests using these fluids.

HEAT RESISTANCE

Aerodynamic heating can produce skin temperatures of 121°C (250°F) in level flight and 176°C (350°F) during high-speed maneuvers. Painted components adjacent to engines and exhaust tracks may experience unusually high temperatures. This heat may exceed the maximum service temperature of some organic coatings, which may cause darkening, embrittlement, and/or premature aging. The heat resistance

TABLE 2—Aircraft operational fluid immersion tests.

Material Duration	Temperature
Lubricating oil (MIL-L-23699) Hours: 24	121°C (250°F)
Hydraulic fluid (MIL-H-83282) Hours: 24	66°C (150°F)
Fire-resistant hydraulic fluid Days: 7	21°C (70°F)
Jet fuel (JP-4, JP-5) Days: 7	21°C (70°F)

of a coating is determined by subjecting a coated panel to a constant temperature for a specific period of time. For example, specification MIL-C-85285B requires that a polyurethane topcoat withstand exposure to a 121°C (250°F) oven for 1 h without a significant color change (maximum delta E value of 1.0).

Thermal Fatigue

Thermal fatigue refers to the resistance of a coating to stresses induced by rapid temperature changes. Often called thermal shock, this simulates the effect of take-off from hot (and sometimes humid) ground temperatures to the cold atmosphere at high altitudes and then back again. The MIL-C-81945B intumescent coating used on weapons must withstand 60°C (140°F), 95% relative humidity for 24 h followed by −40°C (−40°F) for 24 h. The coating is then cycled between the two chambers for 28 days. Cracks extending deep into the coating indicate failure in this test. Method 503.1 of MIL-STD-810 provides further guidance.

Thermal Conductivity

Stored weapons (bombs, missiles, etc.), including those used on military aircraft, must be protected from accidental fuel fires. This is accomplished with exterior, insulating coatings on those weapons that delay ordnance reactions and provide fire fighters sufficient time to extinguish the fire. The efficiency of these coatings is measured by a unique test, originally developed by NASA [*16*]. It uses a small furnace burning JP-4 or JP-5 aviation fuel to produce a constant heat-flux of 10 btu/ft^2-s at a flame temperature of approximately 1800°F (982°C). A coated panel is mounted to an open port above the furnace, and the temperature of the uncoated backside is recorded as a function of time. The thermal efficiency is calculated from these data. It is expressed as the number of seconds/mil of coating thickness for the backside temperature to reach either 500°F (260°C) or 1000°F (537°C). (Most explosives and propellants react between these two temperatures.) Specification MIL-C-81945B requires that intumescent coatings have a minimum thermal efficiency of 2 s/mil to 500°F (260°C).

STRIPPABILITY

Aircraft are periodically returned to depot maintenance facilities for inspection and overhaul. At this time, the aircraft's exterior coating system is removed by chemical and/or mechanical means. In order to insure that this procedure can be adequately performed, strippability tests are conducted in the laboratory as part of the coating evaluation procedure. One common testing procedure is accomplished by applying a chemical paint stripper, such as MIL-R-81294, onto the surface of a coated specimen. After a specified period of time (usually 1 h), the panel is abraded with a stiff bristle brush and rinsed with water to remove loosened paint. Usually, 90% removal of the coating from the substrate is considered acceptable.

CLEANABILITY

Low-gloss aircraft coatings, such as those used in camouflage schemes on military aircraft, become dirtier and are more difficult to clean and restore than high-gloss coatings. This is primarily due to the increased surface roughness of low-gloss coatings, which entraps carbonaceous and oily soils as discussed in References *17* and *18*.

The cleanability or the ease at which dirt and soil can be removed from a coating surface can be quantified by consistently soiling a coating and using a standard cleaner and cleaning motion in attempts to remove this soil. Measuring the color difference of the coating prior to soiling and subsequent to cleaning provides an indication of the coatings cleanability. The following is a detailed procedure for the evaluation of the cleanability of aircraft coatings. The soil in this procedure was generated using a hydraulic fluid. This soil is representative of that found on operational aircraft. Other soils can be derived from greases and lubricating oils.

APPARATUS REQUIRED

1. Test panels 7.62 by 15.24 by 0.05 cm (3 by 6 by 0.02 in.) of 2024 T3 aluminum alloy chromate conversion coated with materials conforming to military specification MIL-C-81706 to produce a coating meeting MIL-C-5541.
2. One-liter, wide-mouth, glass jars.
3. Balance, accurate to 0.1 g.
4. High shear mixer.
5. Hog bristle brush (Gardner WG-2000-B).
6. Acid brushes.
7. Rubber roller, 2270 g (5 lb).
8. Forced draft oven capable of 105°C (221°F).
9. Wear tester (Gardner Heavy Duty Wear Tester).
10. Template for positioning and holding test panels on the wear tester.
11. Cellulose sponge backed with nylon web (Scotch Brite 63).

PREPARATION OF SOIL

1. Place 50 g of carbon black (such as Raven 1040 manufactured by Columbian Chemical Company) in 500 g of hydraulic fluid meeting military specification MIL-C-83282.
2. Homogenize the carbon black and hydraulic fluid mixture using a high shear mixer for 15 min. Prior to application of the soil to the specimen, thoroughly stir or shake the mixture to obtain a thorough dispersion.

PREPARATION OF THE CONTROL FORMULA CLEANER

1. Any desired aircraft cleaned can be used. However, the following is a control formulation meeting a common aircraft cleaner (MIL-C-85570, Type II) as listed in Paragraph 4.6.13.1 of the specification.
2. Mix the first five ingredients listed below, then neutralize the mixture to a pH of 8.0 with acetic acid. Mix the last two ingredients together and then add that to the initial mixture.

Igepal CO-630 (1)	10.0 parts by weight
Monamid 150 CW (2)	5.0
Dipropylene glycol methyl ether	10.0
Deionized water	71.5
Benzotriazole	0.5
Hostacor 2098 (3)	2.0
Morphaline	1.0

(1) GAF Corporation, or equivalent.
(2) Mona Industries Inc., or equivalent.
(3) American Hoechst Corp., or equivalent.

PREPARATION OF TEST PANELS

1. To the chromate conversion coated aluminum specimens described, apply a suitable primer for the desired topcoat. One such material is epoxy primer conforming to MIL-P-23377 Type I or II to a thickness of 15.2 to 22.9 μm (0.6 to 0.9 mil). Allow to dry for 1 h at ambient conditions. Apply the desired topcoat to the intended thickness. Allow the coating to cure under the appropriate conditions.
2. After allowing the desired cure time and conditions, use a bristle acid brush to coat the painted surface of a test panel with the soil described in the "Preparation of Soil" section. Remove excess soil by covering the test panel surface with tissue and exerting pressure by rolling the tissue with the roller. Repeat this blotting three times using fresh tissue each time. Brush the soiled surface ten times in one direction only, parallel to the long dimension of the test panel, using the hog bristle brush. Bake the test panel at 105°C (221°F) for 60 min.
3. Measure the L, a, and b tristimulus values on a suitable colorimeter and record the values as L_i, a_i, and b_i, respectively.

CLEANING PROCEDURE

1. Dilute the control cleaner by one part cleaner with nine parts distilled water (by volume).
2. Clean the test panel within 4 h using the wear tester as follows. Cut the sponge with any texture "ribs" running perpendicular to the cleaning stroke. When the dry sponge is attached to the cleaning head on the wear tester, the combined weight shall be between 1350 and 1400 g. Place the soiled test panel in the template at an angle 45° to the cleaning stroke. Saturate the sponge and cover the test panel with the diluted cleaner. After 55 to 65 s, clean the test panel using 5 cycles (10 strokes) of the wear tester, then immediately turn the test panel 90° in the template and clean for an additional 5 cycles. Rinse the test panel under a flowing stream of tap water at room temperature for 2 min and allow to fully dry.
3. Measure the L, a, and b values on the sam colorimeter used prior to the cleaning procedure and record them as L_f, a_f, and b_f, respectively.
4. Calculate the change in color due to soiling and cleaning according to the following equation

$$\text{DELTA E} = [(L_f - L_i)^2 + (a_f - a_i)^2 + (b_f - b_i)^2]^{0.5}$$

5. A minimum of three replicates should be tested for each coating at each condition.

Architectural Coatings

by Harry E. Ashton[1]

INTRODUCTION

Definition and Scope

THIS CHAPTER IS CONCERNED with the selection and use of procedures for testing organic finishes intended for use on interior surfaces, exterior surfaces, or both interior and exterior surfaces. Coatings comprise more than "paints" since the latter are only one kind of coating as defined in ASTM Terminology Relating to Paint, Varnish, Lacquer, and Related Products (D 16):

> "*coating*—a liquid, liquefiable or mastic composition that is converted to a solid protective, decorative, or functional adherent film after application as a thin layer."
>
> "*paint*, n, specific—a classification sometimes employed to distinguish pigmented drying oil coatings ("paints") from synthetic enamels and lacquers."

Definitions used by the Federation of Societies for Coating Technology (FSCT) [*1*] for these terms are:

> "*Coating* (1) Generic term for paints, lacquers, enamels, printing inks, etc. (2) A liquid, liquefiable or mastic composition which is converted to a solid protective, decorative, or functional adherent film after application as a thin layer."
>
> "*Paint* (2) Noun. Any pigmented liquid, liquefiable, or mastic composition designed for application to a substrate in a thin layer which is converted to an opaque solid film after application. Used for protection, decoration or identification, or to serve some functional purpose such as the filling or concealing of surface irregularities, the modification of light and heat radiation characteristics, etc."

Hence, clear varnishes and lacquers are familiar types of coatings that are not, strictly speaking, paints. As one company has proudly, if not grammatically, referred to their products, "Plain Paint It Ain't."

Since there are many different types of coatings, it is useful to classify them into groups. This can be done in several ways as for example according to:

1. *Appearance*—clear, high gloss, metallic, pigmented, red, stain, textured, etc.
2. *Composition*—alkyd, latex, oil, solvent-borne, zinc-rich, etc.
3. *End use*—service location (interior, exterior), end user (industrial, painter, home), specific substrate (wood, metal, masonry), type of object (transportation, bridge, house), particular exposure (marine, below-grade), etc.
4. *Method of cure*—air-dry, bake, cold-cure, radiation-cure, etc.

At times the terminology used in the coating industry can seem confusing to a tyro in the field. For example, an aluminum finish may be used for application to aluminum objects or it may contain aluminum pigment and be used on various objects. Although an automotive coating is intended for application to automobiles, an architectural coating is not similarly intended for architects. Rather, an architectural coating is for the type of structure customarily designed by architects in contrast to those designed by civil engineers. Another designation intended to reduce this potential confusion is "trade sales coatings" that are coatings marketed through retail-trade stores, in contrast to "industrial sales coatings" that are usually marketed directly to the end user.

The definition for *architectural coating* given in the two ASTM standards, D 5146 and D 5324, referred to below, combines the definition from ASTM D 16 with that in the FSCT's Paint/Coatings Dictionary [*1*] as follows:

> "Organic coatings intended for on-site application to interior or exterior surfaces of residential, commercial, institutional, or industrial buildings, in contrast to industrial coatings. They are protective and decorative finishes applied at ambient temperatures. Often called Trade Sales Coatings."

As with many types of coatings, the titles of the two ASTM guides reflect the two main composition categories—waterborne and solvent-borne. These categories indicate the type of volatile material used, both in manufacturing and in application, to reduce the film-forming ingredients to a suitable application viscosity.

Scope

The intended uses and generic gloss range for conventional types of architectural coatings are as follows:

1. Interior finishes, low-gloss.
2. Interior finishes, semigloss and full-gloss.
3. Exterior house and trim coatings, low semigloss to moderate gloss.
4. Exterior and/or interior floor finishes, gloss varies with the particular type of finish.

Copyright© 1995 by ASTM International

Each of these finishes is intended for application by brushing, rolling, spraying, or other means to the substrates appropriate to its end use, which may include wood, plaster, masonry, wallboard, steel, previously painted surfaces, and other architectural substrates.

One type of architectural interior coating differing from the generally accepted commercial types is called "high performance architectural coating (HIPAC)." Such coatings are extra-durable systems applied as continuous films that cure to hard, tough finishes that are resistant to abrasion, staining, chemicals, detergents, and mildew growth. Coatings of this type usually are two-component epoxides or urethanes, or are moisture-cure urethanes. Other polymer types are not excluded from this high-performance area if they can be formulated into coatings that meet purchaser performance requirements. As with many conventional coatings, these high-performance coatings are formulated at gloss levels that range from very high to satin (low semigloss).

ASTM GUIDES TO TESTING ARCHITECTURAL COATINGS

The ASTM guides listed below provide systematic compilations of relevant properties, the related test methods, and, where possible, typical values, for the guidance of users.

ASTM D 3730: Guide for Testing High-Performance Interior Architectural Wall Coatings

ASTM D 5146: Guide for Testing Solvent-Borne Architectural Coatings

ASTM D 5324: Guide for Testing Water-Borne Architectural Coatings

CONDITIONS AFFECTING THE USE OF ORGANIC COATINGS

Substrate Types

Substrates may be wood products, masonry, bare plaster, metal, wallboard, and even plastic. The nature of the substrate can affect the application and appearance properties of a coating, such as uniformity and gloss, and is an important factor in determining the type of coating to use. Specific examples of this are:

1. A primer-sealer may be required for porous substrates, such as unpainted drywall, new wood, plaster, or porous masonry.
2. Finishes intended only for interior service do not require resistance to weather factors.
3. Low-gloss wall finishes do not need the abrasion resistance required of floor coatings.

Other factors of importance are the quality of the substrate, which with wood products relates to grain, knots, and compositional structure, and with masonry and plaster products relates to the degree of porosity and alkalinity.

Substrate Conditions

The condition of the surface is important in determining the type of coating and surface preparation that might be required. These conditions include porosity, presence of grease, dirt, mold, water-soluble or oily contaminants, and chalking or flaking of previous coatings. The smoothness of the substrate affects the spreading rate, texture, and final appearance of the coating. Building defects arising from poor construction or deterioration in service or direct contact of the substrate with the ground can result in persistent exposure of the coating to interior or exterior moisture with resultant failure by blistering, flaking, or peeling. Similar failures can occur where painted lumber is adjacent to damp masonry surfaces. Weathering of wood before painting probably will adversely affect the performance of exterior coatings. However, some degree of weathering of masonry surfaces may have a beneficial effect on performance by passivating the surface and changing the alkalinity.

Exterior Coatings

The durability and appearance of these coatings can be affected by short- and long-term environmental conditions. Surface dampness during application and drying can adversely affect the adhesion of solvent-borne coatings but not of water-borne coatings. However, low temperatures during the drying stage can prevent water-dispersed (latex) coatings from forming cohesive films. Of course, no water-borne coating can be applied at temperatures below the freezing point of water. A sunny service environment can be expected to encourage chalking and other forms of film deterioration. In contrast, a shady location, such as on the north side of a structure or nearby trees and shrubs, can protect the film from sunlight but it can promote mildew growth. Orientation of the coating toward sun or shade varies on different parts of a building, e.g., fascia boards and porches.

Interior Coatings

The porosity, smoothness, and color of the surfaces are important factors for both new and repaint jobs. On new construction, low temperatures must be avoided when applying water-borne finishes, and painting is preferably done at normal room temperature. If drying temperatures are too low, long drying times are needed and this can result in significant dust and dirt accumulation on the film. If drying temperatures are too high, the film will dry too rapidly and side-by-side application areas may appear different because they did not flow into each other. High relative humidity is also to be avoided when applying both solvent- and water-borne coatings. Primer coats should be allowed adequate time to dry before applying the next coat.

General

It should be recognized that proper surface preparation and correct application techniques are as important as the inherent properties of a coating in contributing to adequate performance. This is especially true for high-performance coatings. After selecting the best material for a given service, it is essential that the manufacturer's instructions be followed.

SELECTION OF TESTS

Service Location

Because coatings on different surfaces, e.g., ceiling, floor, wall, and in different service environments, e.g., exterior or interior, are subjected to a variety of conditions, specialized coatings have been developed. The test methods discussed in this chapter cover practically all of the properties of architectural coatings. Not all of the tests are needed with any one coating type or location. Coatings intended for exterior use only or for both exterior and interior uses require certain properties not relevant to those intended for interior use only. Property selection and methods of testing for these properties must be governed by experience and the requirements in each individual case and, preferably, by agreement between purchaser and seller.

Value Judgments

The purchaser should first determine the properties required of a coating and then select only the test methods appropriate for those properties. After test selection the purchaser should decide which properties are most important and establish specification requirements accordingly. Since coating properties frequently tend to oppose each other, such as low sheen versus good cleansability or good sag resistance versus good leveling, some properties may need to be less emphasized if others are to be accentuated. This balance of properties must be considered when selecting the tests and establishing the requirements. No attempt is made herein or in the ASTM standard guides listed above to indicate relative importance of the various tests. Also, the referenced standards do not recommend specific test values because properties considered very important by one purchaser may be less so to another.

PROPERTIES OF LIQUID COATINGS

Density

While density, measured in pounds per gallon or kilograms per liter (≡g/mL), has no relation to the quality of a coating, it can be used by the purchaser to ensure product uniformity from batch to batch. In production control, density provides a simple check against the formula weight since any significant deviation indicates an incorrectly made or mixed coating, including the presence of entrapped air. Density is generally measured with a pycnometer, a container of precisely known or measurable volume with a capillary cover through which surplus liquid is expelled as the test temperature, normally 77°F (25°C), is approached. Laboratory pycnometers are typically made of glass and have a narrow neck to reduce evaporation of volatile fluids.

The coating industry uses a special type of pycnometer called a "weight-per-gallon" (mass per unit volume) cup. It is a plastic or metal wide-mouth cylinder, a shape convenient for handling viscous coatings and polymers. Weight-per-gallon cups are usually made to hold 83.454 mL so that the weight in grams required to fill the cup divided by 10 is the density in lb/U.S. gallon, or to hold 100 mL so that dividing the weight by 100 results in g/mL or by 10 yields lb/Imperial gallon. The density of water at the test temperature is used for precise work or to establish a correction factor if the device is worn, damaged, or dirty from poor cleaning in a way that effectively changes the internal volume of the cup. Typical coating densities are in the range of 10 to 12.5 lb/U.S. gallon (1.2 to 1.5 kg/L) for water-borne paints. Solvent-borne coatings are in the 8 to 10 lb/U.S. gallon (0.9 to 1.2 kg/L) range due to the lower density of the solvents used instead of water. Instructions for carrying out the test are given in ASTM Test Method for Density of Paint, Varnish, Lacquer, and Related Products (D 1475). Other devices and methods for measuring density are presented elsewhere in the manual.

Coarse Particles

To form uniform films with good appearance, liquid coatings must be free of coarse particles and foreign matter. In general the glossier the film, the more detrimental such particles are to appearance. These particles are far larger than those determined in the fineness of dispersion method described below. They normally occur as a defect in the production process that permits introduction of clumps of dry pigment or foreign matter such as pieces of shipping bags and the like. The content of objectionable material is determined with ASTM Test Methods for Coarse Particles in Pigments, Pastes, and Paints (D 185) by straining the diluted coating through a 325-mesh (45-μm) screen and weighing the amount retained. A typical maximum requirement is 0.5% by weight. Objects such as pigment lumps, polymer seeds, etc. with a generally spherical shape are retained on such a screen. Linear objects like fiber strings can flow through this screen and may require other removal methods, such as centrifuging. Screens are inexpensive and readily available, and results obtained with them are easy to comprehend. Devices such as centrifuges are more expensive and more time consuming than screens, but they often yield more accurate results than the latter.

Fineness of Dispersion

Generally, the more finely a pigment is dispersed, the more efficiently it is being utilized. Also, if pigment agglomerates exceed the thickness of the dry film, it will be impossible to obtain a coating of the desired degree of smoothness. One method for measuring the degree of dispersion, commonly referred to as "fineness of grind," is to draw the liquid coating down a calibrated tapered groove varying in depth from 4 to zero mils (100 to zero μm), which is equivalent to zero to 8 Hegman units. The depth at which continuous groupings of particles or agglomerates protrude through the surface of the wet film is taken as the fineness of dispersion value. Good dispersion is indicated by high readings in Hegman units or low readings in mils or micrometres. Lower gloss finishes do not generally require a fine dispersion, so they might have a dispersion value of 2.5 mils (65 μm or 3 Hegman units). Some interior flat latex paints have finenesses as low as 3.5 mils (90 μm or 1 Hegman unit). Most interior semigloss and gloss enamels have a fineness value of about 1.5 to 0.3 mils (40 to 7 μm or 5 to 7.5 Hegman units), although some full gloss coatings might be near zero in depth, equivalent to 8

Hegman units or as fine as can be measured by this method. Information about conducting the test appears in ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems (D 1210).

Flash Point

This is almost exclusively a concern with solvent-borne coatings. The organic solvents used in these coatings have characteristic temperatures at which their vapors support combustion. This temperature is known as the flash point and is often used for hazard classification in shipping by common carrier. It is also used to determine conditions of storage to meet fire regulations and the U.S. Occupational Safety and Health Act (OSHA). There are several accepted ways for measuring flash point that give somewhat different results. For pigmented and/or viscous materials that require stirring to obtain consistent results, ASTM Test Methods for Flash Point by Pensky-Martens Closed Tester (D 93, Method B) is specified. The small specimen size used with ASTM Test Methods for Flash Point of Liquids by Setaflash-Closed Cup Apparatus (D 3278) eliminates the need for stirring. Since solvents do not require stirring, they are generally tested with ASTM Test Method for Flash Point by Tag Closed Tester (D 56).

Manufacturers of coatings do not always determine the flash points of their products, but classify them on the basis of the solvents they contain. Since this routine does not detect inadvertent contamination, large-volume purchases are sometimes tested for flash point, in some cases after thinning at the job site. Further details about this technique can be found elsewhere in this manual.

Odor

Some solvent combinations produce undesirable odors, particularly when painting indoors with inadequate ventilation and at elevated temperatures. Although interior solvent-borne coatings usually contain low-odor or odorless mineral spirits, they should nevertheless be evaluated for odor. Latex or other water-borne coatings, which contain relatively little if any organic solvent, may contain other ingredients such as ammonia, residual monomer, etc., that might also be objectionable in a confined space. Hence both solvent- and water-borne coatings should be tested to establish whether the odor is irritating or merely unpleasant.

Although not specifically designed for liquid coatings, ASTM Test Method for Odor of Volatile Solvents and Diluents (D 1296) could be a suitable basis for the evaluation. This method is a comparative procedure for observing characteristic and residual odors of volatile organic solvents and is not designed to determine subtle odor differences or odor intensity. There are hazards associated with the test, and the Hazards section of the method should be read and heeded when the test is used. ASTM D 1296 has been approved as a replacement for Method 4401 of U.S. Federal Test Methods Standard (FTMS) No. 141 by the U.S. Department of Defense.

Volatile Organic Compound (VOC)

Volatile organic compounds evaporate into the atmosphere when coatings dry and/or cure, and they are believed to contribute significantly to air pollution. The chief offenders in this regard are solvent-borne coatings, although water-borne coatings certainly contain some amounts of VOC. In addition, many types of coatings that cure by chemical reaction, in contrast to those that dry solely by evaporation of organic solvent or water, generate volatile molecules such as formaldehyde and related compounds. Both types of materials react with each other and atmospheric oxygen in the presence of sunlight (i.e., photochemical reaction) to produce in the lower atmosphere the actual pollutants, one of which is ozone. Some of the VOCs have also been related to the destruction of ozone in the upper atmosphere. Organic volatiles that are considered to have negligible photochemical activity have, at least to the time of writing, not been included in the calculation of the VOC of a coating for regulatory purposes. Such exempt solvents are very few and within a relatively short time there may be none at all. California and its local agencies have been particularly active in specifying and enforcing limits on the amount of VOC in coatings. Examples of such restrictions are maxima of 350 g/L for "clear wood finishes" and 400 g/L for quick-drying enamels. Since other states have established their own limits, a national rule on VOC in architectural and industrial coatings is at present being developed between representatives of the paint industry and the U.S. Environmental Protection Agency (EPA). ASTM Practice for Determining Volatile Organic Compound (VOC) Content of Paints and Related Coatings (D 3960), U.S.A. EPA approved, and the recent manual by Brezinski [*2*] discuss applicable ASTM test methods, provide equations for calculating the VOC content in different ways, and provide other information valuable in this area.

Dilution Stability

This property is of concern primarily with solvent-borne coatings because of the wide differences in solubility characteristics of the binders and the solvent power of the various solvents and thinners employed. It is, therefore, desirable to establish that a coating and the specified thinner are compatible and the reduced material is stable. Hence the suggested diluent should, without excessive stirring or shaking, be readily incorporated into the coating in the recommended proportions or to a specified viscosity. Method 4203 in FTMS No. 141 requires that the mixture be allowed to stand for 4 h and then be observed for curdling, flocculation, precipitation, or separation into layers. If there is doubt about the stability, some of the material is then flowed onto a glass panel where any incompatibility is more evident.

Penetration (Absorption)

This term refers to the tendency of the nonvolatile vehicle or binder in a coating to penetrate and be absorbed by porous surfaces. Good resistance to absorption (hold-out) is desirable with interior primers and undercoats because it enables them to seal such surfaces, thus promoting uniformity in both gloss and color of subsequent finish coats. Conversely, a

high level of penetration is desirable with exterior coatings because it promotes adhesion on substrates that are untreated and have layers of rust or degraded, chalky paint. In general, the binders in solvent-borne architectural coatings tend to penetrate chalk and rust very well owing to their lower molecular weight in comparison to that of latex binders. Since the latter penetrate very poorly, exterior latex paints are sometimes modified with alkyd or oleoresinous binders to bind the chalk layer to the old coating.

Method 4421 of FTMS 141 is a roughly quantitative method for measuring absorption that employs filter paper as a reproducible porous surface. In the test, a friction-top lid for a half-pint can is completely filled with paint and covered with a standard grade filter paper. After 3 h, vehicle migration is observed as a spreading circular stain in the paper, and the mean distance from the rim of the cover is reported as the degree of absorption or penetration. Blotting paper may also be used for this test. Method 6261 of FTMS 141 is a more practical procedure than Method 4421, involving application of the material to an imperfectly primed porous surface and, after drying, observation for variations in gloss and/or color. In the U.S. Federal Specification for Interior Flat Latex Base Paint (TT-P-29) the test paint is applied with an applicator blade to a half-sealed penetration chart, and the above-described differences between the sealed and unsealed areas are measured instrumentally.

Color Compatibility

A colorant sometimes fails to disperse completely and yield the desired color in a white or tint base owing to poor compatibility that can be related to the colorant (color development), the base (color acceptance), or both. If colorants are not adequately compatible with bases, lighter or nonuniform shades are produced. Although the problem is generally related to poor dispersability of the colorant, especially those designed for use with both solvent- and water-reducible coatings, the white pigment in the base may not have been adequately dispersed or may have subsequently flocculated. In that case, if the shear applied to disperse the colorant also disperses the white pigment, the color will be lighter and less colorful (i.e., less saturated) than expected. When both the colorant and the white are poorly dispersed, the color change due to shear stress will be some combination of the two effects.

Poor color compatibility can be a problem both in the production and use of organic coatings. In the factory it causes a loss of monetary value and unpredictable tinting results. In application it results in nonuniform color of the final film due to the variation in shear forces with different modes of application. This is commonly evaluated by applying the coating with an applicator blade and subjecting a small area of the drawdown to high shear by finger rubbing the partially dried film. Since rubbing simulates the high shear involved with some application methods, a variation between the unrubbed and rubbed areas indicates that the product will probably exhibit the same defect in the field. The color difference can be measured photometrically to obtain numerical values that are more useful than visual evaluations for establishing limits for control work. Unfortunately, the finger-rub method has been found to have poor repeatability (same operator, different times) as well as poor reproducibility (different operators).

In ASTM Test Method for Color Development in Tinted Latex Paints (D 5326), a portion of the semi-dry film is subjected to closely controlled brushing for development of a strong shear force. Although the method is written for testing a tinted paint, the basic procedure can be followed for rating how well different colorants perform in the same tint base or vice versa.

Coating Rheology

This term refers to the viscometric characteristics of liquid coatings. Simple liquids that maintain a constant viscosity at varying shear conditions are said to be Newtonian. Most architectural coatings are non-Newtonian in character and have a higher viscosity at low shear rates than at high shear rates and vice versa. Systems of this type require the application of a minimum force to flow and when this force, the "yield value," is exceeded, the phenomenon is called plastic flow. Paints that exhibit plastic flow are called Bingham liquids.

In the coating industry, thixotropy is a favorable form of non-Newtonian flow in which a liquid decreases in viscosity when subjected to a shearing force and then recovers when undisturbed for some time. It is possible for a material to exhibit both plastic flow and thixotropy. These flow characteristics are directly related to practical application properties. High viscosity at low shear rates results in poor leveling and good sag resistance. Low viscosity at moderate shear rates leads to good leveling but poor sag resistance. High viscosity at high shear rates, such as occur during brush application, results in brush drag or poor brushability. Consequently, a balance between the different properties must be sought.

The different instrumental test methods used for coatings are described below. Empirical methods for evaluating various application characteristics are described in a later section. The topics of rheology, viscometry, and related characteristics are dealt with on a theoretical, mathematical basis elsewhere in the manual.

Consistency (Low-Shear Viscosity)

Consistency is a general term that describes the perceived thickness or "body" of liquids and is related to application and flow. While it is related to viscosity, consistency does not distinguish between different viscosity types and does not determine the quality of a coating. It is used mainly to ensure product uniformity and should, therefore, fall within a stated range for satisfactory reproduction of a specific formula. The most common device for measuring the consistency of architectural coatings is the Krebs modification of the Stormer Viscometer in which a small off-set T-shaped paddle is immersed to standard depth in the test fluid and rotated at 200 r/min for instruments with a stroboscopic timer and 200 ± 20 for those without the timer. Weights are varied to obtain the specified shear rate with the greater the load, the higher the consistency that may be expressed in grams/200 r/min or Krebs Units (KU). Although the consistency of most architectural coatings is about 150 to 300 g/100 revolutions (72 to 95 KU), a much wider range is possible because of the great

variation that can occur in the rheological properties of these materials. Two paints of the same consistency may have quite different rheological properties during application. Consistency is determined in accordance with ASTM Test Method for Consistency of Paints Using the Stormer Viscometer (D 562).

Rheological Properties of Non-Newtonian Materials

The two methods covered in this subsection are particularly suited for coatings that display thixotropic characteristics. However, they measure viscosity under different shear rates. In ASTM Test Method for High-Shear Viscosity Using the ICI Cone/Plate Viscometer (D 4287), there is only one very high rate that is similar to that occurring during brush application so that the measured viscosity is related to brush drag, spreading rate, and film build. ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D 2196) employs a rotational viscometer to measure viscosity at several shear rates to determine the amount of shear thinning and the viscosity change at low shear rates. The results can be used to evaluate sag resistance and leveling ability.

Sag Resistance

Some coatings sag and form curtains before the film sets. Resistance to this type of flow is an important property, particularly for semigloss and gloss finishes, because of the resultant unsightly film appearance. Sag resistance is determined in accordance with ASTM Test Methods for Sag Resistance of Paints Using a Multinotch Applicator (D 4400). In this test, a presheared coating is applied to a test chart with a drawdown applicator that contains a number of different-sized notches to form stripes of the coating. The chart is then hung vertically with the drawdown stripes in a horizontal position. The coating chart is allowed to dry and then examined for sagging characteristics.

Leveling Properties

Leveling is an important property when smooth, uniform surfaces are to be produced because it affects hiding and appearance. Brush marks and imperfections are much more conspicuous in semigloss and gloss finishes than they are in low-gloss materials. ASTM Test Method for Leveling of Paints by Drawdown Method (D 4062) is the most recently developed method for evaluating this property. In it, a series of ridges is produced by applying the film using a serrated rod. After drying, the ridges are compared under a strong oblique light to a numbered series of plastic levelness standards. The results have been shown to correlate well with brush applications.

Package Stability

Since paints normally are not used immediately after manufacture, they must remain stable in the can for some reasonable time. At normal temperatures most architectural coatings can be stored for over a year with little change in properties. However, exposure in uninsulated warehouses or during shipping to high temperatures in summer or, for water-dispersed coatings, to low temperatures in winter may cause unacceptable changes in the products. Another unsatisfactory condition that may occur during storage is excessive settling.

Heat Stability—Exposure to high temperatures can be used as an accelerated test to predict stability of a packaged coating when stored at normal temperatures or to test for the heat stability when a material frequently encounters such conditions in service. Although indications of long-term package stability can usually be obtained in several days or weeks at an elevated temperature such at 125°F (50°C) or 140°F (60°C), occasionally the results of such accelerated tests do not agree with those at prolonged normal storage conditions. In ASTM Test Method for Package Stability of Paint (D 1849), the changes in consistency and certain other properties of the accelerated aged material are compared to those occurring in a control kept at normal temperatures for a longer period. When testing for heat stability, as such, changes in viscosity, flow, gloss, pH, foam resistance, color uniformity, and wet adhesion are usually checked.

Settling—Modern coatings are generally resistant to marked or hard settling, but at times they do exhibit separation and soft settling. The degree of pigment suspension in a shelf-aged specimen and the ease of remixing it to a homogeneous condition suitable for the intended use are determined in accordance with ASTM Test Method for Evaluating Degree of Settling of Paint (D 869).

APPLICATION PROPERTIES

Application or working properties of a coating are generally compared to a standard or described by requirements in the product specification. Working properties are determined in accordance with Method 4541 of FTMS 141.

Brush Application

Brushed films should be smooth and free of seeds and when applied to vertical surfaces they should show no sagging, color streaking, or excessive brush marks. Brush drag should not be excessive, although some degree of drag may be desirable for adequate film thickness application. Wall finishes are tested on vertical surfaces and floor coatings on horizontal surfaces, although evaluation of the latter on vertical surfaces may be necessary to determine performance on stair risers, railings, posts, etc. Brushing properties are determined in accordance with Method 2141 of FTMS 141. Even though the test is subjective, someone experienced in the art can produce quite consistent results, particularly in the evaluation of drag qualities.

Brush Drag

As the brush drag (resistance encountered when applying a coating by brush) increases, any natural tendency of the painter to spread the material too far is reduced. All other factors being constant, increased brush drag results in greater film thickness with consequent improvements in hiding and film durability. Conversely, increasing brush drag too much can cause difficulties in easily and uniformly spreading the coating. This can lead to excessive sagging, prolonged drying time and, in highly pigmented materials, possibly "mud-cracking" due to excessive thickness. The determination of the relative brush drag of a series of coatings applied by brush by the same operator is described in ASTM Test

Method for Comparison of the Brush Drag of Latex Paints (D 4958). When testing a group of coatings, they must all be of the same type—all water-borne or solvent-borne. It has been established that the subjective ratings thus obtained correlate well with high-shear viscosities obtained instrumentally using ASTM D 4287 (see above), provided the materials differ in viscosity by at least 0.3 P (0.03 Pa·s).

Roller Application

Both wall and floor coatings are frequently applied by roller. This type of application tends to produce some stipple pattern. The evaluation of a material's characteristics when applied by roller is covered by Method 2112 of FTMS 141. Since foaming often occurs when water-borne coatings are roller applied, the amount of foam produced and the number of craters that remain after the bubbles have broken should be determined during the test.

Roller Spatter—Some coatings spatter more than others when applied by roller. The degree to which a material spatters when roller applied can be determined by the density of the spatter. In ASTM Test Method for Measurement of Paint Spatter Resistance to Roller Application (D 4707) a specially designed notched spool is rolled through a film of the test material that has been applied to a plastic panel. Any spatter generated falls on a catch paper and after drying is rated against photographic standards. This procedure eliminates the influence of the roller cover, thus determining the spattering characteristics of the material alone.

Spray Application

Architectural coatings are some times applied by spray. Both air and airless spray are used on commercial work. Spray application properties are determined in accordance with Method 2131 of FTMS 141. Manual application is very subjective and should be performed only by an individual skilled in the art of using spray equipment.

Touch-Up Uniformity

After a paint has dried, areas where less material was applied sometimes become noticeable. If the paint has suitable touch-up properties, additional material can be applied to these areas only, instead of refinishing the complete object—wall, side of building, etc. The color, gloss, and leveling of the touched-up areas and the previously coated area should be uniform. Differences in these properties are often caused by short wet-edge time, poor leveling on recoat, and pigment orientation or flotation during and after application. Touch-up properties are determined in accordance with ASTM Test Method for Evaluation of Gloss or Sheen Uniformity (D 3928).

APPEARANCE OF THE DRY FILM

Specimens for evaluating appearance properties should conform to ASTM Practice for Selection of Coating Specimens for Appearance Measurements (D 3964).

Color

The appearance of color is greatly influenced by several factors. A color next to a yellow wall looks different than the same color next to a blue wall. The visual appearance of a colored object illuminated by incandescent light, fluorescent light, and natural light differs because the spectral composition of the different incident light sources varies. Gloss also affects color appearance. The same color in a low-gloss finish usually appears to differ when in a high-gloss coating even though instrumentally the colors may be identical. A more theoretical discussion of optical characteristics of coatings appears elsewhere in the manual.

Color Differences by Visual Comparison

Visual comparison of colors is fast and often acceptable even though numerical values are not obtained. ASTM Practice for Visual Evaluation of Color Differences of Opaque Materials (D 1729) covers the spectral, photometric, and geometric characteristics of light source, illuminating and viewing conditions, sizes of specimens, and general procedures to be used in the visual evaluation of color differences of opaque materials relative to their standards.

Color Differences Using Instrumental Measurements

The difference in color between a product and its standard can be measured by instrument. Generally the tolerance is agreed on by the purchaser and seller and may also be required if a product specification is involved. Color measuring instruments provide numerical values that can be compared to subsequent measurements. ASTM Test Method for Calculation of Color Differences from Instrumentally Measured Color Coordinates (D 2244) describes calculation of the small color differences observable in daylight illumination between nonfluorescent, nonmetameric, opaque surfaces such as coated specimens. If metamerism is suspected, visual evaluation should be used to verify the results.

Directional Reflectance

This property is a measure of the appearance of lightness of a coating. It is usually assigned a value in specifications for white and pastel shades with a typical range of 76 to 86% for white finishes. In ASTM Test Method for Color and Color Difference Measurement by Tristimulis (Filter) Colorimetry (E 1347), the directions of illumination and viewing are specified so the effect of gloss on the reflectance determination is eliminated.

Gloss

Gloss is a measure of the capability of a coating surface to reflect light in a mirror-like (specular) manner, i.e., light strikes the surface and is reflected at the equal but opposite angle. In ASTM Test Method for Specular Gloss (D 523), the numerical gloss units are the ratio of light reflected by a specimen to that reflected by the standard black glass that is assigned a gloss value of 100. The gloss of some coatings

varies greatly with the angle of incidence, so that a complete description of their gloss would require measurements to be made over a wide range of angles. In practice, the gloss of architectural finishes is adequately characterized by measurements at 60 or 85° (or both) from a line perpendicular (normal) to the surface. The 85° angle is a very low angle of illumination (a "grazing" angle of 5°) and viewing the surface and gloss at this angle is called "sheen." Attempts to standardize the levels of gloss associated with various descriptive gloss terms have not been very successful since the gloss scale is continuous with no distinct boundaries. Hence, there is considerable overlap among the gloss classifications in common usage.

Gloss, 60°

Semigloss enamels are particularly sensitive to poor enamel hold-out of primers and undercoats. Low or uneven gloss readings are indicative of this defect. Oil and alkyd house paints typically have values of 30 to 70 while trim enamels have values of 70 to 90 for 60° gloss. Floor enamels generally have a high (90+) gloss reading when first applied, but this decreases with time and traffic. Interior semigloss enamels after drying 48 h are usually in the range of 40 to 70, but measurements taken shortly after drying should be repeated after one week because the gloss can decrease significantly in the first few days of drying.

Sheen, 85° Gloss

Although low-gloss paints with good uniformity of appearance at low viewing angles often have little sheen and those with good cleansability usually have moderate sheen, this is not always the case so that sheen should not be used as a measure of other paint properties. ASTM D 523 is useful for characterizing the low-angle appearance of low-gloss coatings when the 85° geometry is employed. Most flat wall paints have a sheen of about 1 to 10 whereas velvets or eggshells range from 15 to 35.

Hiding Power

An in-depth discussion of this appearance property can be found elsewhere in the manual, so this section only briefly reviews the commonly used test methods. ASTM Test Method for Hiding Power of Paints by Reflectometry (D 2805) is precise and gives an absolute rather than a comparative result. The coating is applied with a blade-type applicator to minimize the effects of flow and leveling. Film thickness is precisely measured and film opacity is instrumentally determined. ASTM Test Method for Relative Hiding Power of Paints by Visual Evaluation of Brushouts (D 344) is a more practical test in which paint is applied with a brush on a checkerboard chart, wet-film thickness is approximately controlled by spreading rate, and hiding power is visually evaluated by comparison with a standard paint. However, results are affected by the flow and leveling of the paint. ASTM Test Method for Hiding Power of Architectural Paints Applied by Roller (D 5150) is designed to simulate application with the common tools. Although other tools may be used, the method describes use of a roller to coat a 6-ft^2 (0.56-m^2) chart printed with a series of gray stripes. The test is intended to demonstrate the hiding obtainable when the coatings are applied by experienced workers.

PROPERTIES OF THE DRY FILM

Interior and Exterior Coatings

Abrasion Resistance

This characteristic is a measure of the ability of a dried film to withstand wear from foot traffic and marring from objects rolled or pulled across the surface. Dry abrasion resistance is determined in accordance with ASTM Test Method for Abrasion Resistance of Organic Coatings by Air Blast Abrasive (D 658), ASTM Test Method for Abrasion Resistance of Organic Coatings by Falling Abrasive (D 968), and ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (D 4060). In these methods, dry abrasive is applied to a coated panel using a jet blast (D 658) or the force of gravity (D 968) when the abrasives are free flowing. In the case of the Taber test, a weighted wheel that has abrasive embedded in a resilient rubber matrix is used. Because of the poor reproducibility of abrasion methods, testing should be restricted to only one laboratory when numerical abrasion resistance values are to be used. Interlaboratory agreement is improved significantly when rankings are used in place of numerical values.

Adhesion

The ability of a film to resist removal from a substrate is certainly an important coating property. It is evaluated by many different procedures, almost all of which are not completely satisfactory because the removal force is not applied at the coating-substrate interface but at the coating surface. Consequently, when the adhesive bond between coating and substrate is greater than the cohesive strength of the coating, failure occurs within the film, so that adhesion, per se, is not measured. When multicoat systems are involved, the failure can also be between coats. Nevertheless, the tests are used to estimate whether the adhesion is adequate for the intended service.

The test most commonly used with coatings is ASTM Test Methods for Measuring Adhesion by Tape Test (D 3359). In it, a simple procedure for use in the field comprises cutting an X in the film, applying pressure-sensitive tape over the cut, removing the tape, and qualitatively assessing adhesion on a zero to five scale. The more quantitative procedure involves making a six- or eleven-cut lattice in the film. After applying and removing the tape, coating removal is evaluated by comparison with a scale that is related to the estimated area of removal. If a tool that makes all cuts in one direction is available, the test can be made in the field. However, when individual cuts are made using a metal cutting guide, the test is practical only for laboratory use. Since the cuts must be made through the coating to the substrate, the latter must be sufficiently hard to resist the cutting tool. Consequently, the test is not applicable on soft substrates such as wood, plastic, or wallboard [*3*].

Another laboratory method that requires a relatively hard substrate is ASTM Test Method for Adhesion of Organic Coatings by Scrape Adhesion (D 2197). In this method,

coated test panels are pushed beneath a rounded metal loop that is loaded with increasing weight until the coating is removed. The advantage of this procedure is that the results are numerical. Its limitation is that coatings with very good adhesion, such as coil-coated substrates, require loads of up to 10 kg. Thus, it is difficult to push panels under the loaded loop without causing it to skip along the coating surface.

ASTM Test Method for Pull-Off Strength of Coatings Using Portable Adhesion Testers (D 4541) also provides numerical results. The procedure comprises adhering a metal stud to the coating surface with an adhesive, curing the latter, attaching the test apparatus to the stud, and applying a perpendicular force that is increased until either the coating is detached, a specified value is reached, or the adhesive fails. While the hardness of the substrate is not a factor, its cohesive strength is important. As a result, failure can occur within the substrate, the coating, or the adhesive, or at the stud-adhesive interface, the adhesive-coating interface, or even the coating-substrate interface. As indicated by the title, the testers are designed for use in the field. They can, however, be used in the laboratory unless the adhesive bond strength is very high. In this case, a tensile testing apparatus and high-strength adhesive are required.

Wet Adhesion

It is essential that a finish tightly adhere to a given substrate or primer under the wet conditions of washing or scrubbing. The wet adhesion procedure described in Method 6301 of FTMS 141 is essentially an earlier version of Method A of ASTM D 3359. In it, two parallel cuts are made 1 in. (25 mm) apart instead of the X-cut. Then masking tape, which changes markedly in adhesiveness with time, is pressed against the coating surface with a roller instead of semitransparent tape being rubbed with a pencil eraser. In this method, the water immersion prior to testing is described in detail instead of being referred to in a Note.

Flexibility

Elongation is a measure of a coating's flexibility. Most semigloss and full gloss coatings can be bent over a ⅛-in. (3.2-mm) mandrel without affecting the film. However, interior flat and eggshell water-borne finishes usually pass at ¼ in. (6.4 mm), while solvent-borne coatings of the same category may pass only a ½-in. (12.7-mm) bend. Flexibility of interior coatings is usually evaluated using one of the mandrel procedures in ASTM Test Methods for Mandrel Bend Test of Attached Organic Coatings (D 522). However, measuring elongation directly with a tensile testing machine as described in ASTM Test Method for Tensile Properties of Organic Coatings (D 2370) is a much more discriminating way of estimating the flexibility retention of exterior coatings [*4*].

Resistance to Household Chemicals

An important property of some finishes is their ability to resist discoloration, spotting, softening, blistering, or removal when subjected to household chemicals or strong cleaners. In ASTM Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes (D 1308), the resistance may be evaluated with household items ranging from cold water, to detergent solutions, to staining materials such as mustard. The test may be run as covered or uncovered drops applied to horizontal plane surfaces or by immersing panels in the relevant fluids.

Interior Finishes

Block Resistance

This is an important property for interior semigloss and gloss finishes since it governs the resistance of dried coating surfaces to sticking together when stacked or placed in contact with each other. An interior finish often comes in contact with itself, especially on doors, windows, and drawers where it sometimes adheres to itself. Such blocking is dependent on the hardness of the coating and the applied pressure, temperature, humidity, and time while the surfaces are in contact. ASTM Test Method for Blocking Resistance of Architectural Paints (D 4946) covers an accelerated blocking-resistance procedure especially developed for this type coating.

Print Resistance

The ability of a coating to resist printing is important because its appearance is adversely affected if the surface texture is modified by contact with another surface, particularly one with a pattern. Interior gloss and semigloss systems applied to window sills and other horizontal surfaces are often loaded with flower pots and similar objects that tend to leave a permanent impression from the applied pressure. The tendency for a film to "print" is often a function of the hardness of the coating and the applied pressure, humidity, and time while the surfaces are in contact. In ASTM Test Method for Print Resistance of Architectural Paints (D 2064), the resistance is evaluated by placing a piece of four-ply cheesecloth on a coated glass slide, and a 500-g weight on a rubber stopper are added to create pressure. The test is accelerated by placing the assembly in an oven at 140°F (60°C) for an hour. After cooling, the film is subjectively rated for the degree of imprinting.

Film Porosity

The more porous a coating, the worse are its cleansability and enamel holdout. In ASTM Test Method for Porosity of Paint Films (D 3258), a special, colored penetrating medium is applied to the coating and the change in reflectance indicates the degree of porosity.

Washability and Cleansability

The capability of satisfactorily removing marks without damaging the film is essential for good performance of interior finishes. A coating may be washable, that is, unaffected by the detergent solution, but may not have good cleansability. Washability is evaluated by determining the resistance of the film to wet erosion either by visual assessment or measured film loss. Cleansability is evaluated by applying one or more stains and soils and determining how readily they are removed. Frequently the difference between the two terms, "cleansability" and "washability," is not clearly understood so that there is confusion as to what is really being tested [*5*]. For example, the title of ASTM D 3450 is Test Method for Washability [sic] Properties of Interior Architectural Coatings, while the method's Scope states that it is designed for determining "ease of removal of soilant." In general, the pre-

cision of both types of test is poor because several properties, such as hardness, water and detergent resistance, cohesion, and adhesion, are involved, and the end-point, except for the wet abrasion method, is rather indefinite.

Washability

This parameter is also referred to as "resistance to scrubbing" or "resistance to wet abrasion." ASTM Test Method for Scrub Resistance of Interior Latex Flat Wall Paints (D 2486) was developed for interior latex flat wall paints but can be applied to coatings of almost any type. In the test, the coating is applied to a black plastic panel that, during scrubbing with a nylon brush and abrasive cleaning agent, is raised by a narrow shim to concentrate the test area. The number of back-and-forth strokes (cycles) required to remove the film over the shim is determined. Interior latex low-gloss finishes can vary in scrub resistance from less than 100 to more than 1000 cycles.

ASTM Test Method for Wet Abrasion Resistance of Interior Paints (D 4213) is similar except that a sponge is used in place of the bristle brush and the shim is not used. In the original method, the loss per 100 cycles to erode the film almost to exposure of the black substrate was calculated on the basis of either weight or volume. In the current method weight was eliminated, even though it is easier to determine, because volume characteristics, such as pigment volume content, usually have a more direct relation to performance, which in this case is scrub resistance or washability.

Cleansability

The older of the methods for this type measurement, ASTM D 3450, is similar to the wet-abrasion method, ASTM D 4213, except a sponge is used with either the nonabrasive or abrasive cleaning agent to remove a carbon black-oil stain. The ability to remove the stain is expressed as the ratio (in relative percent) of the reflectance of the cleaned area to that of the area before application of the stain. In ASTM Test Method for Practical Washability [sic] of Organic Coatings (D 4828), numerous staining and soiling agents found in service, and commercial abrasive or nonabrasive cleansers, as well as the standardized cleaning agents, can be used. In the revised edition, the film may be cleansed manually or mechanically, but only the latter is suitable for interlaboratory testing.

Exterior Coatings

Adhesion to Chalky Surfaces

Latex paints generally have little ability to penetrate powdery substrates. Consequently, adhesion to previous coatings that have chalked is poor unless the latex paint has been modified to penetrate and bind the chalk layer to the old coating. However, certain latexes do exist that are designed to adhere well to chalky surfaces and thus do not require modification. At the time of writing, there are no ASTM test methods for adhesion to chalky surfaces, although work toward development of such a test is proceeding. The industry generally uses a pressure-sensitive tape to test for this property. The tape is pressed firmly onto the dried latex film (fresh films do not adhere as well as aged, dried films) and then removed rapidly by pulling back on itself. Method 6301 of FSTM 141 describes a similar method but it includes water exposure.

Dirt Pickup

Low-gloss exterior latex paints generally have good resistance to dirt pickup, but gloss or semigloss latex paints may be more subject to this type of disfigurement. Exterior exposure, particularly under an overhang (soffit), should indicate in a relatively short time (about one year) a paint's tendency to collect dirt when evaluated in accordance with ASTM Test Method for Quantifying Dirt Collection on Coated Exterior Panels (D 3719).

Fume Resistance

Some paints undergo a change in appearance, usually color, when subjected to air containing certain sulfur compounds, notably hydrogen sulfide and sulfur dioxide. This type of atmosphere may be present near industrial or other polluted areas and can cause a paint to yellow or darken in as little time as overnight. At the time of writing, no ASTM or federal test methods are available for evaluating this color change, but one procedure used by the industry is as follows: Apply a sufficient number of coats of the paint to two glass plates to hide completely the glass surface and allow to dry for 6 h. Then expose one plate in a moist atmosphere of hydrogen sulfide for 18 h. Compare the color of the exposed film with that of the unexposed one. The color difference should not exceed that which exists between two plates coated with a paint made with titanium dioxide pigment, lead-free zinc oxide, raw or refined linseed oil, and sufficient cobalt added for drying purposes, and similarly treated.

Artists' Paints

by Benjamin Gavett[1]

AS COATINGS, ARTISTS' PAINTS ARE DECORATIVE IN NATURE and are usually intended to endure for decades or centuries under conditions of indoor storage and display. Relative to other coatings, they are highly loaded, most often with a single pigment. Thickness of application ranges from transparent washes to thick, textural builds. Typical tools used include the airbrush, paintbrush, and palette knife, but paints are also often applied by other means, such as rags, sponges, or with the hands. They are often modified at the time of application to change sheen, texture, color, flow, or other characteristics. The substrate used is usually paper or a cotton or linen duck stretched over an open frame, but may be almost anything else, including solid or compressed wood panels, paperboard, metal, synthetic fabric, glass, figurines, clothing, or walls.

Artists' paints are categorized according to their vehicle or binder. Most common are oil (alkali-refined linseed oil), acrylic (acrylic emulsion), and water color (gum arabic). Variations of these include cold-pressed linseed oil, other drying oils of vegetable origin, and acrylic emulsion copolymers. Other natural and synthetic materials of historic significance or which are in more limited current use are acrylic solution, polyvinyl acetate, casein, egg, wax, and various gums.

Although almost any paint will be used by an artist, those formulated for such use are expected, above all else, to be as permanent as possible. However, paint is only one element in the process of manipulating materials to transform vision and ideas into art. Stability of the finished work is a function not only of the paint used, but also of application technique, substrate, age, storage, handling, and ambient environmental conditions.

TESTING OF ARTISTS' PAINTS

Testing of artists' paints is done to ensure quality and consistency in their manufacture and to establish performance parameters such as flexibility, durability, or adhesion to various substrates. Some performance criteria, such as lightfastness, are similar among different types of paints. Others can be quite different, such as flexibility and drying time of oil paints versus acrylics. It is up to the manufacturer to perform tests necessary to ensure that the paints are of a quality consistent with or exceeding that which is expected and historically true for the type of paint being produced. The artist, through experience and education, must be aware of the particular limitations inherent with each type of paint. When new applications are explored, as is often the case with art, it becomes necessary to select and perform tests which will provide confidence that the finished artwork will have the desired physical integrity.

The tests described in this section have been found to be useful to quantitatively and qualitatively describe various characteristics of artists' paints. Acceptability of quality is determined between buyer and seller. In practice, it is largely dependent upon what is considered characteristic of the particular paint type. Many of these test methods are ASTM standards that the reader should consult for further details. It is important to note that there are ASTM standard specifications for several types of artists' paints, including acrylic emulsion, watercolor, oil, resin-oil, and alkyd. These represent the current consensus, between producers, consumers, and other interested parties, of minimally acceptable performance characteristics and other criteria. Most of the following test methods were not developed for artist paints in particular. Due to the wide spectrum of types of artists' paints and potential uses, this listing does not include all test methods that may be relevant. Those included are of varying importance and applicability. They are in alphabetical order, grouped loosely into several categories: Shelf Stability, Working Properties, Film Properties, and Safety and Compliance.

Shelf Stability

It is common for art materials to languish for years on store shelves prior to being purchased. Once purchased, a container is typically opened and closed many times during a life cycle which may take months or years. Stability is evaluated to help ensure endurance of the product through foreseeable conditions of storage and use.

Appearance

The appearance of the undisturbed paint in the container creates an impression of quality, regardless of the ease of restoring it to a homogenous condition. Evaluations for appearance in the retail container are most accurate when based on true conditions of storage and use. However, this is not practical when developing new products. Potential failure may be more quickly realized by placing samples in a laboratory oven at moderately elevated temperature. As the difference between normal and test temperature increases, accuracy in predicting potential problems may decrease because higher temperatures may exaggerate changes. In a study of

[1]Assistant technical director, Golden Artist Colors, Inc., Bell Road, New Berlin, NY 13411.

Copyright© 1995 by ASTM International

latex paints published in the *Journal of Coatings Technology* [*1*], the authors concluded that an oven temperature of approximately 50°C most accurately predicted shelf life performance. Items to note regarding appearance may include skinning, surface cracking, or separation. Parameters of acceptability will vary depending upon expectations of the customer for the particular type of paint.

Color Change

Sometimes the color of a paint film produced from a container of paint changes during storage, for example, as can happen when a pigment is not compatible with the pH of the formulation. This may be determined by preparing a fresh batch of the paint to be tested and immediately preparing a drawdown from it. Subsequent drawdowns at the same thickness may be periodically prepared from the same batch after the paint has aged in the container. The subsequent drawdowns are compared against the original. The results obtained from this test may be accelerated by using a laboratory oven.

Consistency

During storage and use, it is desirable that the paints maintain their intended texture and body. Evaluations are based on visual observation and workability with typical application tools. Items to note include mealiness, tackiness, elongation, and break, as well as other body characteristics. Conclusions may be drawn by comparing batches of the same formula, made at different times, which have been stored and otherwise treated similarly. It is useful to evaluate both full and partially empty containers.

Flocculation

To determine if the pigment is fully dispersed or has remained dispersed over time, a tint of the color is prepared with a compatible white. A drawdown is made and the excess paint is recovered and set aside until the drawdown is dry. Next, a small amount of the original wet mixture is placed on top of the dried paint film. This paint is then rubbed under pressure in a circular motion (a gloved thumb is suitable) in an effort to cause further dispersion of the pigment. If it has become more fully dispersed, the rubbed paint will appear as a stronger tint against the original drawdown.

Freeze-Thaw Stability

Shipping and storage often expose artists' paints to extreme temperature fluctuations. Water-based paints can be quickly ruined if not formulated for protection from freezing. ASTM Specification for Artists' Acrylic Emulsion Paints (D 5098), in Section 6.10 of the *ASTM Book of Standards*, describes the procedure used for testing acrylic paints. The same procedure is used for watercolors. To meet the requirements of the standard, the paints must pass five freeze-thaw cycles while retaining proper consistency.

Package Integrity

The expected life and use of the package containing the paints should be considered when designing appropriate tests. Consider, for example, how the container will be shipped or how many times a tube will be flexed. Potential interactions between the paint and packaging should also be evaluated. For example, solvents may migrate through the walls of plastic containers, causing them to become drawn inward. Real time evaluations are best, but potential failure can be accelerated by increasing temperature or solvent load.

Seeding

Paint ingredient incompatibilities may result in the formation of agglomerates. This can be readily observed by preparing drawdowns of the paint, as described in ASTM Practice for Preparing Drawdowns of Artists' Paste Paint (D 4941) and examining the dried paint film. ASTM Test Methods for Coarse Particles in Pigments, Pastes, and Paints (D 185) may also be used.

Settling

In low-viscosity formulations, it is common for pigments to exhibit some settling. Ideally this would not happen, but if it does, it is important that the pigments are easily remixed. Settling that occurs over time may be evaluated according to ASTM Test Method for Evaluating Degree of Settling of Paint (D 869).

Spoilage/Putrefaction

It is necessary to protect against microbial contamination from raw materials and packaging or that may be introduced during manufacturing. Also, since artists' paints are typically opened, used, and reclosed many times, it is important that they be formulated to resist microbial growth from contamination occurring subsequent to purchase by the consumer. ANSI Z356.5, American National Standard for Art and Craft Materials-Paints and Inks, Section 4.2, describes a test method for evaluating the effectiveness of preservatives used in paint formulations. Paints to be tested are inoculated with pieces of bread which have been covered with a sugar solution and allowed to mold. After two weeks, the paints are inspected for decomposition.

Viscosity Changes

Paint stability is quickly and quantitatively evaluated by monitoring viscosity. Viscometer type and method have not been standardized for artists' paints. If needed, a method may be agreed upon between buyer and seller. For most purposes, it is sufficient to ensure consistency of test conditions and equipment when doing periodic rechecks. Accelerated aging with the use of a laboratory oven is usually predictable of real-time viscosity stability of water-based paints.

Working Properties

Many attributes of importance to the consumer of artists' paints are difficult to measure and report with repeatability. This subjectivity is often coupled with varying preferences among users. An ideal paint for one artist may be lacking in certain qualities for the next. It is not as important to standardize these characteristics as it is to determine them and transfer this knowledge to the buyer.

Brushing Characteristics

Paints are brushed out on standard substrates by experienced technicians and rated as being smooth, sticky, tacky, or fluid, as described in Section 6.6 of Commercial Standard

(CS98) for Artists' Oil Paints [2]. This was the original quality standard for artists' paints and was the base from which the subsequent ASTM artists' paint quality standards were developed. It is also common to describe artists' paints for their tendency to flow and level or hold brush strokes and peaks.

Color Variation

If constancy of color is desired, it may be determined by placing samples next to each other on a test card and drawing them down together using a thin film applicator. Comparisons of masstone, undertone, and tint are useful. For quantification and reporting, spectrophotometric measurements and C.I.E. L*a*b* color difference may be obtained according to the practices described in ASTM Test Method for Calculation of Color Differences from Instrumentally Measured Color Coordinates (D 2244).

Drying Time

ASTM D 5098, for acrylics, and ASTM Specification for Artists' Oil, Resin-Oil, and Alkyd Paints (D 4302), specify drying time requirements. Dust-free drying time of these and other types of paints are determined by following the procedures described in ASTM Test Methods for Drying, Curing, or Film Formation of Organic Coatings at Room Temperature (D 1640).

Fineness of Dispersion

Finely dispersed pigments are important for smooth brushing, realizing tinting strength potential, and maximizing encapsulation of pigment within the binder. ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems (D 1210) may be followed to measure this characteristic.

Odor

Evaluation of odor may be important in determining potential consumer acceptance of artists' paints. The different vehicles have characteristic odors and what is objectionable to some may not be to others. Formula variations may be rated, based on the acceptability of their odor, by a panel of intended users.

Opacity

Opacity is not standardized for artists' paints. It is expected to vary depending on the pigment and vehicle used. The artist benefits if opacity ratings are reported on the container or in manufacturers' literature. This characteristic is typically evaluated by applying a drawdown over a test panel that has adjoining areas of black and white. A scale is then established and colors are assigned values relating to a range from highly transparent to fully opaque.

Tinting Strength

The potency of a color is indicative of its value to the user, particularly when blending with white (absorption tinting strength). Depending on chemical composition, pigments are expected to vary accordingly in strength. Identically pigmented paints may exhibit differences due to degree of processing or loading. It would not be appropriate to critically compare paints of different vehicles because of differences in the loads they will tolerate. ASTM Standard Test Method for Determining the Relative Tinting Strength of Chromatic Paints (D 4838) may be followed to arrive at instrumentally derived determinations of tinting strength relative to that of a standard or reference paint. Simple comparisons between paints can be made by using a white paint of standard composition and strength to prepare tints, which are then drawn down along side of each other. The tints are most accurately prepared using a weight-based ratio of the standard white to the test color. A ratio based on volume, using syringes, may be useful if an accurate balance is not available or if it otherwise suits the purpose of the user.

Viscosity

Artists' paints are available in a wide range of viscosities, from pourable ink-like to heavy impasto. Oil paints are typically expected to maintain definition of the brush stroke, provide sharp peaks, and retain their shape as they emerge from the tube. Water-based vehicles are highly manipulative, and the desired viscosity is dependent on the intentions of the user and manufacturer. Viscosity, thixotropy, and dilatancy may be determined with the equipment and techniques described in ASTM Test Methods for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D 2196).

Film Properties

Adhesion

Intercoat and substrate bonding of artists' paints are extremely important. They become especially critical to evaluate when determining surface preparation techniques for new or unusual substrates or when considering multi-media applications. There are many types of adhesion testing apparatuses, but a useful and inexpensive test involves cutting the paint films and attempting to lift them with pressure-sensitive tape. This is described in ASTM Test Methods for Measuring Adhesion by Tape Test (D 3359).

Bleeding

Artists' paintings are typically created in a manner that results in overlapped or layered films. The tendency for color of an underlying dry paint film to migrate through to subsequently applied paint is an occasional but usually unwelcome occurrence resulting from the pigment exhibiting some solubility in the vehicle. The tendency for bleeding may be determined by applying an opaque white overstripe onto a smooth, dried paint film. The white is extended off the paint film and onto the uncoated portion of the test support. Discoloration due to bleeding will be readily apparent. This test is described as Test Method B of ASTM Test Methods for Bleeding of Pigments (D 279).

Block Resistance

Artists' paintings are not typically produced, used, or stored in a manner which will cause them to come into contact with and stick to other surfaces. However, there are times when this does occur, such as in production situations or when there is inadequate storage space. If block resistance is important to the user, the paint in question should be evaluated because many artists' paints exhibit inherently poor block resistance. A case-specific test should be designed to simulate worst case scenarios of pressure, temperature, and humidity

fluctuations. Anticipated drying and storage times should also be considered in the test design.

Chemical Resistance

Resistance to the various liquids which a painting may be expected to come into contact with is an important characteristic. These include varnish vehicles, solvents used in varnish removal, and cleaning solutions that may be used on the paint film. Chemicals to be tested with a particular paint vary depending on the type of paint and what is expected of it. A procedure for designing appropriate tests may be based upon the Spot and Immersion Tests described in ASTM Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes (D 1308).

Flexibility

Paints applied to flexible supports, such as stretched cotton or linen canvas, may be susceptible to potentially destructive forces. The different types of artists' paints vary in the degree they will flex without failure. Although there are no established standards, they have different thresholds of expectation and, therefore, acceptability.

During storage or shipping, paintings are often rolled up. ASTM Test Methods for Mandrel Bend Test of Attached Organic Coatings (D 522) describes equipment and methods for determining and rating flexibility. Relevancy is increased by testing the coatings over the intended substrate and primer. Combined with the use of accelerated aging techniques, the mandrel test will help predict natural embrittlement of the paint film.

Paintings must also endure expansion and contraction of the fabric due to changes in environmental humidity and temperature. Sometimes these conditions become extreme, as when a painting is shipped during freezing weather. Failure will occur more quickly if the individual components of the painting have greater relative differences in their moduli of elasticity. Use of a temperature and humidity-controlled environmental chamber programmed to expose paintings to repeated cycles of extreme conditions will accelerate the failure that might be observed over time under normal conditions.

Another force of concern is mechanical impact against the film that may occur during handling. For example, when a painting is mounted on an open-back stretcher, fingers may inadvertently press into it as it is being carried. The risk of damage increases as temperature decreases and the glass transition temperature is approached. The rate at which external forces are applied also influences susceptibility to damage.

Gloss

Some manufacturers of artists' paints will add inert flatting agents to control the gloss values of the various colors so that they are similar within a line. Others will allow a color's gloss to be dictated by the characteristics of the colorant, i.e., tolerable load and particle size. Gloss values for artists' paints have not been standardized. It is a matter of preference and manufacturing philosophy. When required, gloss may be specified between the buyer and seller, with measuring parameters identified.

Lightfastness

ASTM Test Methods for Lightfastness of Pigments Used in Artists' Paints (D 4303) describes three methods used to determine resistance to fading of acrylic, watercolor, alkyd, and resin-oil artists' paints. Included are conditions of exterior exposure under glass, artificial daylight fluorescent lamps, and xenon-arc apparatus. Prior to exposure, samples to be tested are tinted with white until they reach 35 to 45% reflectance at their wavelength of maximum absorption, between 420 and 620 nm. With each method, exposure is continued until specimens have been exposed to a total radiant dose of 1260 MJ/m^2. To meet the ASTM standard specifications for use in artists' paints, the pigments must be tested under at least two of the three methods and exhibit a mean color change of less than eight color difference units (CIE 1976 L*a*b* color difference equation). These test methods are designed to predict performance of artists' paints displayed in typical household or museum environments. Results may not be indicative of performance if the intended use is more rigorous, such as in exterior mural applications.

The most recently developed ASTM practices for determining the lightfastness of artists' materials uses a method of exposing samples indoors to sunlight filtered through window glass while simultaneously exposing a series of eight ISO Blue Wool Reference materials to control the duration of exposure. One half of each specimen and control is shielded from exposure during the test. This test takes longer to run, but it is relatively inexpensive. It is intended for artists' materials which are not specifically covered by other ASTM standard test methods. For details, see ASTM Standard Practice for the Visual Determination of the Lightfastness of Art Materials by the User (D 5398) and ASTM Standard Practice for the Visual Determination of the Lightfastness of Art Materials by Art Technologists (D 5383).

Yellowing

While traditional paint vehicles may be expected to yellow to some degree, this may be considered a serious flaw if encountered in the newer generation of synthetic media. To determine the relative potential for yellowing of a vehicle, a standard titanium dioxide white pigment may be formulated into the test vehicle and into one of known stability. They are then exposed to the accelerated methods described in ASTM D 4303 and amount of yellowing determined with ASTM Practice for Visual Evaluation of Color Differences of Opaque Materials (D 1729) or Test Method D 2244. It is also useful to subject films of the unpigmented vehicles to the same tests.

Safety and Compliance

Flash Point

Solvent-based paints may require flash point determination for label warnings and to determine applicability of shipping regulations. The prescribed test method can vary depending on the authority. ASTM Test Methods for Flash Point of Liquids by Setaflash-Closed-Cup Apparatus (D 3278) is usually applicable.

Toxicological Evaluation

The Federal Hazardous Substances Act (FHSA) requires all art materials to be evaluated by a board-certified toxicologist for potential to cause acute and chronic health effects. This law was incorporated into the FHSA with the Labeling of Hazardous Art Materials Act (LHAMA), the basis of which is ASTM Practice for Labeling Art Materials for Chronic Health Hazards (D 4236). A wide assortment of test methods provide the information required for the toxicological assessment. These are not specified by the Standard Practice or LHAMA, but include all which are embodied in the field of toxicology as well as compositional analysis of the paints and their constituents. For example, test procedures described in EN-71-3:1988, Safety of Toys, are used to determine solubility of metals present in paint, under conditions intended to simulate 4 h in the human alimentary tract. In vitro techniques are also used for determining potential eye and skin irritation. The toxicologist determines any testing that may be required to supplement the information that exists for the raw materials in a product. Appropriate precautionary label information is then assigned. The toxicologist must supply the criteria used in making these determinations to the Consumer Product Safety Commission, the enforcement agency of the Federal Hazardous Substances Act.

Volatile Organic Compounds (VOC)

Artists' paints are sometimes applied to substrates that are covered by VOC regulations. Architectural, sign-painting, and furniture application are examples. ASTM Practice for Calculating Formulation Physical Constants for Paints and Coatings (D 5201) provides equations to calculate the theoretical VOC content of paints, based on the formula and exclusive of water and exempt solvents.

Automotive Product Tests

by Rose A. Ryntz[1]

EACH OF THE MAJOR AUTOMOTIVE COMPANIES requires a specific protocol of testing to be performed on appropriate substrates in order to grant approval of a particular paint or coating. The specification testing is rigorous and often takes up to two years to complete. This section attempts to provide the reader with a general guideline of the required test methods utilized by the big three automotive companies (GM, Ford, and Chrysler) and where applicable relates to testing required by a Japanese counterpart, Toyota, in gaining materials and processes approval.

AUTOMOTIVE PRODUCT IDENTIFICATION

The approval process at the automotive manufacturers is subdivided into specific categories based on the substrate to be coated, i.e., flexible or rigid, and the coating type tested, i.e., cleaner, primer, topcoat. The outdoor durability of the coating is also a consideration, being designated as a weatherable [good resistance to ultraviolet (UV) degradation] or a nonweatherable (poor resistance to UV degradation) quality.

Surface Cleaners and Pretreatments

Surface cleaners are generally defined as waterborne or solventborne materials that pretreat a substrate prior to the coating process to ensure optimal wetting of the surface. The pretreatment then renders the substrate more paintable. Exceptions to either the waterborne or solventborne material class do exist, for example, in the pretreatment processes utilized on thermoplastic polyolefins. In these instances, the surface preparation consists of exposure to plasma, corona, or benzophenone/UV radiation to render the substrate paintable.

The surface cleaner generally acts to remove greases, oils, and drawing compounds from the substrate to prevent paint adhesion loss when coated. In the case of the plasma, corona, or benzophenone/UV radiation exposure of a substrate, the surface is oxidized to promote paint adhesion.

Most solventborne cleaners are based on either methylene chloride or trichloroethylene due to their superior solvency power for greases and oil. At times, isopropanol and naphtha are used on solvent-sensitive plastics such as polycarbonate to prevent degradation of the substrate. However, recent environmental regulations, i.e., the Clean Air Act of 1990, will severely limit or eliminate the use of such cleaners in the future.

Waterborne cleaners are either acidic or basic in nature. Today most cleaners are acidic so that residue remaining as a possible contaminant on the surface does not interfere with topcoat cure.

Waterborne surface cleaners are often applied to substrates in a three-to-nine-zone process. Each zone consists of a specific cleaning or conditioning step. Pretreatment or surface cleaning systems are often limited by space considerations and are designed functionally to adopt as near state-of-the-art as possible. Required zones or stages consist of surface cleaner followed by a water rinse and ending with a deionized water rinse. Additional stages can be added to accomplish several cleaning processes, conditioners, and water rinses. Additional rinsing stages provide more security in removal of trace contaminants, which could lead to topcoat adhesion problems.

After surface cleaning, the substrate is coated and tested to topcoat specifications. In order to be qualified as an appropriate cleaner, the topcoat should conform to all designated testing requirements.

Primer (Nonweatherable)

Electrodeposited Primer

Anodic electrodeposition was first introduced in the 1960s and was subsequently replaced by the cathodic process in the 1970s. Approximately 75% of all cars manufactured in the world are primed using this process.

Following pretreatment, metal parts are immersed in the electrocoat dip tank. The paint itself is 75 to 95% water. Upon application of an electrical potential, i.e., voltage, a paint film possessing 85 to 100% solids is deposited upon the parts.

Once deposited, the paint film acts as a resistor, increasing the resistivity as the film thickness increases. This accounts for the fact that as one area of a part is coated, uncoated, or relatively less coated, areas draw increased current, resulting in a very uniform coating regardless of the substrate shape or complexity.

The electrocoat technology, often consisting of an amino extended epoxy resin cross-linked with a blocked isocyanate, provides corrosion protection over cold-rolled steel for up to 400 to 500 h in a salt fog cabinet. Normal film builds of the dried electrocoat film range from 0.8 to 1.5 mils. The electrocoat technology is referred to as normal build, low build,

[1]Technical specialist, Plastic Trim and Products Division, Ford Motor Co., 24300 Glendale Ave., Detroit, MI 48239.

Copyright© 1995 by ASTM International

high build, or high build and a half, depending on the film thickness achieved.

Conductive Primer

A conductive primer, as the name implies, provides an electrical charge to the surface of a plastic to render it paintable by electrostatic methods. Transfer efficiency of topcoats is thus improved.

The conductivity in the dried paint film is achieved most often through the use of a conductive carbon black pigment. The pigment-to-binder ratio of the conductive primer is adjusted to obtain a dry film conductivity of at least 140 Ransberg units (measured on a Ransberg meter), $<1000\ \Omega$, at a thickness of 0.8 to 1.2 mils.

As mentioned above, the conductive primer is utilized only on plastics since metal is capable of holding a potential. Conductive primers are utilized over both rigid and flexible plastics. Through modifications in the chemistry of the primer, flexibility requirements, i.e., over flexible plastics, can be achieved.

Nonweatherable primers, as the name implies, are not ultraviolet resistant. They must be topcoated. The primer can be of a one-component or two-component nature, depending upon the process capability. The chemistry of the one-component primers for rigid substrates is often comprised of an epoxy ester or alkyd cross-linked with a melamine, while flexible nonweatherable one-component primers consist of a polyester resin cross-linked with a melamine. Two-component primers, on the other hand, are based upon the same basic binder chemistries cross-linked with aromatic isocyanates in the nonweatherable class.

Nonconductive Primer

A nonconductive primer is not capable of holding an electrical potential and is utilized to provide a "Class A" surface. A "Class A" surface is a surface which, when topcoated, will provide the same appearance characteristics (gloss and distinctness of image) as a topcoated metal part. The nonconductive primer can be utilized over metal or plastic parts to provide filling characteristics to porous or marred surfaces.

The chemistry of a nonconductive, nonweatherable primer is often the same as that employed in the conductive primer. Film thicknesses range from 0.8 to 1.2 mils. Very often, the nonconductive primer is utilized over only rigid substrates, i.e., metal and rigid plastics. The primer can be "color keyed" to the topcoat color (i.e., red if a red topcoat is to be applied) so that aberrations in the topcoat (i.e., chips, scratches) will not be as noticeable.

Primer (Weatherable)

Primer/Surfacer

Weatherable primers are utilized to provide a UV durable finish over mostly flexible plastics. The primer is often color coordinated to the topcoat color to provide an aesthetically pleasing accent color. One could also refer to weatherable primers as monocoat topcoats.

Primers in this class are mostly flexible acrylic or polyester-based resins cross-linked with melamine (one-component) or an aliphatic isocyanate (two-component). They must meet the same flexibility requirements as topcoats at 1.2 to 1.5 mils. Flexible, weatherable, nonconductive primers are only utilized over "Class A" plastics.

Conductive Primer

Weatherable, conductive primers can be utilized over flexible or rigid substrates to provide a part which can be electrically grounded. The requirements for conductivity are much the same as those described above for nonweatherable conductive primers with conductive pigments utilized to provide resistance.

Weatherable conductive primers are often utilized in rub-strip areas, i.e., the black strip on a bumper or fascia, to provide a two-tone appearance. Accent colors are applied adjacent to the conductive primer to provide aesthetically pleasing parts.

Weatherability requirements are much the same as those described later for monocoat technology. The chemistry utilized to achieve the weatherable nature of the primer is the same as that described above for weatherable primers.

Topcoats

Interior Topcoat

An interior topcoat is utilized to provide a protective and decorative surface suitable for use on interior parts made of steel, aluminum, zinc-based die castings, plastics, pulp preform molded board, or other substrates. The topcoat often provides a particular feel, i.e., "soft leather feel," or a desired gloss, i.e., less than 6/60° gloss meter, to stop blinding reflections.

The chemistry of the interior topcoat varies depending on the curing process utilized, i.e., air-dry, low-temperature, or high-temperature cure. Acrylic and urethane technology have been the major chemistries utilized. On hard-to-coat substrates, a primer is often utilized to gain adhesion.

Weatherability and "fogging" are two important test specifications to which the topcoat must abide. "Fogging," described later, refers to the migration of plasticizers in the coated substrate. This is of particular concern on instrument panels and dashboards since embrittleness of the substrate and/or windshield contamination will occur.

Exterior Topcoats

Monocoat—A monocoat technology, as the name implies, is a final single coat which provides color, gloss, DOI (distinctness of image), and durability. It is applied to a total dry film thickness of between 1.5 and 2.5 mils depending upon color and hiding requirements. It should be satisfactory for use over specified primers, sealers, or other enamels, as in repair or two-toning operations. Paints specified under this standard can contain acrylic resin, urethane resin, alkyd resin, etc. as the main binder which is subsequently cross-linked with a melamine resin [referred to as a one-component (1K) paint] or an isocyanate resin [referred to as a two-component (2K) paint]. Necessary pigments and additives are blended and included to achieve final color match. Paints shall not contain toxic substances such as chrome, cadmium, etc. under the Toyota specification.

The chemistry of the monocoat is modified as needed to reflect its use over flexible or rigid substrates. The corresponding cure requirements are matched with the substrate

to be coated so as not to exceed the heat distortion temperature of the plastic parts.

Basecoat/Clearcoat—The specifications for a basecoat/clearcoat are much the same as those required of an exterior monocoat in that they require color match to a standard, a particular gloss and DOI, and a minimum durability. The basecoat, containing the necessary pigments and additives to match a particular color standard, is applied to a dry film thickness of 0.3 to 1.2 mils depending on color. It should be satisfactory for use over specified primers, sealers, or other enamels, as in repair or two-toning operations. Paints specified under this standard can contain acrylic resin, urethane resin, alkyd resin, etc. as the main binder which is subsequently cross-linked with a melamine resin (1K) or an isocyanate resin (2K). Paints shall not contain toxic substrates such as chrome, cadmium, etc. under the Toyota specification.

The clearcoat is applied over either a wet (not fully cured) basecoat (referred to as a wet-on-wet application) or a dry (cured) basecoat (referred to as a bake-on-bake application) to provide required gloss, DOI, and "wet look" depth to the cured finish. The clearcoat is applied to a dry film thickness of 1.8 to 2.0 mils. It can contain acrylic resin, urethane resin, alkyd resin, etc. as the main binder which is subsequently cross-linked with a melamine resin (1K) or an isocyanate resin (2K). Necessary ultraviolet absorbers and hindered amine light stabilizers are added to the clearcoat formulation to provide the required exterior durability.

As in the monocoat technology, the chemistries of the basecoat/clearcoat are modified to reflect their use over flexible or rigid substrates. Cure requirements are also designed to reflect the heat distortion temperatures of plastic substrates.

REQUIREMENTS

Material Requirements

Hiding (ASTM D 2805)

ASTM Test Method for Hiding Power of Paints by Reflectometry (D 2805) covers the determination, without reference to a material paint standard, of the hiding power of paints with Y tristimulus values greater than about 15%. It uses the Kubelka-Munk equations to calculate the hiding power from reflectance results obtained by broad-band filter reflectometry. It is utilized by General Motors for all automotive exterior topcoat materials.

Dry Hiding (Ford Laboratory Test Method BI 1-4)—A basecoat is required to provide complete visual hiding at specified film thicknesses (18 to 23 μm unless specified for special colors) over a black and gray straight-line hiding chart.

1. *Black and Gray Straight-Line Hiding Chart*

Hiding chart is 50 by 280 mm, consisting of a black stripe of 25 by 280 mm and a gray stripe 25 by 280 mm in a side-by-side configuration.

2. *CIE L*a*b* Hiding Chart Values*

Black:	L*	25.74
	a*	−0.13
	b*	−0.11
Gray:	L*	65.61
	a*	−1.55
	b*	9.84

(utilizing 10° Standard Observer and Illuminant D65).

PFUND Crytometer Hiding Power—The hiding power in Chrysler Material Standard MS-PP1-1 covering paint requirements and performance over plastics is determined with a Pfund crytometer, utilizing the 0.09-mm (0.0035-in.) wedge (unless otherwise specified). The hiding power is specified in the material standard covering the individual coating.

Odor

The material's odor is reviewed in reference to current production materials. Any significant differences must be evaluated in laboratory and production trials. Odor testing is performed at an approved laboratory.

Flammability

Although not a requirement for the supplier, a flash point of below 27°C necessitates the user to classify paint as a potential fire hazard. Plant security must assure that proper fire precautions are provided.

Smoke Characteristics—General Motors requires that a material's tendency to smoke during processing be reviewed in comparison to current production materials. Any significant differences must be evaluated in laboratory and production trials.

Ultraviolet (UV) Transmission

For exterior topcoats, General Motors and Ford require that a coating be opaque to UV transmission to the underlying primer layer or substrate at a film thickness 20% less than the minimum of the recommended film build range. The coating shall have been baked at the maximum of the acceptable cure range on its bake time and temperature process control chart. Opacity is defined as no transmission between wavelengths of 290 to 350 nm.

Solvent Emissions

All topcoat materials must meet specific plant solvent emissions restrictions at spray viscosities which yield acceptable applied appearance. Chrysler specifies that the material shall comply with all the requirements of the Clean Air Act (USC 1857, as amended) and any applicable federal, state, or local statute pertaining to the establishment and maintenance of the National Ambient Air Quality Standards as administered by the Environmental Protection Agency (EPA) or any authorized state or local governmental unit. The material shall comply with all of the requirements of the Water Pollution Control Act (PL 92-500, as amended) and shall be formulated to eliminate, as far as possible, constituents that would be classified as hazardous under the Resource Conservation and Recovery Act (40CFR 260-265, as amended). The material shall contain no benzene, chlorinated, or other toxic compounds.

Percent Solids by Weight—The weight solids of a material are determined according to ASTM Test Methods for Volatile Content of Coatings (D 2369B).

Percent Solids by Volume—The volume solids of a material is determined according to ASTM Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D 2697).

Volatile Organic Compounds (VOC)—The volatile organic compounds (VOC) of a material is determined according to ASTM Practice for Volatile Organic Compound (VOC) Content of Paints and Related Coatings (D 3960).

Density—The density of a material is determined according to ASTM Test Method for Density of Paint, Varnish, Lacquer, and Related Products (D 1475).

Viscosity

1. *Newtonian Viscosity*

For Newtonian materials, the viscosity is measured according to ASTM Test Method for Viscosity by Dip-Type Viscosity Cups (D 4212) with a dip-tank viscosity cup.

2. *Non-Newtonian Viscosity*

For non-Newtonian materials, the viscosity is determined according to ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D 2196) with a rotational (Brookfield) viscometer.

3. *Viscosity Stability*

The stability of a material to settling or change in viscosity is usually conducted at package viscosity (as shipped). Tests are run after standing for 90 days at room temperature and as a function of accelerated heat aging (oven stability). The material after aging must be free of settling which cannot be dispersed by normal agitation and must not increase in viscosity by a percentage of its original viscosity.

Throwpower

The throwpower, in reference to cationic electrodeposition coatings, is the degree to which an electrodeposited film coats interior or recessed areas. Specific requirements are dependent upon voltage, resin type, and auxiliary electrode type and will vary by production plant.

pH

The pH of waterborne materials shall be determined according to ASTM Test Method for pH of Aqueous Solutions with the Glass Electrode (E 70) and for electrocoat baths according to ASTM Test Method for Measurement of Apparent pH of Electrocoat Baths (D 4584).

Resistivity/Conductivity

The resistivity of a material shall be determined according to ASTM Test Methods for Electrical Conductivity and Resistivity of Water (D 1125).

Performance Requirements

Color

The material shall match the appropriate master color standard after all the baking cycles for the particular color.

Gloss

The gloss of an interior coating is measured on a Hunter specular glossmeter at 60° and shall be specified by means of a letter suffix to the color number assigned by styling as follows:

A 92 min	F 35 ± 3
B 80 ± 4	G 20 ± 3
C 70 ± 4	H 10 ± 3
D 62 ± 3	J 6 max
E 50 ± 3	

The gloss of exterior topcoats is measured on a Hunter specular glossmeter at 20° and should be a minimum of 90 with no more than 4 units decrease in gloss after rebake.

Distinctness of Image (DOI)

The material shall be subjected to a DORIGON (distinctness of reflected image goniometer) and shall be within specified materials standard values.

Appearance

The topcoat shall be smooth and uniform, free of sags, craters, pinholes, seediness, abnormal roughness, or excessive metallic mottling. It shall have reasonable tolerance for ordinary cleaning and exhibit excellent polishing characteristics.

Film Thickness

A material's film thickness shall be determined according to ASTM Test Method for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to a Ferrous Base (D 1186).

Hardness

The material shall have sufficient hardness to resist marring through normal handling.

Micro Hardness—The microhardness of materials applied over rigid substrates shall be determined on a TUKON hardness tester according to ASTM Test Methods for Indentation Hardness of Organic Coatings (D 1474A).

Taber Wear Resistance—There shall be no material removal greater than the approved reference panels when tested according to ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (D 4060-81).

Adequacy of Cure

Upon subjection to solvent exposure by (methyl ethyl ketone or xylene) double rubs with a cloth, there shall be no transfer of the material's color nor dulling or softening of a clearcoat.

Adhesion

Initial Adhesion—The film shall adhere tightly and not flake, crack, or powder from the substrate. When scribed with a crosscut (X-scribe) or crosshatch, the coating should maintain a minimum of 99% adhesion after taping the area.

Moisture Resistance—After exposure to 100% relative humidity [ASTM Practice for Testing Water Resistance of Coatings in 100% Relative Humidity (D 2247)], the coating should maintain 99% adhesion when tested as above.

Gravelometer

The chip resistance of a coating is determined according to SAE J400 and ASTM Test Method for Chip Resistance of Coatings (D 3170). The chipping shall not exceed a predetermined ranking.

Toughness

Dime Scrape—The material shall not flake, peel, or lose adhesion upon subjection to scribing with a dime. This test shall be performed only on rigid substrates.

Knife Scrape—The material shall not flake, peel, or lose adhesion upon subjection to scraping with a knife. This test shall be performed on flexible substrates only.

Fluid Resistance

When subjected to the specified fluids by the methods and times specified in the applicable standards, the coating shall show no loss of adhesion, blistering, softening, swelling, or discoloration:

- xylene
- synthetic gasoline
- synthetic gasohol
- naphtha
- recommended cure check solvent
- tap water
- acid rain mixture

Immersion Test—The material shall show no loss of adhesion, blistering, softening, swelling, or discoloration when subjected to immersion testing in the specified fluids according to ASTM Test Method for Effect of Household Chemicals on Clear and Pigmented Organic Finishes (D 1308).

Cold Checking Resistance

The material shall withstand a minimum of 10 to 15 cycles of exposure to heat, humidity, and freezing conditions (at specified times and intervals) with no resultant cracking, crazing, or adhesion loss.

Crock Resistance

The material shall not transfer any color onto a cloth when exposed to the dry crock method set out in the SAE J861 method.

Flexibility

Coatings intended for use on flexible or semirigid substrates shall exhibit no cracking or induced substrate failure when subjected to bending over mandrels of various diameters at predetermined temperatures.

Water Resistance

The material shall not blister, dull, wrinkle, or peel when subjected to controlled condensation according to ASTM Practice for Testing the Water Resistance of Coatings Using Controlled Condensation (D 4585) method and X-scribed.

Weatherability

Test panels for Florida durability (facing 5° south from horizontal) and accelerated weathering durability are prepared in accordance with manufacturer's recommendations for film thickness and bake. The coating shall meet customer goals for useful life as measured by gloss retention and general appearance guidelines (color, adhesion, etc.).

QUV Exposure—Accelerated exposure is run according to SAE J2020 or ASTM Practice for Operating Light- and Water-Exposure Apparatus (Fluorescent UV-Condensation Type) for Exposure of Nonmetallic Minerals (G-53) methods dependent upon coating type and use (i.e., interior or exterior). Limits for exposure length are set by the manufacturer.

Weatherometer—Accelerated exposure is run with a carbon arc or a xenon arc for a specified interval dependent upon coating type and use. Limits for exposure length are set by the manufacturer.

Fadeometer—Interior coatings are run for a specified time period (usually 100 h) on a Fadeometer and shall not exhibit any discoloration, dulling, or adhesion loss.

Fixed Glass Bonding

Any coating intended for use in glass bonding areas must be qualified to the requirements for a new topcoat material intended as the bond surface. The coating is measured for its adhesive and/or cohesive strength to structural adhesives in a lap shear test.

Corrosion Resistance

There shall be no blistering or more than 3-mm rust creepage or loss of adhesion from a line scribed through to bare steel when exposed to salt spray resistance according to ASTM Test Method of Salt Spray (Fog) Testing (B 117) conditions for a specified time interval.

Permeability

For porous plastic substrates, i.e., SMC (sheet molding compound), certain manufacturers are requiring that coating materials be tested to solvent penetration resistance standards. General Motors, in particular, has developed a "fluorescent dye microscopy" test to limit the amount of solvent permeation into SMC from conductive primers.

Process Requirements

Basic property feasibility must be established as part of material qualification with each automotive manufacturer. Boundary conditions for key process control parameters must be established as to their effects on film build, appearance, and durability.

Viscosity

Viscosity versus temperature charts at various shear rates must be furnished.

Color Feasibility

A statistically designed experiment matrix must be run on a minimum of colors per standard procedure.

Transfer Efficiency

Initial comparisons will be made with current approved materials under controlled laboratory conditions to establish relative transfer efficiency.

Bake Latitude

A chart depicting acceptable, unacceptable, and marginal conditions for cure based on appearance, durability, and glass bonding (if applicable) characteristics of the coating must be furnished.

Circulation Stability

The supplier must establish that coating performance will not be degraded under typical, normal production use. Flow velocity required to maintain suspension or redisperse settled pigment must be provided prior to loading a circulation system.

Crater Resistance

Compatibility with plant-specific materials must be verified with all materials. Typical materials with which the coating must be compatible include sealers, primers, underbody deadeners, plastic substrates, competitive coatings, etc.

The sensitivity of a coating to crater from common in-plant contaminants (i.e., equipment oils, personal hand lotions, etc.) must also be established.

Can Coatings

by Martin B. Price[1]

THE CONTAINER INDUSTRY IS A MAJOR USER of paints and coatings. The reported number of cans used in the United States per year is about 130 billion. The majority of these are coated individually, most with different coatings on each side. These coatings provide corrosion resistance, compliance with strict food safety and taste requirements, and present attractive long lasting identification characteristics to each container. The processes required for the efficient and economically acceptable manufacture of two- and three-piece cans and can ends involve complex engineering. Unique coatings characteristics are required to conform with these complex mechanical systems. A majority of the tests currently in use to ensure that all the requirements are met are discussed. A brief description of the processes for can production is included.

TABLE 1—United States production of beer and beverage cans.

	(Millions of cans)

DESCRIPTION OF THE CAN INDUSTRY

The Can Coating Industry

The volume of coatings consumed by coating cans for food and beverage in the United States places the container industry among the highest users of finishes for all industries. A total of 130 billion cans were shipped in the United States in 1991, most of which were coated with decorative and protective coatings. Over 40 million gallons of coating were used with an estimated sales value of 350 million dollars. The United States is by far the largest user of cans and coatings for cans. Europe, which currently uses about 21 billion cans, is expected to double its usage during the 1990s as this form of packaging becomes more acceptable as a replacement for glass containers.

In addition to being one of the largest consumers of coatings, the metal container industry, because of the variety of coatings required to satisfy its needs, is also one of the most technically sophisticated. The type and quality of products identified with this industry are largely influenced by the unique characteristics of the can manufacturing processes. Therefore, can coating formulations are based on a variety of resins, among which are epoxy, poly(vinyl chloride), acrylic, polyester, or alkyd, oleoresinous, and phenolics. Coatings based on epoxies are often chosen for primers and for can ends, poly(vinyl chloride) for can ends, oleoresinous and phenolics for can interiors, acrylic, polyester and alkyd resins for decorative exteriors. Phenolic and amino based materials are often used as cross-linking agents. Water-based spray coatings (often epoxy-acrylic based) are commonly used as interior coatings for two-piece can bodies.

Recent modifications in coatings products used for this industry have been developed largely in response to federal and state pollution abatement requirements, to an ever increasing need for improved and accelerated production in this highly competitive field, and to the development and implementation of a variety of improved can manufacturing techniques. A significant level of product development effort continues in this field to define new and improved products.

The qualifications and required testing procedures for coatings for two-piece and three-piece containers can vary to some degree. A description of can production processes for these two major can types will be presented.

Can Production Processes

Two-Piece Can Production (Fig. 1)

About 70% of the total U.S. production or 95 billion cans used in the beer and beverage portion of the canning industry are constructed with aluminum and comprise what are commonly called two-piece cans. This can type is manufactured by press punching cups from sheets or coils of aluminum or steel. The cups are then forced through a series of rings to iron out and form a full-length can and to form the bottom dome. The product at this stage is a container with sides and a bottom representing one of the two pieces of a two-piece can. The lid, secured and sealed after filling, is the second piece.

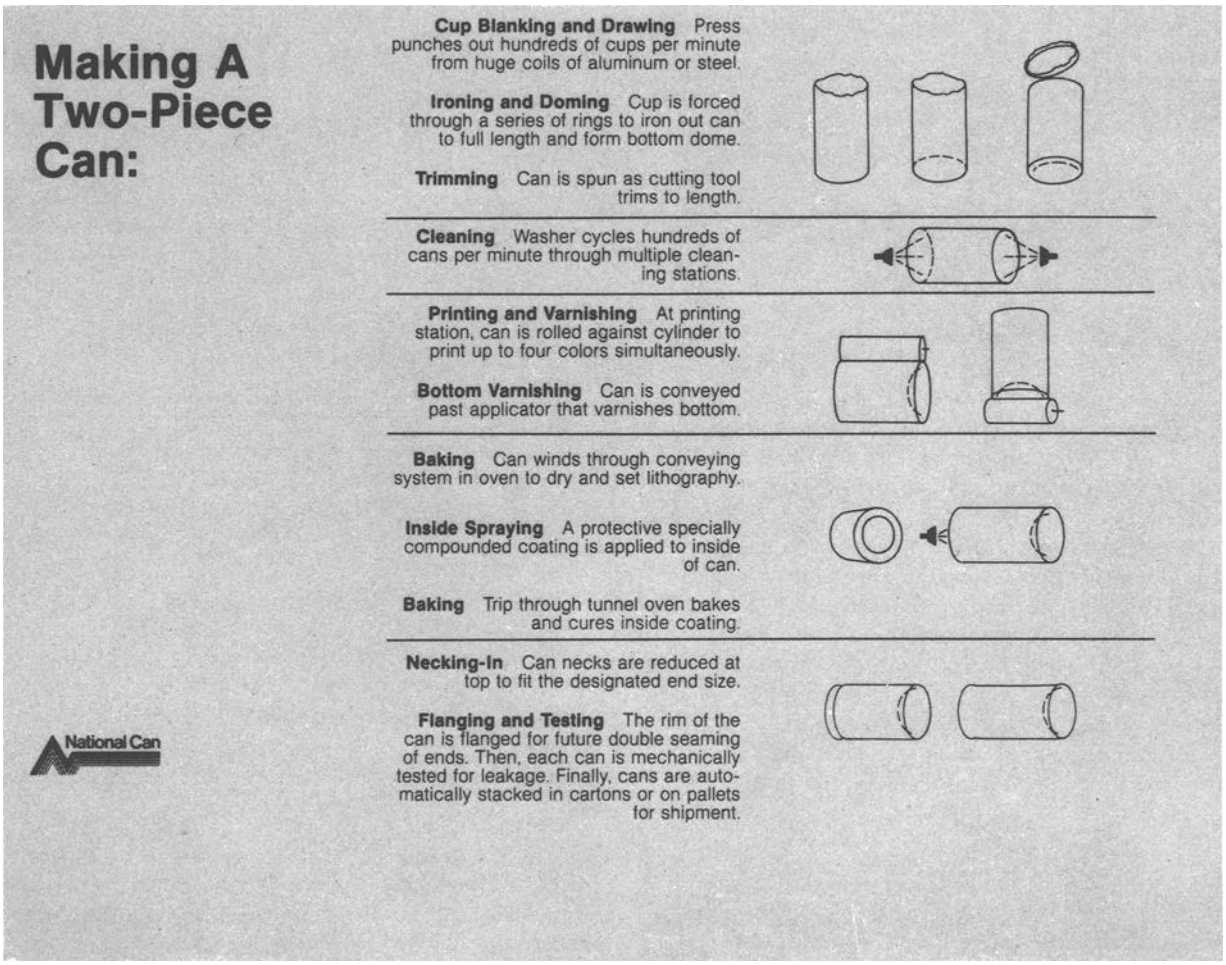

FIG. 1–Two-piece can production process.

These containers require exterior inks and coatings for decoration and identification. Increased manufacturing speed and smooth movement on the production lines requires the proper lubricity in the coating. The containers also require a high degree of abrasion resistance to maintain aesthetics and prevent can failure. Cans rubbing against each other during movement in any of many production process steps and shipping can cause scratches. These are often unacceptable for aesthetic reasons and, in extreme cases, can result in the actual rupture of the increasingly thinner stock from which cans are manufactured. It is interesting to note that cans are frequently so thin that sealing after filling with a carbonated beverage is required to give the container adequate rigidity. In addition, a level of flexibility must be inherent in the coating so that the severe crimping, which is critical to securing the lid onto the container, can be accomplished without coating failure or delamination.

Coatings are usually applied to the interior of these cans by spray techniques. Rapid application is obtained by short bursts of airless spray from a lance positioned opposite the center of the open end of horizontally held cans. This procedure is used with most food and drink containers. If the intended can content is acidic, as is the case with many soft drinks, uncoated cans can erode. Thus a coating must be applied which presents an adequate barrier to this erosion. Although beer is not strongly acidic in nature, a major concern exists regarding taste-alteration potential due to contact of the beer with metal container walls. When a protective coating is used, it cannot alter the taste of the packaged product. It is therefore necessary for beer containers, for example, to have a coating with a low level of extractables. Coatings suitable for container use (a) must be FDA compliant, (b) must pass subjective taste tests to ensure no contribution to the flavor of the product, and (c) must also meet demanding flexibility requirements. Both the interior and exterior coatings must pass most of these tests for the can production to be acceptable. For a majority of cases, after the can is packed and sealed, it is subjected to a thermal treatment to complete the processing of the contents. Many of the commercial beer products require pasteurization that is normally carried out at 150 to 180°F (65.5° to 82.2°C). Higher temperature exposures are required for processing other food products in many packaging operations. Coatings on the crimped edges of the can that may have survived the actual crimping procedure must retain adhesion, clarity, color, and abrasion resistance after these thermal treatments.

Three-Piece Can Production (Fig. 2)

In a typical manufacturing process for the three-piece can, a large metal coil is sheared into sheets. An "inside" coating is

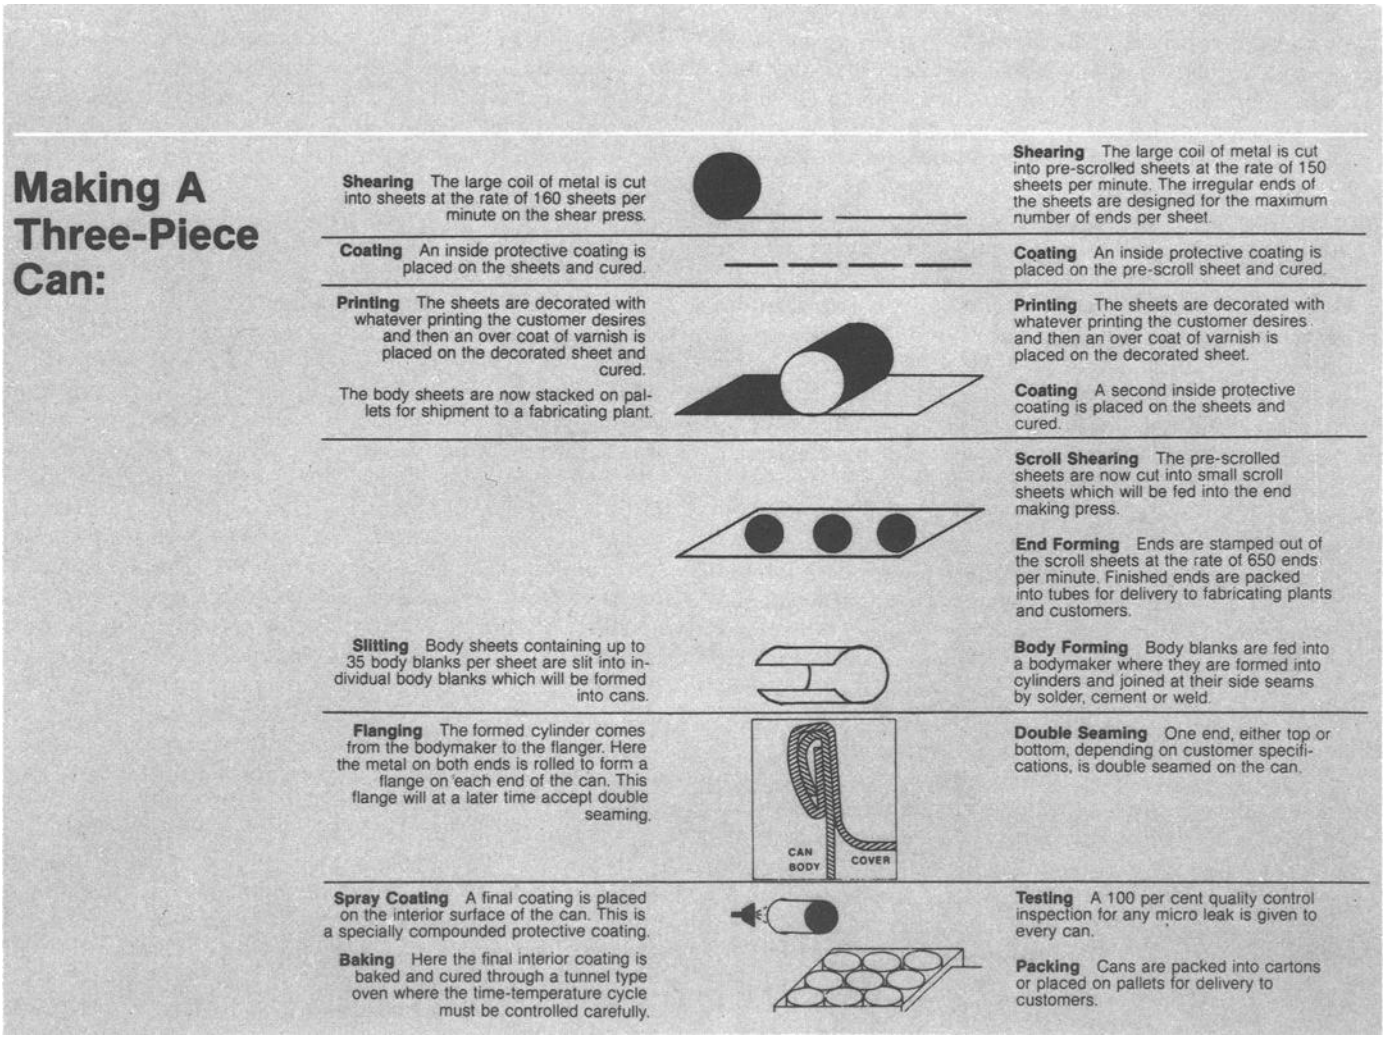

FIG. 2–Three-piece can production process.

placed on these sheets usually by roll-coater application and the coating is cured. When exterior coating is required, the "exterior" of the can is coated with the decoration defined by the customer. This decoration is often overcoated with a clear coating and the sheets are cured for a second time. On low-rust potential metal, when paper is the chosen labeling technique defined by the customer, or when ultraviolet-cured coatings are employed, this second stoving operation may not be required. (The ultraviolet cure process will be discussed later.) The coated sheets that are stacked and shipped to the fabricating plant must easily slide over one another during subsequent processing steps. The coated surface is often tested to evaluate the nonbinding characteristic of the sheets during stacking.

In the fabricating plant, the coated body sheets are slit into individual body blanks; usually about 35 body blanks are obtained from each sheet. These blanks are coiled into a cylinder shape and flanged to permit the formation of a seam that is then welded, soldered, or cemented. A coating is required to cover this seam since the initially applied coating is usually destroyed or deformed during the seaming process. A coating, either liquid or powder, is applied to this seam and cured or fused. This coating must have all the requirements of the main coating, including FDA compliance, and cause no detectable alteration to the taste of the contained product.

Preparation of Can Ends

Ends are stamped from sheets that are already coated on the side to be in contact with the packaged product. With some metals the side destined to become the exterior will also require the application of a coating to impart corrosion resistance. Can-end coatings must have the required flexibility to withstand the crimping necessary to secure the end to the top or bottom of the container. As with the two-piece can, the coating including the crimped sections must maintain integrity through the elevated temperature food processing steps.

Ultraviolet Cured Coatings

About 4 to 5% of can coating in the United States involves the use of ultraviolet curing. This process has several distinct advantages over more traditional oven-bake systems. Among these are the virtual elimination of solvents and related volatile organic compound pollutants, improved production efficiency, and low-cost plant installation. At this writing, industrial production using ultraviolet cure mainly involves external clear coatings.

The process involves the application of a photosensitive coating to the substrate, followed by a brief exposure to a selected ultraviolet wavelength at a defined intensity. The coating is hardened virtually instantaneously. In the two-piece can manufacturing process the individual cans are printed, often with ultraviolet light-curable inks, coated with a clear coating, and then exposed to ultraviolet light. The extremely fast cure permits the process to proceed rapidly to the next stage in the can production process which may be application of a water-dilutable or solvent-based interior coating. As the latter coating requires an oven bake, the ultraviolet-cured coating is oven baked as well. Only one oven pass is required.

The ultraviolet cure technique has also been used in the preparation of three-piece cans. Sheets, often printed with an ultraviolet-curable ink, are oven coated with an ultraviolet light-curable overprint coating. After radiation curing, a dry-to-touch condition required for efficient production often develops within a fraction of a second, permitting the sheet to be flipped to the reverse side. A coating which will eventually be the "inside" coating of the can is then applied and the entire sheet is cured by a standard oven process. This technique is also used for the coating of the exterior of sheets that are to be used for can ends. Again the economic advantage of only one oven pass is realized. The importance of inclusion of some measure of the speed of cure in the quality control of these ultraviolet curable coatings is obvious.

Ultraviolet coatings have been developed which meet the requirements of adhesion, flexibility, slip, gloss, abrasion resistance, and food process stability for exterior use. At this stage of their development, these coatings have not been adequately evaluated to assure compliance with FDA regulations and therefore are not available for use on interior food contact surfaces.

Testing of Can Coatings

Tests Conducted on Liquid Paint

Viscosity—As discussed in the previous section, speed of production is a critical aspect of an economically successful can production plant. The speed of application of paint required for the satisfactory coating of two-piece can bodies or of three-piece can sheets places unique requirements on the flow characteristics of the paint. To ensure complete coverage with the standard thin layer of paint, outstanding flow must be assured. The usual means for the determination of viscosity is with the use of the Brookfield Viscosimeter [ASTM Test Method for Rheological Properties of Non-Newtonian Materials by Rotational (Brookfield) Viscometer (D 2196)].

Alternate means of determining viscosity include the use of the Ford Cup or the Zahn Cup, ASTM Test Method for Viscosity of Paints, Varnishes, and Lacquers by Ford Viscosity Cup (D 1200) and ASTM Test Methods for Measurement of Wet Film Thickness of Organic Coatings (D 212), respectively. These procedures relate flow to the length of time required for a test liquid to flow through a calibrated orifice at the bottom tapered end of a cup. The Ford technique is generally considered more accurate, though less convenient than the Zahn.

Viscosity Stability—The coating can be evaluated for long-term stability by placing a sample in an oven at 120°F (48.8°C) for an extended time period. Forty days is a typical test period. The change in viscosity can be evaluated every seven days using the technique employed to rate initial viscosity. In addition, settling, agglomeration, or other changes in appearance can be noted.

Density—Density can be measured by using a Gardner™ "Weight per Gallon" cup [ASTM Test Methods for Indentation Hardness of Organic Coatings (D 1474)]. The process involves equilibrating the product to 25°C and pouring it into a cleaned cup up to the fill mark, taking care to prevent foaming. The cap is pressed onto the cup and the overflow carefully wiped from the outside of the cup. The cup is then weighed on an analytical balance and pounds/gal calculated by multiplying the number of grams of paint in the cup by 0.1.

Volatile Organic Compounds (VOC)—The determination of the VOC of a coating requires an analytical balance and an oven controllable at 110 ± 5°C [ASTM Test Methods for Volatile Content of Coatings (D 2369)]. The specimen is placed in an aluminum dish and after dilution with solvent is baked for 60 min and the percent weight loss of the sample determined. This is the percent volatile content.

The volatile organic compound content (VOC) is determined according to Federal Reference Method 24, using the weight % volatile content, the density of the liquid coating, and the weight percent water content, using the equations shown in ASTM Practice for Volatile Organic Compound (VOC) Content of Paints and Related Coatings (D 3960).

Fineness of Grind—This test is used for the determination of the fineness of dispersion of pigments in a pigmented coating. A Hegman Grind Gauge with a double-wedge steel scraper placed on a flat, nonskid surface is used (ASTM D 1260). A sample of coating is applied at the deep end of the groove of the gauge surface so it slightly overflows the total groove. The scraper is then drawn down over the entire length of the gauge with sufficient pressure to clean the sides of the gauge. A reading should be made at this point without delay. The reading consists of a visual observation made by viewing the side of the gauge perpendicularly to the drawn coating: the point where the sample shows a definite speckled pattern is read from the numbers on the side of the gauge. The quality of the dispersion is a measure of the effectiveness of the grinding operation in dispersing of pigments for pigmented coatings or of additives, such as wax, for clear samples.

Flash Point—The flash point of a coating is the minimum temperature at which vapor given off by the coating will ignite when exposed to a spark or flame. The Department of Transportation standards for shipment places a minimum flash point requirement for these coatings. A method to determine what is referred to as a closed-cup rating flash point uses a Seta Flash apparatus [ASTM Test Methods for Flash Point of Liquids by Setaflash-Closed-Cup Apparatus (D 3278)]. For an open flash point, a Tag open-cup method is often used [ASTM Test Method for Flash Point by Tag Closed Tester (D 56)]. In both methods the substance under test is heated at a controlled rate (for example, 2°/min) and a flame is passed over the surface. The flash point is defined as the temperature at which definite ignition is observed.

Cure Speed—A variety of methods have been devised for the determination of this difficult to determine and even difficult

to define characteristic of a thermoset coating. One practical definition of cure adequacy is the development of sufficient hardness in the coating that allows the can manufacturing process to advance to the next stage without marring the coating. The customer and the coating supplier frequently agree on an empirical test to satisfy cure speed requirements. A simple technique may involve the use of cotton balls. Nonadherence of fine fiber wads to a surface is often rated as adequate cure because it relates to the ability to permit the continuation of production. Frequently, a higher degree of cross-linking is required, especially for the development of resistance properties encountered by the coating at a later stage of its use. Rubbing a cured surface with a cloth moistened with a strong solvent is a method frequently employed. The determination of hardness using the pencil hardness test described later is a means of assigning a numerical rating to the relative degree of cure.

Tests Conducted on Cured Surfaces

Hardness—The hardness of a coated panel can be determined with the use of a series of pencils that have lead of various, known hardness, that is, lead with the following increasing hardness: 5B, 4B, 3B, 2B, B, HB, 2H, 3H, 4H, and 5H. For more details refer to ASTM Test Method for Film Hardness by Pencil Test—D 3363 06.01.

Film Thickness—An electric film thickness gauge can be used to determine film thickness [ASTM Test Method for Nondestructive Measurement of Dry Film Thickness of Nonmagnetic Coatings Applied to a Ferrous Base (D 1186)]. The device is calibrated with standard sheets of known film thickness placed on an uncoated surface of a similar substrate test section. After standardization, the head of the gauge is placed on the coated sample and coating thickness is reported usually in mils. The film surface is often measured at several locations on the surface of the specimen. The reported reading is the average of the several readings taken.

A StrandGauge™ is often employed in the metal decorator industry because of the ease of determining the thickness of very thin coatings characteristic of this industry. The equipment is available from the Strand Electronics Ltd., Castro Valley, California.

Film Continuity—An important characteristic of a high-quality film placed on the interior surface of a can is freedom from coating voids, meaning the absence of areas where pinholes or discontinuities exist. Can corrosion and contamination of the can contents at these voids could cause taste or color degradation. One of the accepted methods for evaluating a surface for these imperfections is an Enamel Rater Test (Fig. 3).

When using a WACO™ Enamel Rater for this test, a container to be evaluated is filled with a conductive aqueous solution and placed on a platform. Electrical contact is made on a cleaned area of the can exterior. An electrode is placed in the center of the can contents, and the amount of current flowing through the system is measured. The current flow will be impeded by the protective coating on the can interior. Flaws or breaks in the coating are areas which will permit current flow. The customers and suppliers usually agree on a maximum acceptable value.

An alternative test technique for determining film voids is the copper sulfate solution immersion test. In this test a sheet of coated metal is immersed in a solution of acidified copper sulfate for 2 to 4 min. After removal, a careful visual or magnifying glass examination of the coated metal will reveal copper-plated areas where inadequate coating protection permitted the copper to plate out onto the metal surface. The presence of flaws in the coating is an unacceptable condition for most commercial products.

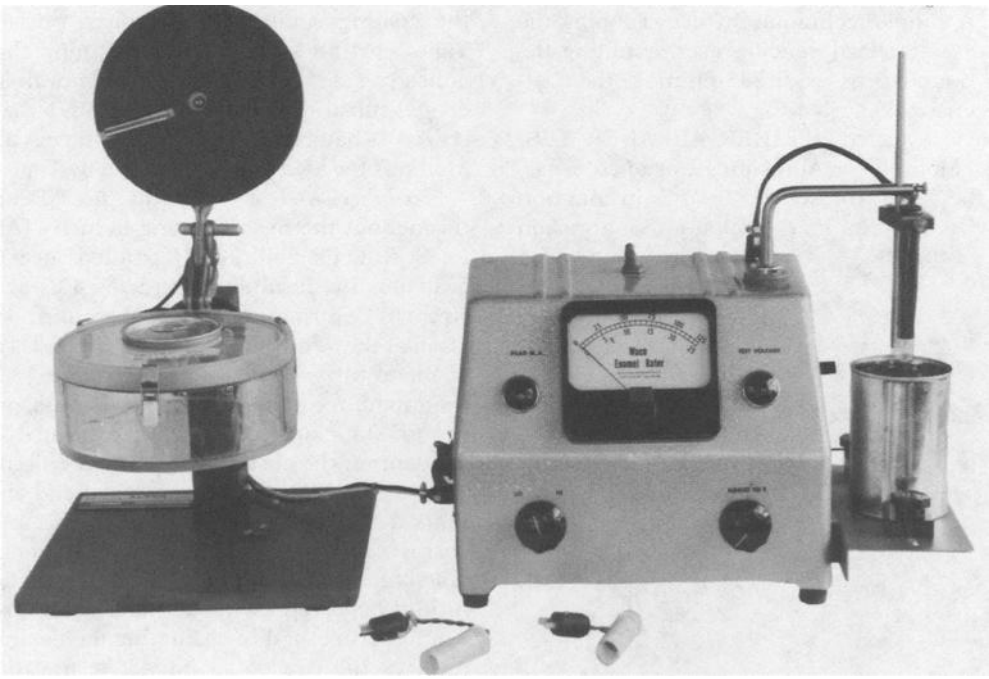

FIG. 3–WACO™ Enamel Rater test device for film voids.

Mobility/Lubricity—This important characteristic of a coating can be measured using an Altek™ Mobility/Lubricity Tester (Fig. 4).

The can or flat sample is mounted on the unit, and a test sequence is initiated by sliding a weight across the sample. The coefficient of friction is determined and is indicated directly on an electronic analog meter.

Stability to Food Processing and Pasteurization Conditions—Many foods are packed into containers in an uncooked state. Cans are sealed and the entire can is processed at an elevated temperature for the period required to complete the food processing. A characteristic test period is 1 h at 250°F (121°C) in an autoclave. Determination of the ability of a coating to withstand this treatment is often made by careful examination of a section of coated substrate which has been mandrel bent (ASTM D 1737). The section so treated is then permitted to cool and next exposed to 100% humidity, at 100°F (37.7°C) for 16 to 24 h. After cooling, visual examination of the surface for discoloration, for film rupture, and for adhesion, especially in those areas where film extension has occurred, presents a useful appraisal of the ability of the coating to withstand food processing conditions.

A less severe test is available for the pasteurization process. This is required for some foods and for some beer packaging. The temperature for this process is 150 to 180°F (65.5° to 82.2°C) for 3 h. Similar visual examination of the surface of the coated steel or aluminum substrate is conducted for discoloration or blushing, adhesion loss, or film failure.

Abrasion Testing—A critical characteristic of an acceptable exterior film is its ability to protect cans from marring and scratching the decoration and identification. As mentioned earlier in the Can Production portion of this discussion, occasionally abrasion resulting from cans rubbing against each other especially during shipment can be severe enough to actually cause rupture of the metal.

Several tests are employed to measure the coatings ability to resist abrasion. A simple technique involves rubbing the coated surface with a standard pencil eraser, counting the number of rubs or double rubs required to remove the coating and reveal the uncoated surface.

A commercial device called a TABER ABRADER TESTER™ [ASTM Test Method for Abrasion Resistance of Organic Coatings by the Taber Abraser (D 4060)] is in common use in the industry for a preliminary evaluation of abrasion resistance. In this test, coated panels are rotated under selected weighted abrasive wheels. The value is often reported as weight loss in milligrams/cycle × 1000. Another specific test requires the use of a Gavarti™ Gv Cat Test Unit (Fig. 5).

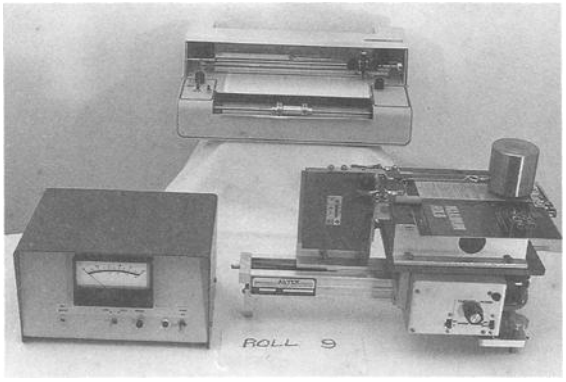

FIG. 4–Altek™ Mobility/Lubricity Tester.

This device involves the mounting of a limited number of specimens and can evaluate coated metal abrasion resistance rapidly. The device vibrates the cans or coated strips at a rate and duration which can be controlled, emulating the abrasion received during transportation. The cans are visually examined after the allotted time of exposure and rated according to individual or customer defined standards.

Pack Testing—A requirement for packaging of many food products is that no undesirable effects on the appearance of the container or to the taste or color of the contents occur when the product is stored on a shelf for three years or more. An accelerated test to evaluate this characteristic involves the actual packaging of the substance in question in a test can. The can is sealed and exposed to the food processing conditions previously described, after which the product is aged at an elevated temperature for an extended period of time. Typical conditions are 120°F (48.8°C) with a generally accepted estimate that one month exposure at this temperature relates to one year of room temperature exposure. The coating product can be periodically examined by initiating several containers at zero time and withdrawing them selectively at one-month intervals. This test is useful for new product evaluation. A three-year actual test is usually required by most customers before they will accept a new product or a significant compositional change in a coating formulation. At the end of the test period, evaluations include can appearance, food taste, and vacuum testing. The latter is accomplished by piercing the container with a device such as a hand held vacuum unit which pierces the can and seals a gauge around the puncture. This gauge determines the pressure before can opening. Chemical reaction of the food product with coating or exposed walls can result in a pressure change.

Adhesion Test—This test is similar to one used throughout the coatings industry. It involves pressing Scotch Brand Tape™ to the surface and examining the surface and the adhesive side of the tape after removal. The surface of the coated substrate is often scored with a razor in an X pattern or a cross hatch pattern before the tape is applied [ASTM Test Methods for Measuring Adhesion by Tape Test (D 3359-83)].

Flexibility—A test known as the T-Bend test is common throughout the metal coating industry [ASTM Test Method for Coating Flexibility of Prepainted Sheet (D 4145)]. The test evaluates the flexibility characteristics of a paint on a substrate by deformation of the substrate and subsequent evaluation of the adhered coating. A 0-T bend is a bend in a section of metal turned back on itself after a 180° bend. The bend examination can be visual, microscopic, or it can use Scotch Brand™ tape or copper-sulfate exposure. This is usually dependent on the customer's stated requirements.

A second 180° bend around the bend already made represents a lesser level of flexure. A coating that satisfactorily passes examination on this surface, and that has already failed the 0-T test, will be considered a 1-T flexibility coating. A third bend represents 2-T, etc.

Another method of evaluating the flexibility of the coating involves the use of an impact testing device [ASTM Test Method for Resistance of Organic Coatings to the Effects of

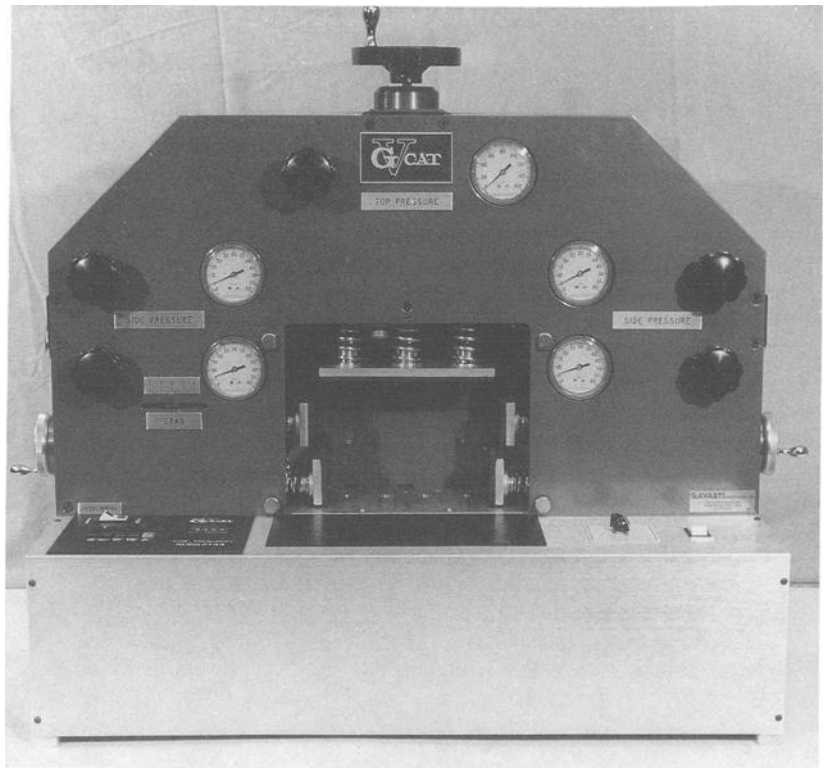

FIG. 5–Gavarti™ abrasion test unit.

Rapid Deformation (Impact) (D 2794)]. In this test flexibility is evaluated by dropping a large bullet-shaped weight from a measured height down a cylindrical guide tube onto the uncoated surface of a test sheet. The test is referred to as a reverse impact test. Microscopic examination of the impacted area is employed for evidence of cracking in the coating. The coating can be tested to the point of metal failure, a factor which depends on the thickness and strength of the substrate used.

A test more specific to the can industry involves use of the Erichsen Lacquer Testing Instrument. With this device a cup is actually formed from a section of coated metal and the corners of the formed cup are examined for signs of inadequate flexibility (T. J. Bell, Inc., 1340 Home Ave, Akron, Ohio or A. M. Erichsen, GMBH 587 Hemer, Sundwig, Germany).

Extraction Testing—Concentrations levels of coating components capable of being extracted by the container contents must be below a defined limit. The Food and Drug Administration has established a series of limits and has defined certain liquids to be used for testing based on the planned contents of the container. They are described in detail in the Code of Federal Regulations, No. 21, Section 175.300. An extraction technique is also described in detail in this government publication.

Gloss Measurement—The specular gloss of a coated sample is measured using a 60° gloss meter [ASTM Test Method for Specular Gloss (D 523)]. The meter should be equilibrated and calibrated against standard panels. The meter is placed over the panel to be tested, several readings are taken at different spots on the panel, and an average of these readings is recorded. Care must be taken to control film thickness as deviations in gloss level will be observed at varying thicknesses.

Color Measurement—The customer will assign an acceptable level of deviation of the final color of the sheets or the cans based on a defined standard. Spectrophotometric analyses using L A B ranges are reported [ASTM Test Method for Calculation of Color Differences from Instrumentally Measured Color Coordinates (D 2244)].

Blocking Resistance—Frequently, sheets of coated product are stacked and stored before being carried to the next station for processing. Such storage can often occur after an oven operation, which means that the sheets are stacked at an elevated temperature. As sheets are fed to a pile, the pressure imposed on the lower members of the stack can become considerable, and the sheets must resist adhering to each other. Efficient and rapid movement of these sheets individually for subsequent processing is essential to achieve an economical container production rate. Simple tests to evaluate the ability of coatings to resist this sticking phenomenon are commonly developed that are acceptable to both the customer and the supplier.

In one such test a series of coated sheets or panels are stacked face to back. Pressure, usually supplied via a properly placed weighted block of metal, is imposed on the top sheet or panel of the stack. The stack which can be stored at controlled temperature for defined periods of time is examined after cooling for ease of separation. The weighted block of metal is often of such a physical dimension that the resistance to sticking of the coated panels can be determined conveniently (usually reported in pounds/square inch).

Masonry

by Frances Gale[1] and Thomas Sliva[2]

AS WITH MOST OTHER MATERIALS, masonry substrates are painted for one or both of two basic reasons: to change appearance or to improve performance in the relevant service environment. Imparting or changing color and increasing surface brightness are two important parts of the decorative function. In some cases coatings are applied to improve the appearance of the masonry substrate by masking defects or repair work. Although, in general, masonry materials do not need protection, per se, coatings can reduce attack in highly acidic atmospheres or salt water immersions. In most cases coatings help the masonry to protect the interior of the structure from penetration of moisture.

Masonry substrates to which paints are applied include stone, brick, tile, and concrete and other cement-based materials. As with other substrates, the ideal coating for masonry should be economical but must also resist soiling, retain appearance, and be easy to maintain. A coating should function effectively for a time appropriate to where it is used. Thus an exterior masonry coating should be able to withstand weathering without losing adhesion to the underlying surface.

This chapter discusses characteristics of masonry substrates that should be considered when selecting paints for application to those surfaces. Information is also provided about laboratory and field tests that are appropriate for evaluating the performance of paints.

PROPERTIES OF MASONRY SUBSTRATES

Definitions

Materials referred to as unit masonry include natural stone, brick, tile, and concrete block. Unit masonry is used in conjunction with mortar or caulk. Standard terms relating to natural building stones are defined in ASTM Definitions of Terms Relating to Natural Building Stones (C 119). Definitions for terms relating to structural clay products are contained in ASTM Definitions of Terms Relating to Structural Clay Products (C 43). In addition to unit masonry, paints are also applied to monolithic concrete. Standard terminology relating to concrete and concrete aggregates is provided in ASTM Definitions of Terms Relating to Concrete and Concrete Aggregates (C 125). ASTM Specification for Mortar for Unit Masonry (C 270) includes information about compositions and properties of different types of mortar and their uses for new construction and tuck pointing or replacement of deteriorated mortar.

Porosity

A physical property that all masonry substrates share is porosity. Their interior structures are systems of fine, interconnected pores. With some materials the pores are extremely small. However, because of this inherent porosity, all masonry is somewhat permeable to water. Hence, moisture can enter them in several ways including through poorly designed or faulty flashing, vapor barriers, etc. The presence of excessive amounts of moisture can adversely affect paint adhesion and thus performance.

Absorption Testing

The sorption of water by a masonry material is an important factor affecting the performance of the coating as well as the substrates. This is because moisture is a necessary condition for most processes of deterioration. Water absorption by masonry substrates can be determined by laboratory testing. ASTM Method of Sampling and Testing Brick and Structural Clay Tile (C 67) contains methods for testing brick and structural clay tile to determine physical properties such as absorption and saturation coefficient. Absorption is measured by submersing a representative whole tile or half brick in water for a 5-h or 24-h period. Percent absorption is determined by comparing the difference between the saturated and dry weights to the dry weight.

The test procedure for absorption by concrete masonry units described in ASTM Standard Methods of Sampling and Testing Concrete Masonry Units (C 140) is similar to that described in ASTM C 67. Three full-size units are used for testing absorption. ASTM Test Methods for Absorption and Bulk Specific Gravity of Natural Building Stone (C 97) provides a standard test method for this type of stone. The test procedure is also similar to that described in ASTM C 67 except the immersion period is 48 h. ASTM Test Method for Specific Gravity, Absorption, and Voids in Hardened Concrete (C 642) contains test methods for measuring absorption and voids in cured concrete. Absorption is calculated after a 48-h immersion and after immersion in boiling water. A method for determining the volume of permeable pore space (voids) is also provided.

Efflorescence

When water-soluble salts are present within the masonry substrate, efflorescence can be an unwanted result. Efflorescence is defined as a crystalline deposit of water soluble salts on the surface of the masonry material. If migration under a painted surface occurs under a painted surface, crystallization of the dissolved salts at the coating masonry interface can push the coating off the substrate. Even if the solution passes through the coating and the salts deposit on the surface, they are unsightly, and recurring efflorescence can be a symptom of deterioration taking place with the substrate. If the salts are deposited below the interface (cryptoflorescence), crystallization pressures within the masonry can lead to eventual disintegration of the masonry material.

The source of soluble salts that results in efflorescence or cryptoflorescence can be the masonry unit itself or components of the mortar. Secondary sources include contaminated groundwater and residues of chemicals used in cleaning masonry walls. A test for efflorescence of individual masonry units is contained in ASTM C 67. Full-size bricks are partially immersed in distilled water for seven days. After oven drying for 24 h, the specimens are inspected for efflorescence.

A test for assessing resistance to efflorescence is described in NBS Technical Note 883 Waterproofing Materials for Masonry. For this test one side of a brick specimen is left uncoated. The brick is placed with the uncoated surface face down in a sodium sulfate solution for seven days. After drying, the coated surfaces are inspected for efflorescence.

Surface pH

The pH of masonry substrates is variable, normally depending on the chemical composition of the material. Some materials such as brick, tile, and many natural stones have a neutral or slightly acidic pH. Others, including cement-containing materials such as concrete and calcareous stones (e.g., limestone and marble) are naturally alkaline. Mortar used with neutral or acidic masonry units can sometimes impart alkalinity to the wall surface. If the pH of the substrate is high, paints that are sensitive to alkalies should be avoided as the alkalinity saponifies them.

Surface alkalinity is not the only cause of coating failure. Subsequent migration to the surface of construction water, condensed interior water vapor through barrier defects, and capillary water from contact with the earth ("rising damp") can all result in the presence of alkalies and soluble salts.

A method for measuring surface pH is described in the ASTM Test Standard Method for pH of Chemically Cleaned or Etched Concrete Surfaces (D 4262). Although ASTM D 4262 is intended for determining whether residual chemicals have been removed following chemical cleaning or etching, the procedure for measuring surface pH of the concrete surface is described. A strip of pH test paper is placed on the wet concrete surface and compared with the color chart to determine pH.

Surface Finish

Masonry materials display a wide range of surface finishes. Adhesion of coatings to glazed tile and brick, polished stone, and highly troweled concrete is problematic because the very smooth surfaces do not develop a mechanical key. Very porous surfaces such as concrete block and natural stone such as travertine present a different sort of problem. Thin paint films do not easily cover their rough or irregular surfaces so that high-build coatings are generally used. Primers or fillers are sometimes required.

COATINGS

Both types of water-borne and organic solvent-borne coatings have been applied to masonry substrates. A brief discussion and examples of each type are provided below. Methods for determining physical and chemical properties of paints for masonry substrates appear elsewhere in this manual and in U.S. Federal Test Method Standard No. 141C. The titles of federal specifications that specifically refer to application on masonry substrates are listed in this chapter.

Water-Reducible Coatings

Water-borne or -reducible coatings are or form dispersions of the pigment, extender, binder, and additive components in water. A distinctive feature of latex coatings is that the binder is also dispersed. Consequently, most of the resulting films are porous or less compact than corresponding solvent-borne coatings and so are more permeable to water vapor. This characteristic is important as most masonry substrates contain moisture at the time the paint is applied. Water vapor permeability is also a factor subsequent to application as it is virtually impossible to completely prevent access of water to masonry walls. Transport of this water to the exterior surface, caused by thermal gradients in the winter, or to below-grade interior surfaces, caused by hydrostatic pressure, forces impermeable coatings off the surface.

Of the water-reducible coatings, portland cement powder paints have the longest service record. Cement paints form hard, flat, porous films that readily permit passage of water vapor. Cement paints help to seal and fill porous masonry surfaces. In addition to portland cement, they can contain specific additives for controlling application, setting time, water repellency, and color. Federal Specification A-A-1555 Water Paint, Powder covers cementitious type paints for protection, decoration, and waterproofing of interior and exterior masonry, concrete, and plaster surfaces. The corresponding Canadian specification was withdrawn when interior latex paints were developed. Although once widely used, cement paints have been largely replaced by latex paints.

Other federal specifications for water-reducible paints for masonry materials are TT-P-19D Paint, Latex (Acrylic Emulsion, Exterior Masonry), and TT-P-55B Paint, Polyvinyl Acetate Emulsion (for Exterior Masonry Surfaces), and TT-P-96D Paint Latex Base for Exterior Surfaces.

Block fillers are sometimes required to fill voids or holes in masonry substrates. TT-F-1098D is a federal specification for

ready-mixed styrene butadiene copolymer resin filler for cinder and concrete block and stucco.

Solvent-Borne Coatings

These materials consist of pigments dispersed in solutions of resins and additives in organic solvents. Unless overpigmented, they form smooth, continuous films that are effective moisture barriers where water intrusion must be prevented. Solvent-borne paints must be applied to dry surfaces as excessive moisture may interfere with development of adhesion and, with some coatings, cause blushing. They are, however, more tolerant than water-borne coatings to application at temperatures near the freezing point of water.

Solvent-reducible coatings are of both the thermosetting and thermoplastic type. The former type cures by oxidative polymerization (oil-modified, air-drying alkyds, and urethanes), by chemical reaction of multi-components just prior to and/or after application (e.g., epoxies and urethanes), and by heat just after application (baking alkyd, acrylic and urethane enamel). Thermoplastic coatings form films solely by solvent evaporation and include acrylic, vinyl, rubber-derivative, and cellulose-derivative resins and are by definition (although not always so called) lacquers. Federal specifications for solvent-borne coatings are TT-P-24D Paint, Oil, Concrete and Masonry, TT-P-95C Paint, Rubber, for Swimming Pools and Other Concrete Masonry Surfaces.

APPLICATION

As with any substrate, masonry surfaces must be free of dirt, oil, grease, mildew, efflorescence, and other contaminants before being coated. It is generally thought that newly constructed masonry walls should age six months before painting, but latex finishes are frequently applied much sooner. Obviously, on older surfaces, any needed repair work should be completed prior to painting. Primers are sometimes recommended for previously painted surfaces and should always be used when specified by the coating manufacturer. TT-P-00620C is a federal specification for conditioner for heavily chalked previous coatings.

Surface Preparation

As with any surface, adequate preparation of masonry substrates is essential for obtaining good adhesion of the material to be applied. With some surfaces, a simple dusting is all that is required; with others more rigorous cleaning is advisable. ASTM Practice for Surface Cleaning Concrete Unit Masonry for Coating (D 4261) and ASTM Practice for Preparatory Surface Cleaning of Architectural Sandstone (D 5107) describe procedures for cleaning with broom, vacuum, air blast, water, detergent water, and steam. ASTM D 5107 also covers a procedure for chemical cleaning.

If optimum bond of the coating to the masonry substrate is desired, alteration of the surface profile may be necessary. For concrete that will be exposed to service conditions such as continuous or intermittent immersion, temperature cycling or mechanical loading, abrading, or acid etching the surface is recommended. ASTM Practice for Abrading Concrete (D 4259) contains information on instructions for abrading concrete. Procedures described are mechanical abrading, abrasive blast cleaning, and water blast cleaning. ASTM Practice for Acid Etching Concrete (D 4260) describes some of the normal practice for this technique. In brief, the etching solution is applied to the pre-wet concrete surface, and after bubbling begins to subside, the surface is flushed with water. In both practices, a roughened, textured surface is the desired result.

Surface pH After Cleaning

Following completion of chemical cleaning or acid etching, the pH of the masonry surface should be tested to confirm that residual chemicals have been removed. This procedure is important because chemicals not removed by water rinsing may adversely affect the performance and adhesion of paints applied to the treated surface. ASTM D 4262 contains a test method for pH of chemically cleaned or etched concrete surfaces. In this method, the pH of the water rinses is taken initially and the end of the final rinse cycle.

Moisture

As stated in the subsection entitled Solvent-Borne Coatings, moisture in the masonry substrate may be detrimental to those coatings that cannot tolerate moisture at or near the surface during application. Consideration of this factor is particularly relevant following cleaning procedures that involve water (e.g., steam cleaning and chemical cleaning). ASTM Test Method for Indicating Moisture in Concrete by the Plastic Sheet Method (D 4263) contains a test method to establish whether sufficient moisture can migrate to the surface to cause problems. In this method a plastic sheet is taped to the concrete surface and allowed to remain in place for a minimum of 16 h. Following its removal, the underside is visually inspected for the presence of moisture.

The methods of sampling and testing concrete masonry units contained in ASTM C 140 include a procedure for measuring the as-sampled moisture content. As mentioned in the sections entitled "Water-Reducible Coatings" and "Solvent-Borne Coatings" above, excessive moisture in masonry may cause coatings either not to develop initial adhesion or be subsequently forced off the surface. Annex A4 of ASTM Method for Preconstruction and Construction Evaluation of Mortars for Plain and Reinforced Unit Masonry (C 780) provides a test method for determining water content of mortar sampled at the construction site.

PERFORMANCE TESTS

Field and laboratory testing are useful for evaluating characteristics thought to be essential to good performance of coatings, hence to predict their performance on masonry substrates.

Alkali Resistance

Federal Specification A-A-1555 contains a procedure for evaluating the alkali resistance of cement powder

coated panel is soaked for 14 days in a sodium hydroxide solution with the painted side ½ in. above the surface. Federal Specification TT-P-19D for latex coatings applied to wood and masonry also contains a procedure for evaluating alkali resistance.

Water Vapor Permeability

Permeability to water vapor is an important characteristic to consider when selecting masonry coatings. The parent standard for determining water vapor permeability is ASTM Standard Test Methods for Water Vapor Transmission of Materials (E 96). Although E 96 is intended for water vapor transmission of materials such as paper, plastic, plaster products, etc., the method has been used to evaluate the permeability of paints to be applied to masonry materials. In fact, Federal Specification TT-C-555b references ASTM E 96 for determining water vapor permeability.

Procedures described in E 96 that are used for evaluating masonry coatings are the desiccant (dry-cup) method and the water (wet-cup) method. Two variations are service conditions with one side wetted and service conditions with low humidity on one side and high on the other. With the desiccant method, coated specimens are placed in test dishes filled with desiccant; with the water method, they contain water. The dish assemblies are placed in chambers where temperature and relative humidity are precisely controlled. The rate of water vapor movement through the specimens is measured as a weight gain or loss versus time.

ASTM Test Method for Water Vapor Permeability of Organic Coating Films (D 1653) contains similar test methods for measuring water vapor permeability. The original version (1959), specifically for the coatings industry, attempted to cover the entire relative humidity range in one step. It was revised in 1985 to include the wet and dry cup methods from E 96. D 1653 still, however, maintains two conditions with large relative humidity ranges—the dry cup exposed to 90% relative humidity at 100°F (38°C) and the wet cup to near 50% relative humidity at 73°F (23°C). To ensure precise results, specimens must be smooth, continuous films of uniform thickness.

Field Testing

Some performance tests rely on exposing coated masonry test specimens to actual conditions in the field. ASTM Practice for Atmospheric Environmental Exposure Testing of Nonmetallic Materials (G 7) covers procedures for exposing nonmetallic materials to natural weather. Practice G 7 is intended to facilitate collection of uniform results of exposure testing by indicating the variables that should be considered and specified. Factors determining degradation due to weathering include climate, time of year, presence of industrial atmosphere, etc. The specifics of weathering, however, can be accelerated by changing the angle of exposure. ASTM Practice for Conducting Accelerated Outdoor Exposure Tests of Coatings (D 4141) includes methods for speeding up natural weathering. The greatest increase occurs when mirrors that concentrate solar radiation on the specimens also follow the sun.

Artificial Weathering Tests

Coated masonry specimens can also be exposed to simulated weathering conditions in the laboratory. It should be recognized, however, that the more accelerated the test conditions the less reliable the results.

Federal Specification A-A-1555 contains a test procedure for artificially weathering specimens. Concrete panels painted with cementitious paint are evaluated for checking, cracking, and loss of adhesion after 500 h of artificial weathering.

Although there are no ASTM methods for artificially weathering coated masonry specimens, three standard practices describe operating conditions for this testing. These are ASTM Standard Practice for Operating Light- and Water-Exposure Apparatus (Carbon Arc Type) for Testing Paint and Related Coatings and Materials (D 822), Recommended Practice for Operating Light- and Water-Exposure Apparatus (Unfiltered Open-Flame Carbon-Arc Type) for Testing Paint, Varnish, Lacquer, and Related Products Using the Dew Cycle (D 3361), and Standard Practice for Conducting Tests on Paint and Related Coatings and Materials Using a Fluorescent UV-Condensation Light- and Water-Exposure Apparatus (D 4587). Equipment used in these practices simulates deterioration caused by sunlight and water as rain or dew. Because the natural environment varies with respect to time, geography, and topography, it may be expected that the effects of natural exposure will vary accordingly.

Resistance to Wind Driven Rain

ASTM Test Method for Water Permeance of Masonry (E 514) contains a procedure for measuring water penetration and leakage through masonry to evaluate resistance to the effects of wind-driven rain. Representative materials and workmanship are used to construct test walls that are exposed to water at a rate of 138 L per square meter (3.4 gal per square foot) per hour for at least a 4-h period.

Federal Specification A-A-1555 contains a test procedure for wind-driven rain resistance of patio blocks painted with cementitious paint. Test panels are placed in a transparent plastic testing box and sprayed with 60 to 70 gal (228 to 266 L) of water per hour. Specimens are inspected at the end of 8 h for the presence of water.

Other Tests

Federal Specification TT-C-555B Coating, Textured for Exterior and Exterior Masonry Surfaces contains several procedures for testing paints to be applied to masonry substrates, including evaluating color, flexibility, impact resistance, moisture resistance, accelerated weathering, resistance to wind-driven rain, and moisture vapor permeability.

Federal Specification TT-P-19D is intended to evaluate performance of paints applied to exterior wood and masonry substrates. Concrete test panels, prepared in accordance with Federal Test Method Standard No. 141, are used for some of the test procedures.

Specimens

Obviously, the use of standardized specimens of the masonry substrate is essential to obtaining reliable data in any testing protocol. ASTM Test Method of Making and Curing Concrete Test Specimens in the Laboratory (C 192) describes the practice for making and curing concrete specimens using precisely controlled materials and conditions. ASTM Test Methods of Making and Curing Concrete Test Specimens in the Field (C 31) contains procedures for making and curing specimens using concrete delivered to the job site.

ASTM Method of Making and Preparing Concrete and Masonry Panels for Testing Paint Finishes (D 1734) contains instructions for making and preparing concrete panels for testing coatings designed for portland cement concrete. Panels are molded to fit the artificial weathering apparatus described in **Artificial Weathering Tests.** The method also describes how to mold panels for use on outdoor exposure testing racks.

Method 2051 of Federal Test Method Standard No. 141, Preparation of Concrete Panels, contains the procedure and materials required to make concrete and masonry panels for testing paints. Three procedures are described for panels with different materials and surface finishes.

SELECTION

There are a number of factors to consider when selecting paint for a masonry substrate. These include the materials and type of structure to which the paint will be applied as well as the desired appearance. As with any application, it is important to determine the service conditions under which the masonry paint must perform. Awareness of these factors should enable selection of a product that will perform effectively on masonry.

Pipeline Coatings

by Loren B. Odell[1] and Al Siegmund[2]

AMERICA IS THE MOST INDUSTRIALIZED NATION on earth. To run this nation, huge quantities of energy are required. Sources of energy vary, ranging from nuclear power to the burning of coal. The most common source of energy used today is based on "fossil fuels," which include oil and natural gas. In many instances, great distances are covered between the source of the fuel and its consumption. The predominant method of fuel transportation is through carbon-steel pipelines.

Pipelines are not restricted by size, product carried, or construction material. This section addresses the most common type, pipelines made of carbon-steel pipe carrying natural gas or petroleum products.

Thousands of miles of pipeline crisscross the United States. The main goal is to deliver a source of energy to the end user. Most pipelines are buried and are therefore not visible. They may be located under streets, near school yards, and near peoples' homes. Most have been in service for many years and may be in need of maintenance and/or replacement.

Building a major pipeline is a costly, time-consuming project. First, an abundant source of fuel must be located and combined with an end user. State and federal permits must be obtained, rights-of-way purchased, and financing obtained. For these and other reasons, pipelines must be long-term commitments. To protect this investment and to provide safe operations, every possible means of protection must be utilized over the service life. The most economical means of protection has proven to be a combination of coatings and cathodic protection. This section focuses on the role of coatings, their design, choice, and use.

MARKET

The U.S. Department of Commerce estimates that loss of steel due to corrosion cost $50 billion a year in the United States alone. The market for pipeline corrosion coating products can be estimated in square feet coated, or dollars of product. In 1990 this estimate for coatings grew to 300 000 ft^2 (27 870 m^2) with an estimated value of $350 000 000.

There are five basic groups of coatings used for pipeline corrosion control. They are shown below in their dollar-value market breakdown:

Asphalt enamels and asphalt mastic	7%
Polyethylene, extruded and bonded	17%
Coal tar enamels	14%
Thin film powder coatings (FBE)	32%
Tape products	30%

This distribution can vary from year to year.

WHY USE COATINGS

Corrosion control of steel pipelines is a complicated process involving several different techniques. Internal corrosion control may be accomplished with the use of coatings and/or inhibitors; external corrosion may be minimized using coatings in conjunction with cathodic protection. In all phases of corrosion control, it is recognized that coatings provide an economical, effective method of control.

In many cases it is necessary and/or advisable to use a combination of coatings with other methods of protection. Careful selection of the coating material in combination with proper application can result in years of trouble-free service. Coatings provide the widest range of protective properties, ranging from excellent mechanical properties to elevated temperature resistance. On a per-square-foot basis, coatings have proven to be the most economical corrosion control system for steel pipelines. This protection is recognized by the Department of Transportation (DOT). It is a DOT requirement that all new steel pipelines involved in interstate transportation must receive external corrosion protection in the form of bonded coatings.

EXTERNAL COATINGS

Coal Tar Enamels

Coal tar enamels are especially suitable for coating steel pipe. Generally hot applied, either in the yard or in the field, they are virtually unaffected by long periods of water immersion, soil stress, punctures, or bacteria while providing a relatively high electrical resistance. These materials work best in the temperature range of 30 to 180°F (1.1 to 82°C). Enamels are degraded by ultraviolet light and therefore should be wrapped with kraft paper when exposed. Coal tar enamels are frequently reinforced with a fiberglass mat or embedded with a felt mat as a means of protection. These products provide years of service and were the first commonly used external protective coatings.

Coal Tar Mastic

Coal tar mastic is heavily filled with clays, silica, fiber glass, etc., which yields a highly viscous material that is cold applied to thicknesses of ½ to ⅝ in. (1.27 to 1.6 cm). This product can also be field applied as a hot extrusion seamless coating. A wide range of pipe diameters can be coated for buried pipeline service.

Coal Tar Epoxides

Coal tar epoxides are two-component materials that require mixing just prior to application. Coal tar plays two important roles in this type of coating: (1) cost reduction, (2) improved water resistance. The two components are designed to air cure, providing a harder film than neat coal tar products. Excellent adhesion is provided by the epoxy component if optimum cure is achieved.

Coal Tar Urethane

As with epoxides, coal tar is used primarily as a cost reducer. In this case, the base components are polyols and polyfunctional isocyanates, which can also be two-component spray applied to yield very rapid cure speeds. This reduces out-of-service time for the pipelines.

Coal tar products have the advantages of lower cost, excellent water resistance, wide range of application ability, and long proven service lives. They can be plant applied or over-the-ditch applied. They comprise the largest group of coatings used for the repair and maintenance of existing pipelines.

Coal tar products have limitations in protection where cathodic protection is combined with coatings. Temperature service is limited to 150°F (66°C).

Fusion Bond Epoxides (FBE)

Fusion bond epoxy coatings are one of the newest technologies viable for external protection of steel pipelines. These materials are heat-activated, chemically cured coating systems. They are 100% solid products applied in the form of "powder coatings." Powder coatings are applied directly to preheated pipe, where they melt, fuse, and cure into a continuous film. To improve application efficiency, electrostatic spray equipment is usually employed. The chemistry is such that cure often occurs through the residual heat in the pipe. This yields very rapid application parameters. Characteristics of the cured coating include excellent mechanical and physical properties. These products are also highly resistant to undercreep from cathodic protection, thereby providing long-term corrosion resistance.

FBE products have one of the highest initial costs of the external coatings and require a greater degree of surface preparation than other coatings to achieve maximum protection. They are usually plant-applied materials, although internal and external girth welds may be coated and cured in the field using portable induction heating devices for cure.

Tape and Wrap Systems

Tape-coating systems are usually cold-applied materials consisting of three layers; a primer, a corrosion-resistant interlayer, followed by a wrap in the form of a tape for mechanical protection. These systems are extremely popular for repair of existing pipelines by the over-the-ditch method of application. Each of the three layers provides special properties. The primer is frequently rubber based and modified with stress corrosion cracking inhibitors to provide good adhesion. The interlayer is olefin based to resist corrosion, while the outer layer is reinforced to resist mechanical damage and provide maximum moisture resistance.

A similar system is based on petroleum waxes. This system uses a wax-based primer, frequently combined with corrosion inhibitors, followed by an external felt or tape wrap for coating protection.

Polyethylene

This system is generally an extruded film that encapsulates the pipe using a mastic, two-part epoxy, FBE, or rubber-based primer for adhesion. The polyethylene offers excellent moisture resistance and mechanical properties. Since polyethylene is an extruded product, its application to pipe is limited to plant environments.

INTERNAL PROTECTION SYSTEMS

It is generally believed that coatings are applied to the internal surfaces of pipelines to improve product flow. As flow enhancers, they can provide increased flow rates of from 5 to 15%. These coatings do, however, provide corrosion protection; and as products carried in the pipeline become more corrosive in nature, the importance of the coatings as corrosion barriers are realized. Active lines where acid gases are involved require the use of coatings as corrosion barriers. The three systems in common use today consist of two-component epoxy polyamide/amine systems that are ambient cured, fusion bond systems that are baked, and in situ systems that are field-applied, air-dried systems based on epoxy or urethane chemistry.

APPLICATION TECHNIQUES

All of the above-mentioned coatings can be plant applied. A limited few are suitable for field application, although there are several good reasons for plant application. The first and foremost is surface preparation of the steel surface to be coated. Cleaning techniques ranging from abrasive blasting to mechanical cleaning can be mechanized and automated, resulting in a controlled surface ready for acceptance of the coating system.

This is closely followed by application technique. Automation can result in a more uniform application of the chosen coating product, resulting in film thickness control and regulation of the bake cycle for heat-cured products. Coatings that require heat to achieve chemical reaction can most economically be achieved in a plant environment.

There are outstanding coating systems that are field applied. Many are used to repair existing coated lines or to coat lines that previously had not employed coating systems. The most popular technique is an over-the-ditch system that employs both cleaning and coating equipment that travels along the pipe without removing the pipe from service. New and better methods of surface preparation that use abrasive blasting and/or high-pressure water blast are used either in conjunction with mechanical cleaning or in place of it. This technique results in cleaner surfaces for coating application. Coating compositions continue to change, improving their performance and taking advantage of new polymers to improve corrosion protection.

QUALITY CONTROL

Success is related to quality control, and the application of protective coatings to pipelines is no exception. The very best coating available can be ruined by poor application or by application to a dirty surface (Tables 1, 2, 3).

A comprehensive quality program covers all phases of a pipeline project, including steel surface quality, coating quality, and proper application of the product. The job does not end there, for improper installation of a pipeline with a good coating job can result in damage that might lead to premature failure.

The enforcement of a quality program is most easily accomplished in a plant environment. Field application is dependent upon terrain and weather conditions that can hamper required processes and procedures. A quality program that includes a representative from each step of the operation with full responsibility for their portion of the process is vital. A clear set of specifications, outlined and discussed with all parties in advance of the project, will bypass many problems. Communications between all representatives will result in a higher quality job, resulting in longer service at a lower cost.

PRODUCT DESIGN/FUTURE CONCERNS

There are several sets of specifications that pipeline coatings must meet in order to gain wide acceptance. The American Petroleum Institute (API), National Association of Corrosion Engineers (NACE), and American Water Works Association (AWWA) have specifications or recommended practices that guide in the development and use of corrosion-resistant coatings. Most specifications are part of individual company purchasing contracts. These company specifications frequently contain test parameters that must be met with corresponding references to ASTM, API, NACE, and other methods.

New products are needed that take into account the ever changing environmental regulations. Coatings that provide enhanced performance at elevated temperatures are required. New systems based upon a combination of the above technologies are trying to find their place in the market. Quality programs based upon ISO/ANSI guidelines are setting the standards for future coating projects. The opportunities are never ending.

Sealants

by Saul Spindel[1]

SEALANTS ARE PRODUCTS INSTALLED into an opening to prevent the intrusion of air, water, dust, heat, cold, and other materials such as gases, e.g., radon. The sealant is installed into the opening by gun or knife. It is then expected to function even though the space it occupies is stressed because of movement, thereby placing significant strain upon the adhesive forces that bond the sealant to the substrate to which it is attached. The sealant is also expected to function regardless of whether it is applied to a horizontal opening or a vertical one or whether it is applied to a building facade subject to rapid expansion and contraction or to a plaza or deck where it is subject to puncture by spiked heels.

The opening, or gap, into which a sealant is installed is usually called a joint. The sides of the joint may be made of similar or dissimilar materials, generally varying in width from 0.250 to 2.00 in. (0.64 to 5.08 cm) with the depth of the joint usually about one half the width. When required, preformed joint fillers made of materials such as open or closed cell rubber or polyurethane foam are installed to control the joint depth. Primers are sometimes used to improve adhesion.

The typical building materials that sealants are used with are glass, steel, concrete, mortar, granite, marble, aluminum, or wood. When the sealant is installed into the joint, the surfaces the sealant contacts must be clean, dry, sound, and free of contaminants or loose particles to provide an opportunity for the sealant to perform as intended.

Caulk or sealant compounds are based on oils, latex polymers, butyl, acrylic and blocked styrene solvent-release polymers, and polysulfide, polyurethane, and silicone elastomers. The oil-based products exhibit relatively little movement capability, generally 5% or less, and thus they are traditionally installed in relatively static joints. Acrylic latex polymers can be formulated to possess significant movement, as much as ±25%, whereas the solvent-release butyl, acrylic, and blocked styrene sealants can move about ±10%. The elastomerics exhibit significant movement, with silicones moving as much as 150% (+100%, −50%).

POLYMERS USED IN SEALANTS

Oil-Based Caulks

Oil-based caulks are generally composed of drying oils, mineral fillers, thixotropes, and driers. The oil oxidizes and thereby dries slowly, though the caulk usually sets up to become paintable within a 24 to 48-h period. Oil-based caulking compounds are easy to apply, easy to tool, and are available in a range of qualities. Generally, oil-based caulks exhibit movement of about 5%. Oil-based caulking compounds are used primarily by do-it-yourselfers.

Butyl Sealants

Butyl sealants are based on polyisobutylene or polybutene, fillers such as talc and/or calcium carbonate and additives such as adhesion promoters, antioxidants, and thixotropes. Butyl sealants dry by solvent release.

Butyl sealants can be formulated to move at about ±7½ to ±12½%. They are widely used in mobile home applications. In addition, another class of butyl sealants which are prepared without volatile solvents are extensively used as the primary seal in dual-sealed insulated glass because of their very low moisture vapor permeation properties.

Acrylic Solvent Release Sealants

These sealants are similar to butyl sealants; however, they are based on polymethylacrylate polymers (or polyethyl or polybutyl polymers), resulting in medium-high molecular weight products that, when formulated with colorants, thixotropes, and additives, are used as sealants.

Acrylic solvent-release sealants exhibit movement similar to butyl sealants, namely up to ±12½%. Acrylic solvent-release sealants are versatile in that they adhere to a wide variety of surfaces and, in addition, exhibit excellent resistance to sunlight. Two prime disadvantages of acrylic solvent-release sealants are: (1) they often require heating in the cartridge when applied at cool temperatures, and (2) they can emit acrylic monomer, which is somewhat odiferous and may be toxic in enclosed areas.

Block Copolymer Sealant

Elastomeric block copolymer sealants, usually based on either styrene, styrene-butadiene, or isoprene, are another class of solvent-release sealants. These polymers exhibit excellent resistance to ultraviolet light, are effective as clear sealants, generally adhere to a wide variety of substrates, and are readily paintable. The sealants can be formulated to move about ±12½%.

[1]President, D/L Laboratories, 116 East 16 Street, New York, NY 10003.

Polyurethane Sealants

Polyurethane sealants are available as single or multi-component products. The one-component sealant is derived from an in situ reaction of an isocyanate with a hydroxyl component. These components cure by the reaction of the isocyanate (NCO) with atmospheric moisture, forming a polyurea. The sealants contain fillers, thixotropes, additives, and adhesion promoters.

Two-component polyurethane sealants are usually based on an isocyanate-terminated polyether reacted with a hydroxyl-terminated polymer. As with other sealants, two-component polyurethane sealants are combined with fillers, adhesion promoters, and other additives and stabilizers.

Polyurethane sealants exhibit good movement capabilities, easily exhibiting ±25% movement. They generally adhere well to a variety of surfaces and are widely used in commercial applications, especially where abrasion resistance, i.e., traffic applications, is a prerequisite.

Polysulfide Sealants

Polysulfide sealants are sold as both one-component and two-component materials. Two-component sealants are formulated with polysulfide polymers, hiding and color pigments, clays, and mineral thixotropes. The second, or reactive component, consists of a curing agent (e.g., lead peroxide), adhesion promoters, fillers, and stabilizers. Both components are mixed just prior to use.

The one-component polysulfide sealants are formulated with ingredients similar to the two-component material except that the cure chemistry is different. One-component polysulfides cure by reaction with atmospheric oxygen and moisture and are generally relatively slow to attain full cure.

Polysulfide sealants can be formulated to move at ±25% and are used on a wide variety of surfaces. Polysulfides are used widely in insulated glass applications.

Silicone Sealants

Silicone sealants are primarily used as one-component products usually referred to as RTV (room temperature vulcanizing) materials. They are polysiloxane prepolymers which react with atmospheric moisture and ultimately cure to form an elastomer. Silicone sealants are cured generally by one of three mechanisms, namely:

1. *Acetoxy cure*—A reaction between methyltriacetoxy silane with polydimethylsiloxane to form an acetoxy-terminated polymer "intermediate." This material is then reacted with atmospheric moisture in order to cure. Acetic acid is liberated during cure, and its odor can readily be noted.
2. *Neutral cure*—These sealants are the result of a reaction between polydimethylsiloxane with methyltrimethoxysilane to form the "intermediate." This "intermediate" then reacts with atmospheric moisture in order to cure. Alcohol is generally liberated during the cure process.
3. *Amine cure*—In this cure mechanism, methyltricyclohexylaminosilane is reacted with the polydimethylsiloxane to form an "intermediate" which cures when reacted with atmospheric moisture. Cyclohexylamine, a heavy musty-odored material, is released during cure.

Silicone sealants can be formulated to move as much as 150% and are used in many applications, especially where long-term durability is required. Silicone sealants are the primary polymers used in structural glazing.

Acrylic Latex Sealants

Acrylic latex sealants are essentially formulated from relatively high molecular weight acrylic polymers prepared by emulsion polymerization in an aqueous media and include fillers, surfactants, additives, and thixotropes. Acrylic latex sealants dry by evaporation to form easily applied, highly weatherable products that exhibit good adhesion.

These acrylic sealants can be formulated to move as much as ±25%; however, they should not be applied at low temperatures and are not recommended for use in continuous damp or wet environments.

TEST PROCEDURES

The following is a brief summary of the test methods and procedures used to evaluate sealants. Where appropriate, reference is made to specific specifications and/or procedures where these tests are covered.

Extrusion Rate and Application Life

This test is performed to measure the extrudability of single and multi-component sealants. Single-component sealants are extruded through a cartridge of known volume and predetermined orifice at 50 psi air pressure. The time to empty the cartridge is recorded. Multi-component systems are mixed and allowed to stand for 3 h before being extruded in order to develop information on their application properties after mixing.

Rheological Properties (Flow and Sag)

This test is employed to determine the horizontal or vertical flow properties of the sealant under conditions of extreme variations in temperature. Stainless steel channels, open ended for testing vertical (non sag) sealants and close ended for testing horizontal (self leveling or pourable) sealants, are filled with the sealant and exposed at an elevated temperature (122°F, 50°C), and at a low temperature (40°F, 4.4°C). Sag (vertical displacement) is measured, and horizontal deformation is noted.

Hardness

This test is used to measure the indentation hardness of a cured sealant using a Shore A Durometer. If a sealant is too hard, it may be indicative of future problems that can result in a loss of resiliency, thereby resulting in either cohesive breaks or adhesive loss.

Effects of Heat Aging

Exposure to the atmosphere may cause loss of volatile components after cure, resulting in shrinkage, hardening, or

cracking, which may affect the durability of the sealant. This test can be used to predict premature failure. Sealant specimens are cured, then heat aged for 21 days at 158°F (70°C) and evaluated for volatility (weight loss), cracking, and hardness.

Tack-Free Time

This is the time required for the surface of a sealant to attain a tack-free state. This time may be indicative of the time interval required for the sealant to resist damage from light surface contact, job-site or airborne dirt pickup, or impinging rainfall.

Staining of Porous Substrates

This test method is useful to determine possible staining by the sealant on porous substrates. The sealant is applied to standard-size joint specimens made of porous materials such as white marble or granite. The specimens are compressed and clamped and then stored for 28 days at various conditions including room temperature, elevated temperature, and ultraviolet-fluorescent weathering. Upon completion of the exposures, the specimens are evaluated for changes in surface appearance and depth of any stain.

Adhesion and Cohesion Under Cyclic Movement (Durability)

The primary intent of an elastomeric sealant is to fill joints in buildings and other structures and thereby render them impervious to the elements. These joints are considered active, meaning that they will expand and contract with temperature.

This test method is designed to evaluate the ability of the sealant to withstand expansion and contraction with temperature change and not develop any loss of adhesion to the substrate or any cohesive cracks. When adhesion loss to the substrate or cohesive cracks within the sealant develop, water can penetrate, thereby resulting in damage to the structure.

Joints are prepared using two similar substrates. The sealant is extruded between the joints (substrates), cured, and then immersed in water for seven days. The specimens are then hand flexed and evaluated for adhesion loss. If no adhesion loss is noted, the specimens are compressed and subjected to elevated temperature (158°F, 70°C) for seven days to determine whether any heat set or deformation occurs. These test joints are then subjected to ten cycles of compression at elevated temperature (158°F, 70°C) and expansion at low temperature (−15°F, −26°C) to simulate joint movement during extreme temperature changes. (Buildings contract when cold, thereby opening up or expanding the joints. On the other hand, buildings expand when hot, thereby closing or compressing the joints.) On completion of this cycling, the specimens are examined for the presence of any adhesive bond loss or cohesive breaks.

Adhesion-in-Peel

This test is used to evaluate the adhesive characteristics of a sealant and its ability to maintain a bond to a substrate. The sealant is applied to the substrate, cured, and immersed in water for seven days. After the immersion period, the 180° peel strength of the sealant is measured and the amount of adhesive loss to the substrate is determined. An additional set of specimens is prepared, exposed to UV radiation to simulate sunlight, and then evaluated for the effect of the actinic radiation on the interface of the sealant-to-glass bond by once again measuring peel strength and adhesion properties of the sealant.

Effects of Accelerated Weathering

This procedure is used to evaluate the effects of exposure to ultraviolet radiation and water spray to simulate weathering on the sealant. After exposure, the sealant is evaluated for surface cracking. Specimens are then bent over a 0.5-in. (1.27-cm)-diameter rod under cold (−15°F, −26°C) temperature to evaluate low-temperature flexibility and brittleness.

The following section lists specifications and standards for sealants, including their sources.

SEALANT SPECIFICATIONS

Federal Specifications

TT-S-00227E	Sealing Compound Elastomeric Type, Multicomponent (For Caulking, Sealing, and Glazing Building and Other Structures).
TT-S-00230C	Sealing Compound Elastomeric Type, Single Component (For Caulking, Sealing and Glazing Building and Other Structures).
TT-S-01543A	Sealing Compound, Silicone Rubber Base (For Caulking, Sealing, and Glazing in Buildings and Other Structures).
TT-C-598B	Caulking Compound, Oil, and Resin Base Type (For Masonry and Other Structures).
TT-S-001657	Sealing Compound, Single Component-Butyl Rubber Based, Solvent Release Type (For Buildings and Other Types of Construction).

ASTM Standards

ASTM C 570	Specification for Oil- and Resin-Base Caulking Compound for Building Construction.
ASTM C 669	Specification for Glazing Compounds for Back Bedding and Face Glazing of Metal Sash.

Traffic Marking Materials

by Larry R. Hacker[1]

TRAFFIC MARKINGS GO RELATIVELY UNNOTICED by most people but affect almost everyone every day. They are used not only on city streets, highways, and interstates but also at airports, parking lots, and many commercial and industrial sites. A variety of materials are used for these applications. Some have specific uses, but all must adhere to the surface on which they are applied, show resistance to abrasion and weathering, and perform adequately over their expected lifetimes.

The following discussion will focus on the different types of marking materials being used and the testing of these materials for acceptability.

TYPES OF PAVEMENT MARKING MATERIALS

There are three general-type materials used for pavement markings. These include liquid coatings, thermoplastics, and tapes. All pavement markings fall into one of these general categories. Glass beads are used with each of these pavement marking materials to improve night visibility. Reflective devices are also used in conjunction with pavement markings to improve visibility but are beyond the scope of this manual.

Liquid Coatings

Solvent-Borne Coatings

This is the standard coating in use for traffic marking for decades. These materials are usually alkyds or chlorinated rubbers that dry by the evaporation of their solvents, followed by oxidation of their binders. They are usually applied hot and under pressure with conventional spray equipment to achieve fast-drying markings. The advantages of using solvent-borne coatings are the vast body of knowledge and experience with these materials—they can be applied over a wide range of environmental conditions and have a low cost. The major disadvantages are the need for frequent applications, especially in high-traffic areas, the release of large quantities of solvent to the atmosphere during drying, and the need for solvent to clean equipment. These solvents contribute to air pollution and become hazardous waste when used to clean equipment.

Senior analytical chemist, Virginia Department of Transportation, 1401 E. Broad Street, Richmond, VA 23219.

Water-Borne Coatings

Within the last decade, water-borne traffic coatings have overcome many of their early problems with water sensitivity and dry time to become acceptable as traffic marking materials. Applied with the same equipment as solvent-borne coatings, favorable environmental conditions are more limited for water-borne than solvent-borne coatings. Low air and surface temperatures, high relative humidity, and low air movement will adversely affect the film formation of the coating. Washout from a rainstorm soon after application can also be a concern. With the reduction of solvent emission and hazardous waste, water-borne coatings are the traffic marking material of the future where solvent emission is a concern and favorable environmental conditions are obtainable during a large part of the striping season.

Polyester

This is a two-component system used mainly on portland cement concrete surfaces since proper adhesion is a concern on asphalt concrete surfaces. This coating is a durable, high-quality material that has a useful life of three years or more. It is used mostly in high-traffic areas where repeated application of traditional coatings would disrupt traffic, be costly, and be possibly unsafe. Adjusting mix ratios of resin and catalyst gives appropriate cure times. Some disadvantages include monomer emission, hazardous waste generated from solvents used in equipment clean up, and the need for special two-stream spray equipment.

Epoxy

This is also a two-component, durable, high-quality pavement marking material. Its applications and use are similar to the polyester material. A variety of cure times can be achieved through formulation adjustments. Close attention must be paid to the mix ratio of the components to obtain optimum performance and durability.

Thermoplastic

Thermoplastic pavement markings are another durable, high-quality marking material. This is a mixture of either maleic-modified glycerol resin esters or hydrocarbon resins with plasticizers, pigments, and glass beads. The formula is melted at 400°F (204.4°C) and can be extruded or sprayed on the surface to be marked. Thermoplastic may be applied to

Copyright© 1995 by ASTM International

any clean surface but performs best when applied on asphalt concrete. Mixing is absolutely necessary during heating to prevent local burning of the material. Application thicknesses are usually in the 30 to 125-mil (0.229 to 0.318-cm) range.

Pavement Marking Tape

Pavement marking tapes can be used as a durable, long-life marking material or as a removable or temporary marking in construction areas. All tapes are composed of three layers: an adhesive layer, a backing material usually made of plastic or aluminum foil, and a pigment and glass bead layer. Application of these tapes will vary between manufacturers with primers being used for some tapes. All are rolled with a weighted roller to increase surface contact between the tape and the pavement.

Permanent Tapes

These tapes can be divided into plastic-backed and foil-backed tapes. Plastic-backed tapes are 60 to 90 mil (0.152 to 0.229 cm) thick and are used as stop bars, crosswalks, arrows, and long lines in lighted areas only. Foil-backed tapes are greater than 24 mil (0.061 cm) in thickness. They are used in unlighted areas that are free of curves, turns, or stops.

Temporary Tape

This tape is used on construction sites where the marking will eventually be paved over. Thickness of this tape are greater than 25 mil (0.064 cm).

Removable Tape

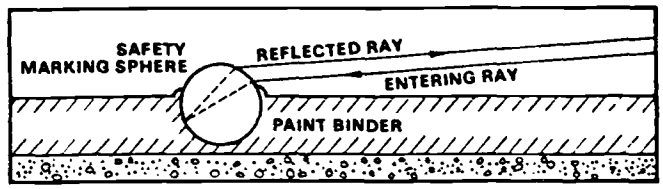
This tape is also used on construction sites but on projects that require the tape to be removed. To facilitate removal, a plastic mesh or similar material is added between the adhesive layer and the backing material of the tape. Film thicknesses are greater than 30 mil (0.076 cm).

Glass Beads

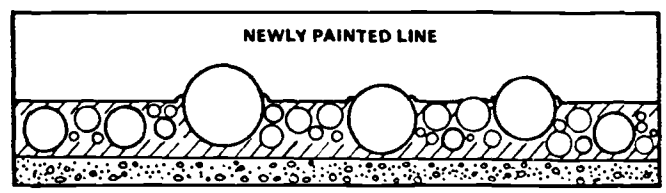
Glass beads are used with pavement markings to increase night visibility. Without the beads, most marking would be invisible at night. Figure 1 gives an excellent explanation of how glass beads improve visibility. Glass beads must be round to work. Broken beads or pieces will not refract light. Beads vary in refractive index (RI) from 1.50 to 1.90. The 1.50 RI beads are most commonly used for highways, while the 1.90 RI beads are found on airport runways. Glass beads also come in a variety of sizes with a specific size distribution usually being specified. The application of glass beads is done immediately after a pavement marking material has been applied. This is usually done by a pressurized spray nozzle so that many of the beads, about 70%, are buried in the marking material. The quantity of beads added to a line will vary with the marking material from 6 to 25-lb/gal (0.720 to 3.003 kg/L).

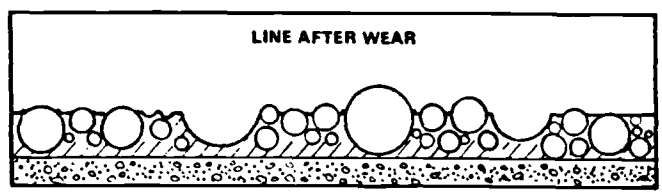
HOW DO GLASS SPHERES WORK

The reflectorization of markings which brings about the increase in night driving safety is accomplished by the use of tiny glass spheres which operate on the principle of retro-reflection. That is, they reflect light back to the source; i.e. the automobile headlight from which it came. As a result, highway lines and markings into which millions of these tiny reflective spheres have been embedded, shine brightly under headlights and are many times more visible to drivers than the same lines or markings without reflectorization.



A headlight ray entering a marking sphere is refracted to the opposite side from where it is reflected along a parallel line to the source. Non-round spheres do not reflect light but scatter it in random directions. Quality control to assure a proper number of true round spheres assures optimum retroreflection.





Safety Marking Spheres of carefully graded sizes are used to reflectorize the line. Thus, as the line wears under traffic flow and larger spheres which provide immediate reflectorization are dislodged, the smaller spheres, previously completely embedded, are uncovered and become active.

FIG. 1–How do glass spheres work? (from *Potters Safety Marking Spheres*, Potters Industries Inc.).

MATERIAL TESTING

Pavement marking materials are tested for conformance to specification in the laboratory and for performance in field evaluations.

Laboratory Testing

Liquid Coatings

Many of the tests performed on liquid coatings are standard coating tests and are referenced where applicable.

Liquid Properties

1. *Skinning*—Paints that contain binders that dry by oxidation can form skins in a partially filled container. These must be removed before use. This test can be performed in accordance with ASTM Methods of Testing Varnishes (D 154).
2. *Fineness of Dispersion*—Commonly called "fineness of grind," this test is not generally specified for traffic marking except in the case of some application equipment. The test is performed in accordance with ASTM Test Method for Fineness of Dispersion of Pigment-Vehicle Systems (D 1210).
3. *Density or Weight/Gallon*—The density is determined for unbeaded paint by using ASTM Test Method for Density of Paint, Varnish, Lacquer, and Related Products (D 1475).
4. *Consistency*—Determine the consistency using a Stormer Viscometer in accordance with ASTM Test Method for Consistency of Paints Using the Stormer Viscometer (D 562).
5. *Stability*—Traffic paints should remain stable in the container for at least six months. Stability can be checked by heating and cooling a specimen through several cycles or by storing at room temperature for a period of time. Use ASTM Test Method for Setting Properties of Traffic Paints During Accelerated Storage (D 1309) for the accelerated test and ASTM Test Method for Evaluating Degree of Setting of Paint (D 869) for an aged sample.
6. *Chemical Analysis*—Identification and quantification of traffic paint components can be made by several means. Infrared spectroscopy can be used for resin identification. Use ASTM Test Method for Infrared Identification of Vehicle Solids from Solvent-Reducible Paints (D 2621) to aid identification of solvent reducible resins. Oils and oil acids can be identified by using gas chromatography. ASTM Test Method for Fatty Acid Composition by Gas-Liquid Chromatography of Methyl Esters (D 1983), ASTM Test Method for Identification of Oils and Oil Acids in Solvent-Reducible Paints (D 2245), and ASTM Test Method for Preparation of Methyl Esters from Oils for Determination of Fatty Acid Composition by Gas Chromatography (D 2800) can be determined using either the Jones Reduction method or the aluminum reduction method found in ASTM Test Methods for Chemical Analysis of White Titanium Pigments (D 1394). Chrome yellow may be quantified using atomic absorption spectroscopy or by wet chemical methods using ASTM Test Methods for Analysis of Yellow, Orange, and Green Pigments Containing Lead Chromate and Chromium Oxide Green (D 126).
7. *Pigment Content* —ASTM Test Method for Pigment Content of Solvent-Reducible Paints (D 2371) is used for solvent reducible coatings and ASTM Test Method for Pigment Content of Water Emulsion Paints by Low-Temperature Ashing (D 3723) is used for water emulsion paints. ASTM Test Methods for Pigment Content of Paint by Low Temperature Furnace Ashing (450°C) (D 4451) is a low-temperature ashing method useful for all coatings that do not contain organic pigments.
8. *Non-Volatile Content*—Sometimes referred to as "total solids," use ASTM Test Methods for Volatile Content of Coatings (D 2369) to determine the non-volatile content of the paint.
9. *Epoxy Content*—Many epoxy traffic markings specify an epoxy content. Use ASTM Test Methods for Epoxy Content of Epoxy Resins (D 1652) for this determination.
10. *Amine Value*—An amine value is also specified on many epoxy traffic markings. Use ASTM Test Methods for Total, Primary, Secondary, and Tertiary Amine Values of Fatty Amines by Alternative Indicator Method (D 2074) for this determination.

Appearance and Physical Characteristics

1. *No-Pick-Up Time*—A quality control test that is useful in the laboratory uses a steel cylinder fitted with two replaceable O-rings that is rolled down a ramp over a test stripe as shown in Fig. 2. This is a control test and shows no correlation with field applications. The no-pick-up time can be determined using ASTM Test Method for No-Pick-Up Time of Traffic Paint (D 711).
2. *Bleeding*—This test attempts to measure the amount of material that passes from an asphalt pavement through the traffic marking material. An arbitrary scale of photographic standards are used, where 10 shows no bleeding and 2 shows considerable bleeding. Use ASTM Test Method for Laboratory Determination of Degree of Bleeding of Traffic Paint (D 969) to determine bleeding. ASTM Test Method for Evaluating Degree of Bleeding of Traffic Paint (D 868) contains the photographic standards.
3. *Hiding Power*—Hiding power is the measure of the ability of the coating to hide the substrate. Using a reflectance measuring instrument, ASTM Test Method for Hiding Power of Paints by Reflectometry (D 2805) gives the procedure for performing this determination.
4. *Color*—The color of traffic markings are usually compared to a specified standard. Color differences can be determined visually between the product and a standard. This

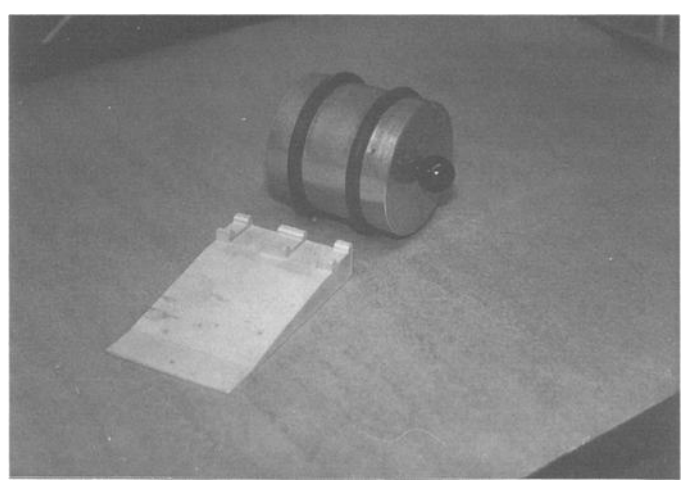


FIG. 2–ASTM D 711 equipment.

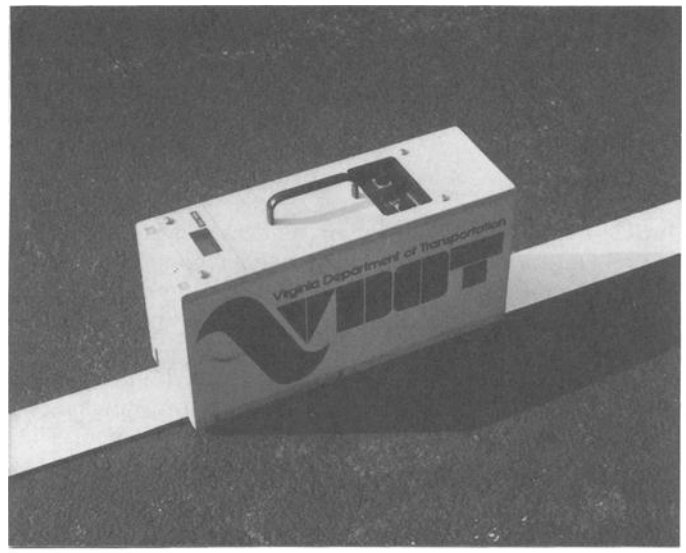
comparison is fast and acceptable although numerical values are not obtained. The advantage of using color difference instruments are that they provide numerical values that can be compared to later measurements. Visual color comparison can be made in accordance with ASTM Practice for Visual Evaluation of Color Differences of Opaque Materials (D 1729). To determine the color in terms of tristimulus values or chromaticity coordinates, use ASTM Test Method for Computing the Colors of Objects by Using the CIE Systems (E 308). Color difference measurements are instrumentally obtained by following ASTM Test Method for Calculation of Color Differences from instrumentally Measured Color Coordinates (D 2244).

5. *Reflectance and Retroreflectance*—Reflectance is the measure of light reflected from the surface of a material. To determine which of two samples appear lighter when viewed in average daylight, each sample is illuminated at a 45° angle and viewed at a 0° angle using the standard CIE source C, and the Y-tristimulus value is recorded. Determine the reflectance in accordance with ASTM Test Method E 97. Retroreflectance is a measure of light reflected close to the direction in which it came. In practice, it simulates the light reflected from a pavement marking by the vehicles' headlamps. In the laboratory, retroreflectance can be measured in accordance with ASTM Test Method for Retroreflectance of Horizontal Coatings (D 4061). Portable retroreflectometers are used to test pavement markings in field evaluations. Although there is not yet a standard procedure to use these instruments, the theory behind their use is the same as the laboratory procedure. The Mirolux 12 portable retroreflectometer which is used by several state Departments of Transportation is shown in Fig. 3. It has an internal calibration, an illumination angle of 86.5°, and an observation angle of 1.5°. After the instrument is zeroed and calibrated, it is placed over the test line and the reading is obtained. Testing has shown that there is a correlation between readings obtained with a portable retroreflectometer and those obtained in the laboratory using ASTM Test Method D 4061.
6. *Resistance to Wear*—This is a measure of a pavement markings' ability to withstand wear from traffic. The test procedure involves dropping sand on a dry test specimen until the substrate is visible. The test is usually performed on an unbeaded material that is the appropriate thickness. A variation of the test is to drop a specific volume of sand on the specimen and calculate the amount of material lost by weight. The abrasion resistance can be determined by using ASTM Test Method for Abrasion Resistance of Organic Coatings by Falling Abrasive (D 968).



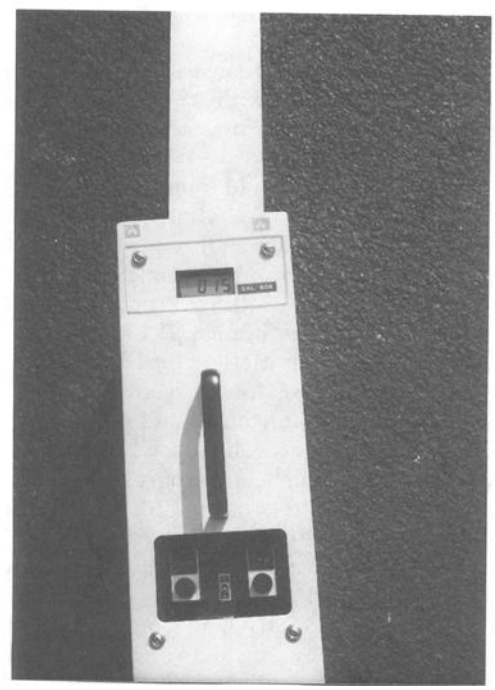


FIG. 3–Mirolux 12 portable retroreflectometer.

Thermoplastic

Thermoplastic material is supplied in a powdered form or in block form. The material is prepared for testing by melting a sample at its application temperature under constant agitation. A guideline for testing thermoplastics can be found in the American Association of State Highway and Transportation Officials (AASHTO) Standard Test Method T-250.

Gravimetric and Chemical Analysis—A melted thermoplastic patty is allowed to cool to room temperature. It is then broken into pieces and ashed in a muffle furnace at 540°C for 1 h. From this sample, the amount of binder, glass beads, titanium dioxide, or lead chromate can be determined. These can be determined in accordance with ASTM Test Methods for Chemical and Gravimetric Analysis of White and Yellow Thermoplastic Traffic Marking Containing Lead Chromate and Titanium Dioxide (D 4797).

Appearance and Physical Characteristics

1. *Reflectance*—Measuring reflectance on thermoplastic is the same as for liquid coatings except a patty is used instead of a drawdown coating. Use ASTM Test Method for Evaluation of Color for Thermoplastic Traffic Marking Materials (D 4960) to determine reflectance.
2. *Softening Point*—Thermoplastic marking material does not have a distinct melting point but will become gradually

softer as the temperature rises. The softening point is useful in predicting the tendency of the material to flow at elevated temperature. To measure the softening point, melted thermoplastic is cast into brass rings and allowed to cool. The ring of thermoplastic, which is supporting a steel ball, is placed in a liquid bath and heated at a controlled rate. The softening point is reported as the temperature at which the steel ball falls a distance of 1 in. (2.54 cm). The softening point can be determined in accordance with ASTM Test Method for Softening Point of Bitumen (Ring-and-Ball Apparatus) (D 36).

3. *Specific Gravity*—The specific gravity of the thermoplastic is determined on the premelted sample. The material is ground so it will pass through a 0.600-mm (No. 30) sieve. The thermoplastic is tested in accordance with ASTM Test Method Test Methods for Specific Gravity of Pigments (D 153) Method A to determine its specific gravity.
4. *Bond Strength*—The bond strength of thermoplastic marking material is determined instrumentally using concrete bricks and steel blocks. A melted specimen is applied to a concrete brick with a drawdown blade. Two steel cubes are placed in the hot thermoplastic, and the excess thermoplastic is scraped away from the cubes. After trimming, the steel cubes are removed and the material is allowed to cool. A heated steel cube is bonded to the thermoplastic square with an epoxide adhesive and allowed to cure before the bond strength can be determined on a dynamometer. The bond strength is determined in accordance with ASTM Test Method for Bond Strength Test for Thermoplastic Traffic Marking Materials (D 4796).
5. *Impact Resistance*—Impact resistance is determined on blocks of thermoplastic using an Izod-type impact apparatus. The procedure given in ASTM Test Methods for Impact Resistance of Plastics and Electrical Insulating Materials (D 256) is used except the specimen is not notched.
6. *Flowability*—This test is a measure of the thermoplastic marking materials' ability to flow. It is closely related to the viscosity of the material. The test involves melting a weighed sample in a pint can for 4 h with constant agitation. The can is suspended at a 45° angle, allowing material to flow over the edge until the flow ceases. The residue is weighed and the flowability is calculated. Test the material in accordance with AASHTO Test Method T-250.

Pavement Marking Tape

Film Thickness—The adhesive layer is removed from the tape with a suitable solvent, and the thickness is measured with a micrometer. The glass beads are included in this measurement, which is in contrast to films from liquid coatings where the glass beads are not included.

Reflectance and Retroreflectance—Reflectance and retroreflectance are measured in the same manner as liquid coatings. Some newer tapes are measured at a variety of illumination and observation angles because of their geometry, but the theory remains the same. For information, see No. 5 under subsection entitled "Appearance and Physical Characteristics."

Glass Bead Adhesion—A qualitative test to check glass bead adhesion is to firmly scratch the surface of the tape with a thumbnail. Acceptable adhesion for this test is when beads are not easily removed from the surface.

Tensile Strength—A 1-in.-wide strip of tape is tested in accordance with ASTM Test Method for Tensile Properties of Plastics (D 638) at a test rate of 0.25 in./min (0.64 cm/min).

Adhesive Shear Strength—The adhesive shear strength is a measure of the adhesive strength between the tape and the pavement. A 1 by 3-in. (2.54 by 7.62-cm) piece of carborundum extra course emery cloth is applied to the adhesive face of a 1 by 6-in. (2.54 by 15.24-cm) strip of tape with a 1-in. (2.54-cm) overlap. A pressure of 50 psi (35 235 kg/m) is applied to this overlapped area. The specimen is then tested in accordance with ASTM Test Method D 638 at a speed of 0.50 in./min (1.27 cm/min).

Skid Resistance—The skid resistance of tapes are measured on a British Pendulum Tester. This pendulum impact tester measures energy loss as a rubber slider travels over the specimen. The test can be used in the laboratory or in the field. The values are measured in British pendulum numbers (BPN). The test should be made in accordance with ASTM Test Method of Measuring Surface Frictional Properties Using the British Pendulum Tester (E 303).

Glass Beads

Gradation—The gradation by size of glass beads is a measure of how well a pavement marking will perform as a retroreflective media. AASHTO specification M-247 gives two gradations of glass beads. Type 1 is known as a standard gradation, and Type 2 is known as a uniform gradation. The distribution specified by AASHTO is shown in Table 1.

To perform the test, the beads are hand sieved through standard sieves starting with the largest opening and progressing through to the smallest opening sieve. The glass beads are weighed on each sieve, and the percent passing each sieve is calculated.

The test is performed in accordance with ASTM Test Method for Sieve Analysis of Glass Spheres (D 1214).

Roundness—The roundness of glass beads is another measurable indication of how well a pavement marking will perform as a retroreflective media. As mentioned earlier, only round spheres can reflect light back toward the light source.

To test for roundness, the glass beads are mechanically separated by controlled vibration of a glass plate held at a fixed slope as shown in Fig. 4. The glass spheres that are round will roll down the slope while irregular-shaped particles will vibrate to the top. After testing the complete sample, the percent rounds can be calculated by weighing the amount of spheres that have rolled down the slope. The test is performed in accordance with ASTM Test Method for Roundness of Glass Spheres (D 1155).

TABLE 1—Glass bead gradations as specified by AASHTO Standard M-247.

Sieve Designation		Mass Percent Passing	
Standard, mm	Alternate No.	Type I	Type II
0.850	20	100	. . .
0.600	30	75–95	100
0.425	40	. . .	90–100
0.300	50	15–35	50–75
0.180	80	. . .	0–5
0.150	100	0–5	. . .

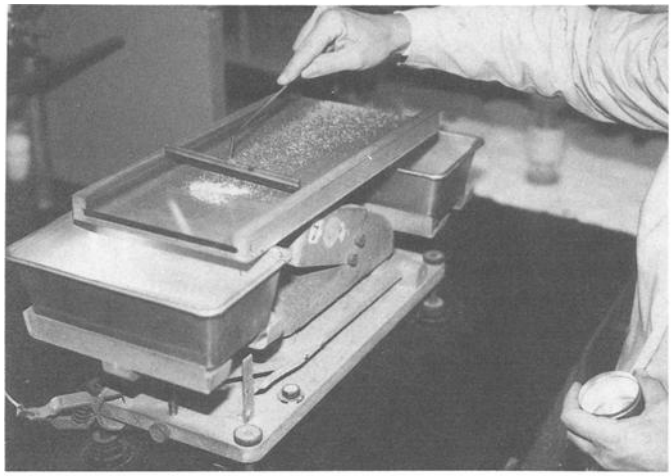

FIG. 4–Glass bead roundness apparatus.

FIG. 6–Applied test stripes.

Refractive Index—To determine the refractive index of glass beads, the beads are treated as a pigment and are tested in that manner. Most pigments are tested using the liquid immersion method (Becke Line method or equivalent) at a temperature of 25°C.

Field Evaluation of Marking Materials

Field evaluation of traffic marking materials is useful in determining the relative service life of these materials under actual road conditions using transverse lines (Figs. 5 and 6). As a guide, ASTM Method for Conducting Road Service Tests on Traffic Paint (D 713) is excellent for performing field evaluations.

FIG. 5–Field evaluation application check.

Application Process

Location For Tests—Pavements should be selected where traffic is free flowing without grades, curves, intersections, or other phenomena that would cause excessive braking or turning. The area should have uniform wear, full exposure to sunlight throughout the day, and have good drainage. Interstate highways are usually excellent choices for testing.

Wet Film Thickness Measurement—Wet film thickness is measured with a wet film thickness gage. The most popular one is a piece of metal with calibrated notches cut at various mil thicknesses as shown in Fig. 7. The gage is placed in a freshly applied line and withdrawn. The notch with the highest reading that has paint on it is the wet film thickness.

The wet film thickness is measured and adjusted before the test line is applied to the pavement. On a piece of roofing paper, place a rigid metal test panel. Apply a test line to the panel using a motorized striper. Immediately determine the wet film thickness. Adjust the pressure and repeat until the proper thickness is obtained.

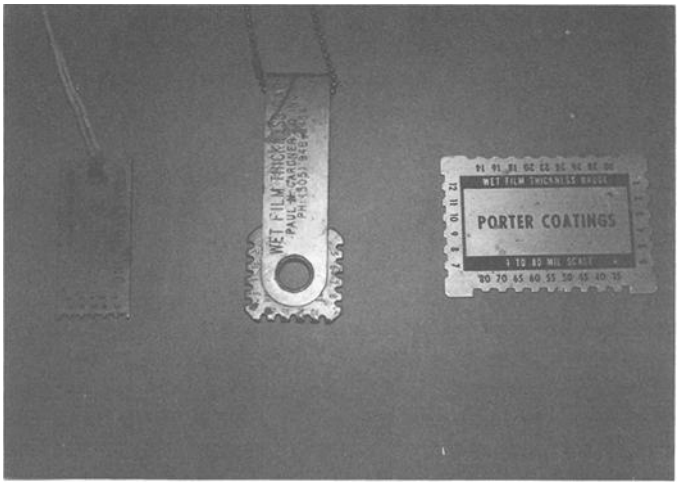

FIG. 7–Wet film thickness gages.

Film thickness for thermoplastic is usually measured on a test panel after cooling with a pair of calipers.

Glass Bead Measurement—There are two methods that can be used to quantify the weight of glass beads used. The first involves weighing a freshly applied stripe without beads on test panel and a test stripe with beads. The difference in weight is used to calculate the quantity of glass beads. This procedure is described in ASTM Method D 713.

The second procedure involves securely tying a bag around the bead nozzle of the striper and catching the beads in the bag as the striper moves over a measured distance. The weight of beads caught is determined and used to calculate the application rate for the beads.

Glass bead distribution is checked on a beaded test panel. The beads should be evenly distributed across the width of the stripe, approximately 70% of the beads should be buried in the material, and the remaining beads should be 50% embedded in the material. Nozzle pressure and angle should be adjusted until the distribution is acceptable.

Application Procedures—Before applying any test lines, wet film thickness, line width, glass bead application rate, and glass bead distribution should meet the specification. Several transverse test lines are usually applied. The first is for the Auto-No-Track Time determination (see next section). Two glass-beaded lines and one unbeaded line are usually applied. Often a test panel is placed in one of the beaded lines between the wheel tracks as a double check for line quality.

Performance Criteria

Auto-No-Track Time—The auto-no-track time is determined by passing over a freshly applied line in a standard-sized passenger car. This is usually done at 25 to 35 mph (40.25 to 56.35 km/h) at the specified no-track time. Any deposit of paint on the roadway or exposure of the pavement under the test line is considered as not meeting the no-track requirement. The laboratory no-track time described in ASTM D 711 has little or no correlation with the field results.

Appearance—This is the general condition of the test lines when viewed from a distance of 10 ft (3.05 m). It takes into consideration color, bleeding, darkening, fading, dirt collection, etc. This is done for each wheel track. A numerical value is usually assigned from 0 to 10 with 10 being the highest quality.

Durability—The durability is rated as to the percentage of material remaining on the pavement. The determination is made in each wheel track. A numerical value is usually assigned from 1 to 10 as determined by the percentage of material remaining, with 10 representing no material has worn away. ASTM Test Methods D 821 and Test Method for Evaluation Degree of Chipping of Traffic Paint (D 913) are used as guidelines.

Night Visibility or Retroreflectance—Retroreflectance measurements are made in each wheel path using a portable retroreflectometer as previously described. On the day of application, the meter reading of a beaded line is assigned a value of 10 and the reading of an unbeaded line is assigned a value of 0. Subsequent readings will be assigned a value in relation to a percentage of the original reading.

Evaluation

Periodic inspections of the test stripes are made, usually monthly. At each inspection, daytime appearance, durability, and retroreflectance values are recorded. It is good practice to obtain data during the winter season.

1. *Weighted Rating*—An excellent method to compare the relative performance of the test stripes is to assign each stripe a weighted rating. Each performance criteria that receives a rating is weighted as a percentage of the entire test. The weighting system used by the Virginia Department of Transportation is as follows:

$$R = 0.1A + 0.2D + 0.7N$$

where

R = overall weighted rating,
A = daytime appearance rating (10%),
D = durability rating (20%), and
N = retroreflectance (70%).

Other percentages can be assigned to the rating components according to the importance of the user.

2. *Length of Useful Life*—This can be defined as the projected or actual useful life in days from the day of application to the day on which the weighted rating reaches a value of 4 or if any of the rating values (appearance, durability, or retroreflectance) reaches a value of 3. If the evaluation is terminated and neither of the above is reached, the projected useful life can be calculated as follows:

$$L = D(10 - 4)/10 - R = 6D/10 - R$$

where

L = length of useful life,
D = days since application, and
R = overall weighted rating on the termination day.

3. *Weighted Cost Factor*—A weighted cost factor is useful in determining which material has the best performance at the lowest cost. It is calculated as follows

$$WCF = R[(C + AC)/L]$$

where

WCF = weighted cost factor,
C = material manufacturers price,
AC = cost to apply a given quantity of material,
L = length of useful life, and
R = overall weighted rating.

Special Considerations for Pavement Marking Tapes

Application of pavement marking tapes will vary with type of tape and manufacturer. Many tapes require primers or adhesives to be applied to the pavement before applying the marking tape. Most are rolled with a weighted roller after application to assure good contact between the adhesive and the pavement. The manufacturers directions for application should be followed closely.

In addition to the previously discussed evaluation criteria, removable tapes are also evaluated for their ability to be easily removed. About 90 days after application, a test line is removed by lifting a corner with a putty knife and pulling up the line. An acceptable tape should be removed in large sheets, not small pieces that are difficult to remove.

Water-Repellent Coatings

by Victoria Scarborough[1] *and Thomas J. Sliva*[2]

WATER REPELLENTS ARE TRANSPARENT COATINGS formulated for the purpose of protecting porous substrates by preventing the penetration of liquid water. Unlike waterproofing materials and sealers, water repellents allow the passage of water vapor and generally are not designed to prevent the intrusion of liquid water under hydrostatic pressure.

Water is known to penetrate porous materials and contribute to their deterioration [*1–3*]. Examples include warping and swelling of wood and cracking and spalling of concrete and masonry caused by freeze/thaw cycles and dissolved salts. Further, chloride ions in deicing salts can accelerate the corrosion of reinforcing steel in concrete. Water repellents are used to provide protection against such damage.

Water repellents provide protection by depositing hydrophobic compounds on the substrate, thus modifying the surface tension of the treated area. The result is that water no longer "wets" the surface but is instead repelled. Visually, the result after the application of water repellents may be beading of water.

Composition

Most water repellents are composed of 1 to 65% monomeric or polymeric hydrophobic compounds suspended or dissolved in a carrier solvent. The products are generally classified by the type of compounds used to deliver the water repellency, e.g., acrylic, siliconate, silane, siloxane, metallic stearate, etc. The applied material may "cure" by simple carrier evaporation, or a chemical reaction may occur between the hydrophobic compounds and the substrate.

The carrier solvent used is selected based on its compatibility with the hydrophobic compounds. Organic solvent carriers can be aliphatic, aromatic, or chlorinated solvents which can be derived from petroleum distillation. These carriers are considered volatile organic compounds (VOC) and, in recent years, have been subject to restricted use by state and federal air emission control regulatory agencies. Thus, using water as a carrier in water repellents has been the focus of recent formulation efforts.

[1]Group leader, Research & Development, Thompson-Minwax, Inc., 10136 Magnolia Dr., Olive Branch, MS 38654.
[2]Assistant technical director, D/L Laboratories, 116 East 16th St., New York, NY 10003.

Classification

Water repellents can be classified as either film formers or penetrants. As film formers, the substrate pores are filled and there is a continuous film on the surface. Examples of film formers include acrylic polymers or silicone elastomers. In most cases, the film-forming portion of the water repellent is a blend of several different hydrophobic compounds.

Water repellents that are penetrants line the pores of the substrate and generally do not visibly alter the surface of the substrate. Examples include solutions of metallic stearates or paraffinic waxes. Penetrants also include reactive chemicals such as silanes and siloxanes which covalently bond to the silicate minerals in cementitious substrates. This latter reaction may be catalyzed by moisture and/or alkaline material present within the substrate.

SCHEDULE OF TESTING

Most of the major laboratory tests used for the evaluation of water repellents are outlined in the following sections: Tests on Physical Properties, Tests for Water Repellency of Treated Wood, and Tests for Application on Treated Masonry. All the tests described may not be required for each water repellent, and the selection of the tests to be conducted may be guided by the type and recommended use of the treatment or as agreed upon by buyer and seller.

Tests on Physical Properties

Typical physical properties tested on a liquid water repellent prior to application include weight per gallon, viscosity, drying time, color, flash point, pH, storage stability, percent nonvolatile content, and volatile organic compound content (VOC).

Many of these tests are outlined in Section 8 of this manual on "Physical Characteristics of Liquid Paints and Coatings" and are summarized as follows:

Weight per gallon	ASTM D 1475
Viscosity	ASTM D 1200, Ford Cup
	ASTM D 2196, Brookfield
Drying time	ASTM D 1640
Color	ASTM E 1544, Gardner
Flash point	ASTM D 56, Tag Closed Cup
pH	ASTM E 70

Copyright© 1995 by ASTM International

Storage stability	ASTM D 2243 Freeze/Thaw
	ASTM D 1849 Heat Aging
% nonvolatiles	ASTM D 2369
	ASTM D 5095
VOC content	ASTM D 3960

Tests for Water Repellency of Treated Wood

Dimensional Stability

The relative ability of water repellents to retard dimensional changes in wood submerged in water is measured using the "wood swellometer test" and is detailed in Federal Specification TT-W-572b Par 3.7, Water Repellency [*4*]. This test compares the swelling of untreated control specimens with the swelling of treated specimens after each has been submerged in water for 30 min. Similar procedures are described in: the National Woodwork Manufacturers Association Test Method NWMA-M-2-81 [*5*]; in ASTM Test Method D 4446, "Method for Determining the Anti-Swelling Effectiveness of Water-Repellent Formulations and Differential Swelling of Untreated Wood When Exposed to Liquid Water Environments"; in American Wood Preservers Association Standard M-18, "Standard Method of Testing Water Repellency of Pressure-treated Wood" [*6*]; and in ISO/DIN 4496, "Wood Test Method-Determination of the Radial and Tangential Shrinkage" [*7*].

In Federal Specification TT-W-572b, water repellent effectiveness is measured on treated Ponderosa pine sapwood that is cut into 0.25 by 1.5 by 10-in. (6 by 38 by 254-mm) wafers. The wafers are cut from two adjacent specimens from each of five different boards. Specimen pairs of ten wafers are required to make a set for testing, one for the treated wafers and one for the untreated controls. Five wafers (one from each board) are immersed in the test water repellent for 30 s. The wafers are cured under standard conditions for four days or until constant weight is attained.

The wafers are inserted into a holding device fitted with a micrometer at one end known as a swellometer gauge. One end of the wafer touches the base of the gauge, while the other just touches the plunger dial of the micrometer. The wafer apparatus is immersed in water for 30 min, and a dial reading is made before and after immersion.

The difference between the dial reading of the treated and the untreated control wafers is divided by the dial reading of the untreated control wafers and multiplied by 100. The average of these five readings represents the water-repellent effectiveness in percent of the product. Federal Specification TT-W-572b requires that a water repellent exhibit a minimum of 60% water repellent effectiveness. ASTM Test Method D 4446 differs from the federal specification in that it requires a 3-min dipping time for water-based water repellents, and it specifies that all control untreated specimens must swell a minimum of 0.325 in. (0.8 cm).

Water Absorption

Water repellent effectiveness can also be measured gravimetrically using ASTM Test Method D 5401, "Evaluating Clear Water Repellent Coatings on Wood." Water absorption is tested by cutting matched 2 by 4 by 12-in. (50 by 100 by 305-mm) Ponderosa pine sapwood boards. Five boards are treated with the test water repellent by immersing for 30 s. Five boards serve as untreated controls. After curing the boards under standard conditions to constant weight, they are weighed, immersed in water for 30 min, and reweighed. The difference between the absorption of the treated and the untreated boards is divided by the absorption of the untreated boards and multiplied by 100. The average of the five treated boards represents the water repellent effectiveness in percent of the product.

Unlike with Federal Specification TT-W-572b, the boards used in this test can be exposed to exterior weathering cycles, returned to the conditioning room to attain constant weight, and water repellent efficiency can be determined over periodic exterior exposure intervals to determine long-term effectiveness.

Beading

Water repellents for application on wood can be evaluated for their ability to form and hold a water bead [*8*]. A suitable test is described in ASTM D 2921, "Test Method for Qualitative Tests for the Presence of Water Repellents and Preservatives in Wood Products." After the wood has been treated and allowed to cure, several water droplets are placed on the wood with an eye dropper or other device. The time required for the droplets to lose their spherical shape and flatten out is recorded. The test can be used to compare water-beading ability before and after either artificial or natural weathering. The ability to bead water does not prevent water absorption as described in ASTM D 5401, nor does it necessarily correlate with the ability to retard dimensional changes in wood as described by Federal Specification TT-W-572b.

Paintability

If wood is to be painted and a water repellent is used as an undercoat, it may be necessary to evaluate the effects of the water repellent on the primer or topcoat. Evaluations can include checking the adhesion of the topcoat to the substrate, observing any changes in color to the topcoat, and measuring the drying characteristics of the topcoat. These evaluations may also be made after a periodic weathering of the water repellent–treated surface before the topcoat is applied.

Weathering

Substrates treated with water repellents can be subjected to artificial or outdoor weathering, e.g., using ASTM G 53, "Practice for Operating Light- and Water-Exposure Apparatus (fluorescent UV-Condensation Type) for Exposure of Nonmetallic Materials," and ASTM D 4141, "Practice for Conducting Accelerated Outdoor Exposure Tests of Coatings." The substrate is evaluated for appearance properties like cracking (as shown in ASTM pictoral standards D 661, "Test Method for Evaluating Degree of Cracking of Exterior Paints"), discoloration, mold and mildew growth, and dirt pickup. The substrate may also be evaluated for beading ability or water repellent effectiveness.

Tests for Application on Treated Masonry

Water Repellency

Water repellency on masonry is determined following procedures described in Federal Specification SS-W-110c, Par.

4.3.2. [9]. Mortar cubes are prepared as described in the method. These are weighed, immersed in water, and the amount of weight gain recorded. The same cubes are dried to constant weight and then immersed in the test water repellent for 10 s. Three cubes are tested for each water repellent under evaluation.

After the water repellent has cured, the cubes are immersed in water for 72 h. The percent water absorbed by the treated cubes is calculated based on the weight of the dry treated cubes.

Chemical Resistance

The resistance of a water repellent to the intrusion of various chemicals is determined following methods modified from procedures described in: ASTM C 267, "Test Method for Chemical Resistance of Mortars"; ASTM C 67, "Method of Sampling and Testing Brick and Structural Clay Tile"; Report 244 of the National Cooperative Highway Research Program, "Concrete Sealers for Protection of Bridge Structures" [*10*] and ASTM C 672, "Test Method for Scaling Resistance of Concrete Surfaces Exposed to Deicing Chemicals." Mortar cubes are prepared and then treated, cured, and immersed in a specified chemical solution. Uncoated control cubes are included in the immersion. Typical chemicals used in this test include fuels and oils, various salt solutions, and acid and alkaline solutions.

Differences in weight gain or loss over time are measured and plotted as compared to the untreated control. The rate of weight gain or loss over time during immersion may be more significant than the actual difference. By charting the weight gain or loss over time, the rate of deterioration may be determined.

Chloride ion penetration resistance is of particular interest in testing for the resistance of water repellent–treated masonry since reinforcing steel in concrete will corrode and deteriorate after prolonged exposure to salt. A method of determining the resistance of concrete to chloride ion penetration is described in the AASHTO Method T 259 [*11*].

Freeze/Thaw Resistance

Freeze/thaw resistance is determined by methods modified from procedures outlined in ASTM C 67, mentioned above and ASTM C 666, "Test Method for Resistance of Concrete to Rapid Freezing and Thawing." Treated cubes are subjected to cycles of freezing and thawing, and the amount of water absorbed and the change in absorption with time is determined. The cubes are evaluated for weight loss and physical deterioration such as cracking and spalling after each series of cycling.

Moisture Vapor Transmission

Because the passage of moisture vapor through masonry may affect the long-term performance of a structure, water repellents applied to that structure may be required to demonstrate their ability to allow the passage of moisture vapor. Several methods are available to measure moisture vapor transmission of the applied film and include ASTM D 1653, "Test Method for Water Vapor Transmission of Organic Coating Films," and ASTM E 96, "Test Methods for Water Vapor Transmission of Materials." Generally, these methods measure the rate at which water vapor passes through a coating film. The specimen is sealed to the open mouth of a cup or dish containing desiccant, and the assembly is placed in a test chamber with a controlled atmosphere. The cup or dish is exposed to a specified relative humidity, and periodic weighings are made to determine the rate of water vapor through the film. Another method is described in NBS Technical Note 883, Par. 2.2.2, "Moisture Vapor Transmission on Brick" [*12*] which measures the moisture vapor transmission of the treated brick rather than the film.

Efflorescence

Efflorescence is a crystalline deposit on the surface of masonry which is whitish in appearance and often detracts from the appearance of the substrate. Water repellents may be used to prevent the formation of efflorescence. Their efficiency at preventing efflorescence can be measured using the method described in NBS Technical Note 883, Par. 2.2.3. [*12*].

Part 14:
Analysis of Paints and Paint Defects

68

Analysis of Paint

by Darlene Brezinski[1]

SAMPLING

The importance of appropriate sampling for analytical work cannot be overemphasized. Unfortunately, this topic is often not given sufficient thought, and there is often not enough training on the subject. A clear understanding of the nature of the problem or the reason analysis is needed must be established prior to obtaining a sample. It is extremely important to know the compositional makeup of the bulk material from which the sample is being taken. Without this knowledge, improper sampling can very easily occur. The homogeneity or heterogeneity of the sample along with its stability is very important to consider. The composition of a sample may change once it is removed from its natural matrix or environment due to interactions with a container, ultraviolet light, or air, for example. One should also know in advance what level of precision is required of the analysis and what compositional information is required.

Development of a sampling plan is one of the most important steps in providing reliable samples and consequently accurate and reliable data. The types of samples usually encountered are:

Representative Sample: A sample considered to be typical of the bulk material and whose composition can be used to characterize the bulk with respect to the parameter measured.

Systematic Sample: A sample taken according to a systematic plan with the objective of investigating systematic variability of the bulk. Systematic effects due to time or temperature are typical matters of concern.

Random Sample: A sample selected by a random process to eliminate questions of bias in selection and/or to provide a basis for statistical interpretation of measurement data.

Composite Sample: A sample composed of two or more increments that are combined to reduce the number of individual samples needed to average compositional variability [*1*].

There are basically three kinds of sampling plans that can be used in a measurement process. Intuitive sampling plans may be defined as those based on the judgment of the sampler. General knowledge of similar materials, past experience, and present information about the bulk material, ranging from knowledge to guesses, are used in devising such sampling plans. Because the samples are based on judgement, only judgmental conclusions can be drawn when considering the data. In the case of controversy, decisions on acceptance of conflicting conclusions may be based on the perceived relative expertise of those responsible for sampling [*1*].

Statistical sampling plans are those based on statistical sampling of the bulk materials and ordinarily can provide the basis for probable conclusions. Hypothesis testing can be involved, predictions can be made, and inferences can be drawn. Ordinarily, a relatively large number of samples will need to be measured if the significance of small apparent differences is of concern. The conclusions drawn from such samples would appear to be noncontroversial, but the validity of the statistical model used could be a matter of controversy [*1*].

Protocol sampling plans may be defined as those specified for decision purposes in a given situation. Regulations often specify the type, size, frequency, sampling period, and even location and time of sampling related to regulatory decisions. Not specifically following any part of the protocol could be reason for discrediting a sample. The protocol may be based on statistical or intuitive considerations but is indisputable once established [*1*].

When decisions are based on identifying relatively large differences, intuitive samples may be fully adequate. When relatively small differences are involved and the statistical significance is an issue, statistical sampling will be required [*1*].

General Sampling Techniques

It is obvious that the sample submitted for analysis must accurately reflect the bulk material from which the sample was taken. Personnel taking samples should be trained in proper protocol for obtaining samples from bulk material. Equally as important as training is the use of proper containers necessary for storing samples. Many types of containers can alter the integrity of the sample. A paint sample submitted in the original container is not necessarily a representative sample as often volatile components have already been lost or the contents have been adulterated. Assumptions regarding the integrity of the sample are extremely difficult to make, and good analysts need to constantly bear in mind the history of the sample itself.

Detailed procedures regarding sampling of all sorts of coatings would be impossible to write; however, ASTM Practice for Sampling Liquid Paints and Related Pigmented Coatings

[1]Consolidated Research, Inc., 200 E. Evergreen Avenue, Mount Prospect, IL 60056.

Copyright© 1995 by ASTM International

(D 3925) and ASTM Method for Sampling Industrial Chemicals (E 300) should be examined for detailed recommendations.

All the precision in weighing, measuring, calculating, and so forth has absolutely no meaning if the sample is not a valid and representative sample. The sample taken for analysis must totally and accurately reflect the composition of the bulk material from which it was taken. If there is any doubt about the integrity of the sample *as a representative sample*, the analysis should not be conducted as the data has no meaning. This becomes extremely important when dealing with samples where the bulk is large and perhaps not always completely homogenous [*1*]. In the real world of sampling, it is often very difficult to even know if the sample was obtained properly and if it is representative. The analyst usually has no control over the sampling step itself. In these cases, it becomes important for the analyst to stress that the data are only representative of the sample which has been analyzed and not necessarily representative of the bulk. Rather serious management decisions can be falsely made if the decision is based on data which is not representative data.

Care should be taken to assure that all containers, agitators, and sampling apparatus are clean and that they can in no way contribute to contaminating the sample. Reusable syringes in particular can pose problems, particularly in trace analysis, if they are not cleaned extremely well. Contaminant materials will lead to erroneous test results as the contaminate will be assumed part of the sample. For pigmented coatings which are dispersions, finely divided pigment particles may settle upon standing. Consequently, very thorough agitation is necessary at every stage of the sampling and analysis procedure.

Airtight storage containers are necessary to prevent evaporation of sample material. Volatile solvents may also diffuse through the walls of plastic containers. The loss of volatiles subsequently introduces significant error in such tests as viscosity, weight per gallon, and nonvolatile content. If cap liners are used for samples, they must be made of a nonreactive material. It is also very important in all stages of sampling/analysis that the samples be kept at fairly constant and consistent temperatures. Extremes of temperatures may change the properties of some coatings.

Proper labeling of the sample cannot be stressed enough. Labeling should be done in accordance with prior established standard operating procedures (SOPs) for the laboratory. The more information available on the label, the less likely error will be introduced either in the handling of the sample or in the analysis. Formula composition, if known, can be an asset to the analyst in choosing the best analytical methods and save valuable and costly analytical time.

Laboratory Protocol

The analytical laboratory today must have standard operating procedures (SOPs). This is standard, acceptable practice today, and laboratories that have not implemented these procedures will find it more difficult to maintain credibility of the data with their clients. Standard operating procedures define clearly how each step of the laboratory operates. Clear SOPs are necessary for training, logging samples, calibration, quality assurance, receipt of samples, chain-of-custody, report formats, analytical methods, handling of hazardous materials, etc.

Whatever kind of sampling plan is developed, it should be written as a protocol containing procedures (SOPs) that must be followed. It should address the following:

- when, where, and how to collect samples
- sampling equipment, including its maintenance and calibration
- sample containers, including cleaning, addition of stabilizers, and storage
- criteria for acceptance and/or rejection of samples
- criteria for exclusion of foreign objects
- sample treatment procedures such as drying, mixing, and handling prior to measurements
- sub-sampling procedures
- sample record keeping such as labelling, recording, and auxiliary information
- chain of custody requirements [*1*]

Appropriate laboratory protocol has established SOPs in place for every facet of the operation. Sample control has to include not only the receipt and handling of the sample but the handling and storage of the data.

Implementation of a chain-of-custody plan for each sample is most critical to good operating practices in the analytical lab today. It provides traceability for the sample upon receipt and distribution of the sample for analysis. The purpose of chain-of-custody is to ensure control of the sample and corresponding data and that the data are verifiable. The flow of samples for analysis and the associated paper must be clear to everyone involved in the laboratory.

Analytical Quality Assurance

The validity of analytical data must be clearly established through the documentation of quality assurance practices. This is particularly important because often analytical determinations and the subsequent data may be used as evidence in a court of law. Standard operating procedures should be established and encompass the following: record keeping, sample homogeneity, calibrations, reference standards, calculations, laboratory housekeeping, the statistics of interlaboratory studies, and practical quality control.

Laboratory accreditation is becoming increasingly important in today's environment to provide a level of confidence in the laboratories' capabilities, personnel, testing procedures, and equipment. It establishes integrity and reliability in the testing and the data. As regulatory requirements become more demanding, the nature of the analytical methodology has been changing to more sophisticated analyses and, along with these changes, there has been an increased emphasis on quality assurance (QA) and quality control (QC). Successful laboratories have made major commitments to quality products and quality data. Therefore, the process of verification of laboratory procedures is becoming more important for providing precise and accurate data.

GENERAL TESTING

Before any tests are run on the coating and prior to separation, testing to establish some basic parameters or con-

formance properties should be run. Among these are: flash point, density, water content, nonvolatile content by weight and/or volume, and pigment or ash content. Reference should be made to elsewhere in this manual for more information regarding determination of density, specific gravity, and so forth.

Flash Point

The flash point of a material is defined as the lowest temperature, corrected to a pressure of 760 mm Hg (101.3 kPa, 1013 mbar) at which application of an ignition source causes the vapor of the specimen to ignite under specified conditions of test. Flash point is one of the properties used to classify liquids according to their flammability by governmental regulatory agencies. Several different flash point methods are available. The analyst must determine which one of these methods is appropriate for the sample to be analyzed and then follow the recommended ASTM procedures. Both Tag open cup and closed cup methods, Pensky-Martens closed cup, and Setaflash tester methods are commonly used in the coatings industry. [ASTM Test Method for Flash Point and Fire Points of Liquids by Tag Open-Cup Apparatus (D 1310); ASTM Test Method for Flash Point by Tag Closed Tester (D 56); ASTM Test Methods for Flash Point by Pensky-Martens Closed Tester (D 93); ASTM Test Methods for Flash Point of Liquids by Setaflash Closed-Cup Apparatus (D 3278)]. Laboratories need to be certain of the shipping requirements and the appropriate methods prior to analysis of the sample.

Density

Density is weight per unit volume. It is a key property in the identification, characterization, and quality control of a wide range of paint materials. The density of water at various temperatures is used to calibrate the volume of the container. The weight of the paint liquid contents of the same container at the standard temperature is then determined and density of the contents calculated in terms of grams per milliliter, or pounds per gallon, at the specified temperature.

Density measurements in terms of weight per gallon are commonly used to check paint quality. If the density is not within specification, there is a good chance that there was a mischarge or other serious problem. This could indicate further chemical analysis is required to determine the nature of the problem. ASTM Test Method for Density of Paint, Varnish, Lacquer, and Related Products (D 1475) is suitable for the determination of density of paint and related products and components when in liquid form.

ASTM D 1475 provides for the maximum accuracy required for hiding power determinations. Automatic equipment for measuring density is available from several manufacturers [see ASTM Test Method for Density and Relative Density of Liquids by Digital Density Meter (D 4052)]. For higher precision if working with nonpigmented materials, ASTM Test Method for Specific Gravity of Drying Oils, Varnishes, Resins and Related Materials at 25/25°C (D 1963) can be used to determine specific gravity and the corresponding density.

Water (Content) Determination

Control of water content is often important in controlling the performance of paint and paint ingredients and is certainly critical in determining and controlling the volatile organic compound (VOC) content. ASTM Test Method for Water in Paints and Paint Materials by Karl Fischer Method (D 4017) is applicable to all paints and paint materials, including resins, monomers, and solvents, with the exception of aldehydes and certain active metals, metal oxides, and metal hydroxides. The Karl Fischer Method has been evaluated for pigmented products containing water in the 30 to 70% range; however, it is believed that the method is also applicable for higher and lower concentrations. The method consists of dissolving the sample in pyridine, or other appropriate solvent, and titrating directly with standardized Karl Fischer reagent to an electrometric end point.

ASTM Test Method for Water Content of Water-Reducible Paints by Direct Injection into a Gas Chromatograph (D 3792) is also used for determining water in many latex systems. That method has not been evaluated for other water reducible paints, but is believed to be applicable. The established working range of the method is from 40 to 55% water, but there is no reason to believe that it will not work outside of this range. In this method, a suitable aliquot of whole paint is internally standardized, diluted, and injected into a gas chromatograph. By choosing the correct column and conditions, water can be separated from the other volatile components.

Water content in pigments may be determined in accordance with ASTM Test Methods for Common Properties of Certain Pigments (D 1208).

SEPARATION OF SOLIDS AND VOLATILE CONTENT

Separation of solids is routinely performed for determining the percent composition of the coating, i.e., % NVM (nonvolatile materials), % pigment, and % solvent. In many cases, however, separation of these materials is also necessary for further identification purposes, to check formulation related problems, and for general problem solving.

Nonvolatile Content by Weight

Nonvolatile measurement is one of the most widely used tests for coatings characterization. It determines the quantity of coating remaining after all solvents or water and other volatiles have been removed. When used in conjunction with volume nonvolatile content, the area covered by a gallon of paint or coating can be determined.

It has become customary to determine the amount of nonvolatile material, or solids, in a coating and that information is useful to producers, users, and to environmental and health and safety interests in comparing the coverage of competing products and in estimating the volatile organic content. Standard practice has been to accurately weigh by difference from a syringe a small sample of paint into a tared aluminum foil, flat-bottomed dish. The dish is heated for a specified temperature and time (usually to constant weight at 105°C), cooled in

a desiccator, and weighed. From this weight and the original weight of the empty dish the weight of nonvolatile material may be calculated. The procedure is not as simple as it first appears, and different types of coatings require different methods. ASTM Guide for Determining Volatile and Nonvolatile Content of Paint and Related Coatings (D 2832) is intended to aid in the selection of the proper standard for determining the volatile and nonvolatile content of coatings. This guide should be examined carefully and followed prior to determining nonvolatile content.

Perhaps the most commonly used method is ASTM Test Methods for Volatile Content of Coatings (D 2369). This method is the procedure of choice for determining the volatiles in coatings for the purpose of calculating the volatile organic content (VOC) in coatings. Correspondingly, the nonvolatile (NVM, or solids) is used to determine the weight percent solids content.

Another commonly used procedure is ASTM Test Method for Nonvolatile Content of Latexes (D 4758). This method should not be used for determining VOC of formulated coatings; however, it is appropriate for obtaining the weight percent of a commercial latex product that, when incorporated into a coating product, constitutes the binder content of the coating.

The nonvolatile content of resin solutions is useful to coatings producers and users for the determination of the total solids available for film formation and for the estimation of VOC. ASTM Test Methods for Nonvolatile Content of Resin Solutions (D 1259) provides the detailed procedures.

Nonvolatile Content by Volume

A measure of the volume of dry coating obtainable from a given volume of liquid coating is considered by some to be a better measure of value than percentage of nonvolatile matter by weight. ASTM Test Method for Volume Nonvolatile Matter in Clear or Pigmented Coatings (D 2697) is applicable to the determination of the volume of nonvolatile matter (volume solids) of a variety of coatings. This method is intended to provide a measure of the volume of dry coating obtainable from a given volume of liquid coating. This value is useful for comparing the coverage (square feet of surface covered at a specified dry film thickness per unit volume) obtainable with different coating products.

The value obtained may not be equal to that predicted from simple additivity of the weights and volumes of the raw materials in a formulation. One reason is that the volume occupied by a solution of resin in solvent may be the same, greater, or less than the total volume of the separate ingredients: such contraction or expansion in resin solutions is governed by a number of factors, one of which is the extent and direction of spread between solubility parameters of the resin and solvent. The spatial configuration of the pigment particles and the degree to which the spaces between the pigment particles are filled with the binder also affect the volume of a dry coating formulation. Above the critical pigment volume concentration, the apparent volume of the dry film is significantly greater than theoretical due to the increase in unfilled voids between pigment particles. The use of volume nonvolatile matter values in such instances should be carefully considered as the increased volume is largely due to air trapped in these voids.

In the method, the weight and volume of a stainless steel disk are determined. After the disk is coated with the material being tested, the weight and volume of the disk plus dried coating is determined by weighing in air and then by weighing in a liquid of known density, the volume being equal to the quotient of the weight loss of the coated disk (due to the Archimedes buoyancy effect) divided by the density of the liquid displaced. The liquid may be water or an organic liquid, such as low solvency mineral spirits, depending on the nature of the coating being tested. From the measured weights and volumes of the disk before and after coating, the weight and volume of the dried coating film are calculated. Based on the density of the liquid coating and the weight percent nonvolatile matter, the volume of the liquid coating deposited on the coated disk is calculated. The volume of the dried coating divided by the volume of liquid coating, multiplied by 100, provides the volume percent nonvolatile matter in the total liquid coating.

Pigment Content

For most water emulsion paint systems, the pigment content (often called ash) is most often determined following the determination of the weight percent nonvolatiles. ASTM Test Method for Pigment Content of Water-Emulsion Paints by Low Temperature Ashing (D 3723) covers a procedure for the pigment content determination. After weighing the dishes for NVM, the dishes are transferred to a muffle furnace and heated at a low ashing temperature of about 450°C for 1 h. Of course the analyst must keep in mind that the method is only applicable to pigments that do not decompose or lose weight at temperatures below 500°C. This would include most metal oxides, silicates, and a majority of anhydrous inorganic salts.

A note of caution is advised as this may be too low an ashing temperature for some paints. Each system is different, and one cannot assume that this temperature will be sufficient.

To separate pigment from solvent-based paints, ASTM Test Method for Determination of the Pigment Content of Solvent-Reducible Paints by High-Speed Centrifuging (D 2698) should be followed. Also ASTM Test Method for Pigment Content of Solvent-Reducible Paints (D 2371) provides a centrifugation method for separation of pigment from the vehicle.

Vehicle Separation

Separation of the vehicle from the pigment in solvent-reducible paints is desirable and often required in order to further characterize paint vehicles by chemical or instrumental methods of analysis. ASTM Standard Practice for Separation of Vehicle from Solvent-Reducible Paints (D 2372) covers the procedure for separating the vehicle from the pigment by centrifugation.

Solvent Separation

If it is desirable to separate the solvents from the vehicle, ASTM Standard Practice for Vacuum Distillation of Solvents

From Solvent-Reducible Paints for Analysis (D 3272) details a vacuum distillation procedure. For analysis purposes, however, most people prefer direct injection of paint sample into the gas chromatograph for solvent identification.

Sample Preparation

For many types of analysis, the previously discussed separation techniques are sufficient. Many chemical analyses require further sample treatment in the form of either extractions or digestions. The standard analytical techniques are always applicable in these cases. Extractions are often more attractive techniques for separating inorganic species than precipitation methods which are more time consuming. Of course the extent to which inorganic and organic species distribute themselves between two immiscible solvents differs greatly depending on the species and the extraction solvents.

Decomposition of the organic material for further analysis requires rather drastic sample treatment and typically involves oxidation techniques. Wet ashing makes use of liquid oxidizing agents such as sulfuric, nitric, and perchloric acids. Dry ashing usually implies ignition of the organic compound in air or in a stream of oxygen.

Sample dissolution is one of the most common operations in analytical chemistry. Because most quantitative techniques require that samples be introduced in liquid form, thousands of sample dissolutions are performed every working day in analytical laboratories. Despite the importance and widespread applicability of sample dissolution, most conventional digestion procedures are tediously labor-intensive, and a number of them, such as perchloric acid digestion, are potentially hazardous to laboratory personnel [*2*].

New microwave dissolution techniques make it possible to speed the preparation of solid samples by combining the rapid heating ability of microwave energy with the advantages inherent in the use of sealed digestion vessels. Researchers have found microwave dissolution to be faster, more controlled, more elegant, and more amenable to automation than conventional open-beaker or closed-vessel techniques [*2*].

The advantages of microwave dissolution include faster reaction rates that result from the high temperatures and pressures attained inside the sealed containers. These containers are made of polymers that will not contaminate or adsorb the sample and do not absorb microwave energy. The caps are designed to safely vent container gas in case of excess internal pressure buildup [*2*].

The use of closed vessels also makes it possible to eliminate uncontrolled trace element losses of volatile molecular species that are present in a sample or that are formed in the course of dissolution. Such losses can easily destroy the integrity of a measurement. In the field of elemental analysis, significant percentages of elements such as arsenic, boron, chromium, mercury, antimony, selenium, and tin are lost at relatively mild temperatures with some open-vessel acid dissolution procedures. Several of these elements have already been shown to be retained when closed vessels are used [*2*].

Another advantage of closed vessels is a decrease in blank values as compared to open-beaker work because contamination from the laboratory environment is lower and smaller quantities of reagents are used. The blank value incurred in sample preparation is an important parameter because it frequently determines the limit of detection [*2*].

CHARACTERIZATION AND CHEMICAL ANALYSIS

Analytical Data

The reporting of analytical data is exceedingly important, and every effort must be taken to ensure that the data are sound, defensible, and meaningful. Most basic texts on analytical chemistry discuss the appropriate statistical methods used in dealing with data, standard deviation etc., as well as significant figures. An excellent text by Taylor [*1*] deals with all aspects of chemical measurements and should be examined thoroughly by all analysts. Also available is ASTM Procedure for Intralaboratory Quality Control Procedures and a Discussion on Reporting Low-level Data (D 4210).

In the analytical laboratory, a method of measurement (procedure) is usually followed which specifies the equipment, reagents, sample handling, etc., and the instructions to be followed. The analyst who carries out the method is following what is called a measurement process. The most important attribute of a measurement process is whether it can be made to run in a state of "statistical control." Although repetition of measurement is subject to variability, the achievement of statistical control implies that the statistical properties of this variability are uniform over time, so that it becomes meaningful to use measurements over a limited time span to predict limits of variation for both those and future measurements and to assign the level of confidence to be associated with the limits. To achieve statistical control, all assignable causes of significant variation are removed from the process [*3*].

Given the existence of statistical control, the two most important other attributes of the process are generally the precision and the accuracy of the results. Precision is universally considered to be the mutual agreement of individual measurements about some mean value (not necessarily the true value), while accuracy refers to the degree of agreement of individual measurements with some true or accepted reference value of the property being measured. When the mean value is not identical with the reference value, the systematic difference is called the bias. We should avoid using the terms accuracy and bias interchangeably; accuracy has to do with the difference between individual measurements and some reference value, while bias represents the systematic difference between the process mean and the reference value [*3*].

Structural Analysis

All aspects of coatings manufacture, from the screening of raw materials to finished product quality assurance, depend on analysis data. The ultimate goal of analyses is to identify the chemical species contained in a sample and then determine the amount of each species. As such, both qualitative (what) and quantitative (how much) analyses must be performed. It is extremely important to try and obtain all the background information regarding the sample to be analyzed

as this information can often save time and expensive analysis costs.

Organic Structural Analysis

A. Instrumental Methods

Spectroscopy is the study of the interaction of electromagnetic radiation with matter, that is, the interaction of wavelengths of visible light, infrared light, ultraviolet light, X-rays, and radio waves and their effect on chemical substances. Spectroscopy allows the study of these effects with instruments which give an enormous amount of information in a short period of time with less stringent sample requirements than is needed with classical chemical techniques. All of the wavelengths in the ultraviolet, visible, and infrared regions provide valuable information about the structural makeup of molecules.

Infrared Spectroscopy (IR) provides a unique fingerprint useful in the identification of a wide variety of chemical species [*4*]. Certain infrared wavelengths are absorbed in the sample by the bonds between the atoms, and the absorbance is measured and plotted as a function of wavelength. Since each chemical material has its own particular and unique arrangement of atoms and bonds, its absorbencies are slightly different from those of all other chemicals.

Normally specific functional groups will give characteristic absorbencies, and these groups can be recognized. Thus, there are very specific absorbencies for groups such as carbonyls, amines, alcohols, nitro groups, and isocyanates. Although it may not always be obvious from a spectrum which chemical is being examined, the analyst will recognize these functional groups and know something about the chemical structure.

In addition, IR can be a very valuable tool for: reaction kinetic studies, hydrogen bonding, dipolar attractions and solute-solvent interaction studies, examination of the nature of hydration and the nature of inorganic lattices at various temperatures, and for studying the surface of a material by attenuated total reflection (ATR) and variation of composition with depth by variable angle ATR. These are but a few of the numerous applications of IR in the coatings field [*4*].

If more detailed information is desired and if the sample has some degree of solubility, then *nuclear magnetic resonance* (NMR) analysis can be extremely valuable. NMR spectrometry not only provides information regarding the functional groups which are present but it also provides information about the location of those functional groups relative to each other. In other words, the placement of the functional groups in the molecule can be discerned from NMR data [*5*].

If the compound is volatile and has some degree of thermal stability, *gas chromatography* (GC) can be very useful for identification purposes as well as for determining purity/impurities of materials. If a material is identified qualitatively by GC, then that material can be further analyzed quantitatively. If the compound is not very volatile or is unstable under GC conditions it may be possible to analyze it by *high performance liquid chromatography (HPLC)*. Here, as in GC, both qualitative and quantitative determinations can be made [*5*].

For both GC and HPLC, if the peak of interest can not be readily identified, it can be trapped and further analyzed by either IR or NMR techniques. Current instrumentation allows the analysis of materials like this quite readily by offering instrument capabilities such as the following: HPLC-MS, GC-IR, and GC-MS (mass spectrometry). These instruments allow accurate separation of components followed by subsequent identification.

Mass spectrometry can be applied to the quantitative analysis of organic, organometallic, inorganic and ionic compounds and materials including metals, and alloys. It is used both to confirm the presence of known compounds and to identify compounds of unknown structure. Volatile or gaseous samples, usually organic compounds, can be examined using electron impact (EI) or chemical ionization (CI) to give positive or negative ion mass spectra. Nonvolatile samples can be examined by fast atom bombardment (FAB) or thermospray ionization for inorganic and organic salts, while plasma discharge ionization is used for metals and refractory materials.

The value of mass spectrometry, of course, is absolute identification of either known or unknown compounds, particularly when combined with information from other spectroscopic techniques. Pyrolysis can also be carried out prior to ionization inside the spectrometer and thus used for characterizing both linear and cross-linked polymers.

Raman spectroscopy [*5*] is used to determine molecular structures and compositions of organic and inorganic materials. Raman, like infrared, provides characteristic frequencies of various functional groups. However, since the selection rules governing the allowable transitions are different, some frequencies may be observed in the Raman spectrum which do not appear in the infrared and vice versa. Some applications include:

- Examination of aqueous solutions of inorganic compounds. While water gives rise to intense absorptions in the infrared, making unavailable major regions of the spectrum for identification purposes, it is a poor Raman scatterer, thereby allowing the observation of vibrational transitions in the regions obscured in the infrared.
- Structural identifications of water-soluble organic compounds such as amino acids.
- Detection of weak infrared frequencies, such as the stretching vibrations of the following groups:

  —C≡C—, —C=C—, —S—S—, —C—S—, —N=N—, and —O—O—

- Determination of configurational isomers in both the solid and liquid state [*4*].

B. Chemical Methods

The techniques used in chemical analysis are of two general types: gravimetric and titrimetric. In a titrimetric analysis, the volume of known solution required to completely react with a functional group is measured. This volume is then related to the concentration of reacting species in the sample. The primary criteria for titrimetric analyses are that the sample be soluble in a suitable solvent and a reagent is found which fully reacts with the species of interest. Determination of acid, hydroxyl, and oxirane functional groups, as well as elemental analysis for nitrogen content, utilize titri-

metric techniques. Titrimetric analyses are quite sensitive, and measurements of concentration at the 0.1% level are routine. During gravimetric measurement, the weight of material formed during analysis is used to determine the composition of the original sample.

Classical chemical analyses can be further divided into two categories depending upon the type of information desired: functional group determination and the measurement of elemental composition.

The presence of functional groups in polymers and coatings can normally be determined using a combination of chemical and instrumental measurements. Building upon qualitative functional group information obtained from spectroscopic techniques, quantitative analysis can begin. In some cases specific chemical tests are also required to confirm the presence of species indicated by other techniques. The quantitative measurement of the following chemical species is routinely performed in the laboratory:

Acid (mg KOH/g sample) $COOH + KOH \rightarrow COO^-K^+$
Amine (meq/g sample) $NH_2 + HCl \rightarrow NH_3 + Cl^-$
Hydroxyl (mg KOH/g sample)
Epoxy or oxirane (meq/g or g/eq)
Isocyanate (%)
Acrylate (%)
Olefinic unsaturation
Thiol or mercaptan (meq/g) $SH + Ag^+ \longrightarrow S\text{-}Ag + H^+$

Many of the above are chemical functional groups that may be part of a large molecule or polymer. The level of these species provides information regarding a polymer or coating. For example, many of the polymers used in coatings are formed using multi-step reactions, and the reactions are monitored by functional group analysis. In addition to monitoring polymerization processes, the levels of species in coatings is of importance. When two coatings components are designed to be blended prior to application, functional group determination is needed to insure that the components are mixed in proportions which give optimum physical and durability properties.

Inorganic Structural Analysis

A. Instrumental Methods

Most inorganic compounds are not sufficiently volatile or soluble to allow identification by either gas or liquid chromatographic techniques. *Ion Chromatography* can, however, play a major role in inorganic analysis. *Infrared* analysis (*IR*) is notable for pigment identification as is discussed in a subsequent section.

X-ray Fluorescence (XRF) [5] and other emission techniques are used for elemental analysis of inorganic compounds. *X-ray Diffraction (XRD)* analysis [5] is an important tool not only in compound identification but in identifying crystal structures and in crystalline phase analysis.

Thermal analytical techniques such as *differential thermal analysis (DTA), differential scanning calorimetry (DSC)*, and *thermal gravimetric analysis (TGA)* are all used on a routine basis for identifying and analyzing inorganic compounds, as well as organic compounds. These techniques provide information about the melting points, other phase transition temperatures, and thermal stability of both inorganic and organic compounds. Also, particle size, surface area, and porosity analyses provide useful characterization information about inorganic materials [6].

Inductively coupled argon plasma spectroscopy (ICAP) [5] allows the determination of numerous elements in aqueous and organic solvent solutions. ICAP methods rely on the emission of light by atoms in the sample as opposed to the absorption of light, the principle behind atomic absorption (AA) spectrometry. Liquid and/or solid samples are readily analyzed using ICP techniques after appropriate sample preparation steps are taken. ICP analytical procedures employ classical sample preparation methods such as acid digestion, fusion, dry ashing, dilution, and extraction. In practical applications, AA and ICP are quite similar. The major differences are the speed with which ICP handles samples and most importantly its relative freedom from interferences. The technique is desirable for: quantitative determination of trace elements in aqueous and organic solvent solutions, quantitative analysis of pigments in paints and coatings, evaluation of waste materials and total metals content, and detection of trace metallic impurities in polymers.

The surface upon which a coating is deposited plays an important role in the protective properties of a coating system. A single molecular layer of oily contamination can interfere with proper bonding and result in coating adhesion failure. In addition, the oxide layer that forms in a clean metal surface is often mechanically weaker than the bulk of the metal. Under stress, this layer may flake off and carry with it the coating. Techniques for the examination of surfaces may take many forms, but all involve bombarding the sample with atomic or subatomic particles. The bombardment excites the surface of the sample, releasing energy, which can be used to determine elemental or molecular composition. Depending on the technique chosen, the "surface" examined will vary between the first several atomic layers of a sample down to the first several micrometers.

Electron beam X-ray analysis (microprobe) is one of the capabilities generally included with a *scanning electron microscope (SEM)* [5]. High-energy electrons that strike a sample during the image forming process interact with the atoms comprising that surface. Among the species formed during this interaction are X-rays having specific energies depending on the elements present in the sample. Once detected and analyzed, X-ray spectra can yield information on the elemental composition of the sample, as well as indicate the quantity of each element present. Two types of X-ray detectors are in general use. The energy dispersive detector is useful for detecting elements above sodium in the Periodic Table but is not suitable for low-level quantitative analysis. A wavelength dispersive detector observes all elements more massive than carbon and has significantly improved quantitative analysis capabilities. An instrument that contains all the imaging ability of the SEM and has full quantitative analysis capability is called a microprobe. This instrument has sufficient resolution to allow the elemental analysis of a particle less than 1 μm in diameter. The primary disadvantage of the microprobe is that X-rays can emerge from atoms several micrometers below the surface of the sample. Consequently, the signal from a thin layer of surface contamination can be lost in the signal from the substrate.

Ion scattering spectrometry (ISS) and *secondary ion mass spectrometry (SIMS)* techniques involve bombarding the sam-

ple with gas ions and analyzing the products removed from the surface [5]. Both methods exhibit very high sensitivity for all elements, including hydrogen, and can analyze a few atomic layers of exposed surface at a time. Resolution is normally on the order of millimeters with the exception of specialized instruments known as microprobes. These techniques are very useful for hazing and chalking problems where very minute amounts of material cause appearance problems at the surface of the coating. ISS and SIMS readily determine the nature and extent of the contaminating material. Cases of substrate contamination leading to adhesion problems are also more easily solved using the data provided by these analytical methods.

Electron spectroscopy for chemical analysis (ESCA) and *scanning auger microscopy (SAM)* are techniques in which a sample is irradiated with a beam of X-rays (ESCA) or electrons (SAM) to liberate electrons from the top 2 to 5 nm of the surface [5]. The energy of the liberated electrons is then analyzed to provide information regarding the composition of the surface layers in the sample. In addition to elemental composition, information can be obtained on the chemical environment of the elements present on the surface. Through comparison of spectral fingerprints with the spectra of standard materials or a library of reference spectra, compounds present on the surface can be readily identified. ESCA has the capability of observing particles approximately 1 mm in diameter and is well suited to paint films on a variety of substrates. SAM has the ability to study much smaller particles (approximately 0.2 μm in diameter), but the surface must be conductive, limiting its utility to metal surfaces.

B. Chemical Methods

In conjunction with titrimetric and gravimetric measurements, analysis of elemental composition provides important information on coatings systems. Among the many elements determined are: carbon (%), hydrogen (%), nitrogen (%), sulfur (%), chlorine (%), bromine (%), phosphorous (ppm).

The level of nitrogen in an industrial coatings system is an important analytical value because nitrogen is present in melamine, urea, and benzoguanamine oligomers, which are used as cross-linking agents in many coatings. Correct levels of cross-linking agent are essential since physical, chemical, and performance characteristics are directly related to cross-linker levels. Low concentrations of cross-linking agent yield coatings which are soft, water sensitive, and do not resist detergent solutions and the weather. Elevated levels of curing agent have equally undesirable effects since coatings become brittle and lack sufficient adhesion to the substrate. In addition to cross-linking agent, nitrogen content provides information on the presence of polyamide and urethane polymers, which also contain nitrogen.

Vehicle Identification

Infrared Spectroscopy

Qualitative infrared spectroscopy is a valuable analytical tool which allows the examination of the multitude of materials utilized in the coatings industry. It is the primary tool for vehicle/resin identification in a coating. An infrared spectrum indicates the overall composition of any unknown material in terms of its functional groups. With a minimum of background knowledge, substantial information can be gained from an infrared spectrum by simple functional group identification. However, beginners should be cautioned against making unfounded conclusions based strictly on this technique. As one becomes more acquainted with infrared spectroscopy, the limitations and real complexity of this analytical technique will become more apparent. All laboratories involved in the infrared analysis of any aspect of coatings should have available a copy of "An Infrared Spectroscopy Atlas for the Coatings Industry" published by the Federation of Societies for Coatings Technology [4]. This atlas (inclusive of a 2500-spectra library) is an invaluable tool and a true benefit to the spectroscopist in the coatings industry.

Occasionally, it is possible to obtain some qualitative information from the infrared spectrum of a pigmented binder system if the system is relatively simple. However, a binder free from pigment should be obtained for an infrared analysis. This means prior separation of pigment, vehicle, and solvent and a further breakdown of these fractions if possible. The elemental composition of the fraction should be obtained because in some cases the presence of certain elements will not be obvious from the infrared spectrum [4].

In most cases, band positions are indicative of the functional groups present. The shape of the bands also gives information concerning the functionality of a molecule. The relative intensity of a band in comparison to the intensity of other bands provides information pertaining to the amount and identity of a specific functional group present in a molecule. Functional groups that give rise to a large change in the dipole moment of a molecule, upon undergoing a vibration, will have very intense absorption bands. Excellent examples of this phenomenon are the carbonyl and ether groups [4].

Once it is known which bands are characteristic of certain functional groups, the absence of these bands from a spectrum can be used to establish which functional groups are not present in detectable amounts. This method of analysis is important since the spectroscopist is frequently requested to establish the presence or absence of a particular functionality. If there is absorption present in a particular region, no information can be obtained from that region by negative interpretation. Positive interpretation or other techniques must then be relied upon [4].

The simplest method of interpretation is to consider the entire spectrum as though it were a picture and compare this picture with the spectrum of known materials which have been physically or mentally cataloged. If the spectra are the same, or very similar, it is a reasonable assumption that the materials are nearly identical. As experience is gained and more spectra are committed to memory, a great many materials can be recognized by inspection. Reference spectra prove invaluable in this type of interpretation, especially when a definite identification must be made [4]. There are also very extensive collections of reference spectra with which one tries to match "fingerprints" of unknown materials in order to make positive identifications.

In most cases, the limit of detectability of one material in another by infrared spectroscopy is 5%. However, depending on the type of material, it may be less than 1% or as high as 30%. The limit of detection will depend on the phase, the absorptivity of the particular absorption being used, and the proximity of this band to other strong absorptions. Therefore,

it is important to rely upon previous knowledge of the system and to use other confirmatory methods to verify the infrared analysis [4].

In addition to determining polymer type and concentration, the detection of contaminants in complex matrices and the examination of residual reactive functional groups can be done by infrared. The technique has advantages over other analytical techniques in that literally any type of sample can be examined by IR: solids, liquids, or gases. Special techniques are also available to examine surfaces.

Extension of a UV-VIS experiment into the near-infrared region allows examination of materials which absorb in that region. Wavelengths in the near-IR region are those longer than visible wavelengths and occur below the red portion of the visible spectrum. A special source and detector are needed to extend into the near-IR, but instrumentation is available which will automatically switch to these at the proper wavelength. A special technique is utilized in the near-IR called diffuse reflectance and is used to measure the total reflected light off of a painted surface. This is done with a device called an integrating sphere which collects all of the reflected light from a surface and focuses it to the detector. In this way, one not only measures the amount of light a sample will absorb, but how much is reflected as well.

Infrared has great utility for the quantitative analysis of polymers, inorganic pigments, solvents, and additives. Solubility of the sample is not a requirement, and many complex mixtures can be determined in this fashion. With the increased utilization of Fourier Transform and computer-assisted dispersive infrared spectroscopic techniques, quantitative applications have been further enhanced. The basis for quantitative analysis is, of course, the Beer-Lambert Law [4].

Nuclear Magnetic Resonance Spectroscopy (NMR)

Nuclear magnetic resonance spectroscopy permits the qualitative and quantitative analysis of many organic materials. When certain nuclei are placed in a strong magnetic field, their nuclear spin states are split into two or more levels due to the magnetic properties of these species. Transitions between these magnetically induced energy levels can then be brought about by the absorption of radio frequency energy. The specific frequencies of the radiation subsequently re-emitted depend on both the chemical and magnetic environment of each nucleus, such that detailed structural information is possible. NMR, as an analytical technique, provides information about how the atoms in a molecule are arranged. It is possible to determine which carbons are present as methyl groups, methylene groups, and so forth. The number of hydrogen atoms attached to oxygen and nitrogen can also be determined, and with these pieces of information the analyst is able to generate a molecular structure.

Samples that are soluble in a variety of solvents can be examined using nuclear magnetic resonance spectroscopy. It is ideal for structural identification of organic compounds. Qualitative and quantitative analysis of polymer composition, quantitative measurement of polymer mixtures, analysis of copolymer sequence distribution and tacticity, analysis of type and degree of polymer branching, and polymer end group analysis can all be done with NMR. An NMR spectrum of a typical polyester would show each of the dibasic acids and the polyols used in the synthesis of the polyester. NMR can be a superb asset to the analyst along with other tools such as IR for identification of true unknowns and for assisting polymer synthesis identification work.

Miscellaneous Testing

A host of chemical methods exist for further identification of resin components by chemical treatment of the resin to break it down into its original starting components, which can then be analyzed by conventional methods. For example, a resin may be subjected to aminolysis to form amides of the carboxylic acids and to release the polyols. Upon further treatment, these materials can be readily identified. Scanning of available ASTM methods and Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC Methods) [7] will provide insight into other useful techniques and procedures.

Thermal analytical data can also aid in the identification and characterization of a polymer. DTA or DSC can be used to obtain a melting point, a T_g, and a measure of the thermal stability of the polymer. XRD analysis of the polymer will determine if the polymer is partially crystalline, help to identify the chemical structure of the polymer, and provide information on the preferred conformation of the polymer chains in the crystalline regions [6].

Electron microscopy and XRD techniques describe the submicron morphological features of polymers such as lamellae and crystallites, while optical microscopy is used to study large morphological features such as the size and nature of spherulites in a polymer [6].

Electron probe microanalysis (EPMA) is an elemental identification technique associated with SEM. When materials are bombarded by a high-energy (10 to 50 keV) electron beam, characteristic X-ray fluorescence radiation is produced. By incorporating either energy dispersive or wavelength dispersive spectrometers directly into the instrument, it is possible to obtain X-ray spectra directly on the area as seen by the electron beam. Thus, it is possible to obtain qualitative and quantitative elemental data from a small volume of material for the elements boron through uranium. EPMA has been used extensively for impurity and inclusion identification in polymers [6].

Some unique vehicles may be particularly difficult to analyze, and the determination of residual monomer by gas chromatography often can shed some light on the resin system.

Pigment Identification

The following sections discuss the qualitative and quantitative identification of pigments.

Infrared Spectroscopy

As noted in the discussion on vehicle identification, IR analysis for the qualitative identification of pigments is most common. Procedures and reference spectra may be found in the Infrared Atlas [4]. Infrared is also used for identification of extender pigments.

Inductively Coupled Argon Plasma Spectroscopy

Inductively coupled argon plasma spectroscopy, often referred to as ICP or ICAP, is a technique used to determine the concentration of various elements present in any sample or

material. The instrument can provide qualitative and quantitative information and can complete an analysis on numerous elements simultaneously and in a matter of a few minutes. The major strength of the technique, aside from speed, is the ability to detect trace amounts of elements.

A solution is aspirated into the instrument, where a fine aerosol is formed. This aerosol is then introduced into a high-energy argon plasma, where the elements present in the sample are raised to an excited state. When these elements return to ground state, they emit light at wavelengths characteristic of the elements present. The intensity of the light is proportional to the concentration of the element present in the sample. Generally, sensitivity is in the low parts-per-million range for most elements.

The plasma is a highly ionized, chemically inert, hot gas which achieves a temperature estimated to be 10 000°C. A radio frequency generator provides energy to the plasma torch by creating an oscillating magnetic field. A sample introduction device, known as the nebulizer, converts the sample solution into fine droplets or aerosol mists which are transported to the torch by means of argon carrier gas. The high temperature of the plasma dries the droplets and decomposes the sample into individual atoms which are excited and emit light as they return to the ground state. The wavelength of the light produced differentiates one element from another. The intensity of the light produced is a measure of the concentration of the element present in the sample.

The light emitted from a sample containing many elements passes through an optical path which separates the spectrum of light into discrete wavelengths. A detection system, made from many photomultiplier tubes, each representing a wavelength of an element, measures the intensity of light and converts it to electrical energy. The electrical energy is converted into concentration by means of a dedicated computer. The computer performs all instrumental control functions and prints the data.

Some applications of ICP are the following: pigment composition in coatings, industrial influent and effluent analysis, soluble cations and anions in electrocoat baths, organo-metallic additives in coatings, driers and catalysts in coatings, competitive product analysis, quality control of raw materials, and industrial hygiene analysis.

Atomic Absorption Spectroscopy

Atomic absorption spectroscopy, commonly referred to as AA, is designed for measuring the concentration of metallic elements in solution at the parts-per-million level. Atomic absorption is an efficient and sensitive method for performing routine quantitative analysis with a high degree of precision and accuracy. Unlike inductively coupled plasma (ICP) spectroscopy, this instrument is only capable of analyzing the concentration of one element at a time. Thus, it is more often recognized for its quantitative power rather than its qualitative capabilities.

Atomic absorption methods rely on the absorption of light by atoms. If a solution containing metal ions is aspirated into a heat energy source, such as a flame, the high temperature and environment of the flame causes the formation of free, ground-state atoms in the flame. These free atoms are capable of absorbing light of a particular frequency. If a beam of light having the appropriate frequency or energy passes through the flame, the free atoms in the flame will absorb some of this energy. The decrease in the intensity of the light beam can then be taken as a measure of the concentration of that particular element in the sample solution.

Atomic absorption instrumentation requires a light source, an atomizer, a monochromator, and a detector. The normal light source used in AA is a hollow cathode lamp. It consists of a hollow cup made from the element to be analyzed. Application of a high potential causes formation of positively charged ions which bombard the cathode, forming excited metal ions which emit light. AA is important since free, uncombined atoms must be formed before light absorption occurs. A solution containing the metal ions is heated to a temperature sufficient to dissociate the ions into atoms. The heat energy can be provided using an air-acetylene or nitrous oxide-acetylene flame. The primary function of the monochromator is to isolate a single atomic resonance line from the spectrum of lines emitted by the light source and direct it through the flame and onto the detector. Photomultiplier tubes are employed as detectors. They measure the changes in light intensity and convert them to electrical signals.

Sample preparation is an essential part of AA. Solid and pigmented samples are ashed to remove organic species. The inorganic components are dissolved in acid and diluted with deionized water prior to introduction into the flame. Nonaqueous AA is an ideal way of determining organometallic compounds to prevent sample loss or conversion of the metallic species into insoluble components.

Atomic absorption complements ICP techniques for the analysis of paints, resins, UV curable coatings, and other materials. It is also a very useful tool in analyzing waste materials, pigment composition, pollution studies, raw material evaluation, and analysis of organometallic compounds.

Several pigment analysis procedures using AA are standard ASTM methods. Typical procedural examples of AA analysis for pigments can be found in the following:

Standard Test Method for the Determination by Atomic Absorption Spectroscopy of Titanium Dioxide Content of Pigments Recovered from Whole Paint (D 4563)

Test Method for Detection of Lead in Paint by Direct Aspiration Atomic Absorption Spectroscopy (D 4834)

X-Ray Fluorescence Spectroscopy

X-ray fluorescence (XRF) is a relatively simple and, in general, nondestructive method for the analytical determination (qualitative and quantitative) of elements. This method is extremely useful because of the ease of sample preparation and its ability to "scan" the periodic table for all elements down to aluminum and sometimes boron. The technique allows for rapid qualitative determination of the elements present. ASTM Test Method for Determination by X-Ray Fluorescence Spectroscopy of Titanium Dioxide Content in Paint (D 4764) is a typical application for the technique.

X-Ray Diffraction

The X-ray diffraction (XRD) pattern obtained from a material is characteristic of that material. The intensity of a diffraction peak is entirely due to one component of a mixture and is dependent upon the amount of that substance in the mixture. To a minor extent the peak intensity of the component is also dependent on the mass absorption coefficient of

other materials present. Since the method utilizes the ratio of diffraction maxima of two chemically similar materials, it is expected that the effects of other constituents will be the same for both materials.

Diffraction measurements can be made on single pigments, pigment mixtures, on films of pigmented coatings and on films prepared from liquid coatings if interfering materials are not present. ASTM Test Method for Ratio of Anatase to Rutile in Titanium Dioxide Pigments by X-Ray Diffraction (D 3720) is an application well suited to this technique.

Chemical Methods

The typical chemical methods using titrimetry and gravimetric procedures are always appropriate for quantitative pigment determinations. Some of these techniques have been replaced in recent years by more efficient (not necessarily more accurate) and time saving instrumental methods; however, there are situations where the traditional testing methods are still most appropriate.

Numerous ASTM methods exist for these types of analysis, and one needs to check the index of available test methods. By way of example, the following are noted:

ASTM Test Methods for Chemical Analysis of White Titanium Pigments (D 1394)

ASTM Test Method for Arsenic in Paint (D 2348)

Additive Identification

Additives can often be the most difficult components to analyze and identify in a coating. They frequently are present in small quantities (often at a few percent or less), and their presence can be masked by major components. In addition, the number of possible additives is large and includes surfactants, plasticizers, defoamers, thickeners, anti-oxidants, etc. It takes a skilled and experienced coatings analyst plus good deductive problem-solving ability to become adept at additive analysis. The volatile nature of some co-solvents, coalescing agents, and some plasticizers makes their identification by gas chromatography fairly straightforward.

Infrared Spectroscopy

For samples containing mixtures, the IR spectrum generally gives information only about the major component(s). However, computerized infrared instrumentation allows one to subtract spectra of the major constituents from a mixture and get the resultant spectrum of minor materials such as additives and contaminants. Thus, it is possible to do a spectral "separation" in just a few seconds rather than a true chemical separation which may take hours. Water and hexane extractions of dried films followed by IR can point to some of the following, for example:

- Cellulosic thickener (which can be confirmed by spot test).
- Long chain aliphatic hydrocarbon "oil" is indicative of defoamers.
- Carboxylate containing component may indicate a polyacrylate salt.
- Nitrile component may indicate mildewcide.
- Di-alkyl sodium sulfosuccinate is indicative of a wetting agent
- Inorganic sulfate may be a possible persulfate polymerization catalyst.

High Performance Liquid Chromatography

High Performance Liquid Chromatography is frequently referred to as HPLC or just often as LC. This technique is used to separate components from mixtures, especially nonvolatile components which are not amenable to GC analysis. Since these nonvolatile components represent about 90% of all organic compounds, HPLC separation techniques offer extraordinary versatility and capability. Components may be separated either by size or subtle differences in molecular configuration and solubility. Separations based on size are commonly called gel permeation chromatography (GPC) or size exclusion chromatography (SEC). Separations based on subtle differences in molecular configurations and solubility are called partition chromatography. Both quantitative and qualitative information can be obtained by using HPLC techniques.

Samples to be analyzed by HPLC are dissolved using an appropriate solvent or a combination of solvents before they are introduced into the liquid chromatograph. Samples which are not soluble in HPLC solvent(s) are not suitable for analysis using this technique. The actual separation process takes place on a packed column or a series of packed columns through which solvent is constantly pumped. The separated components elute from the column(s) directly into a detector. The detector is connected to a recording device which produces a trace of the separated components versus time, i.e., a chromatogram.

The two most common detectors in HPLC are the differential refractometer and the ultraviolet (UV) spectrometer. The refractometer measures the difference in refractive index of the solvent and the component being analyzed. The ultraviolet spectrometer measures a compound's absorbance at various wavelengths in the ultraviolet (or sometimes visible) region of the light spectrum. The refractive index detector is most commonly used with size separations, while the ultraviolet detector is usually used in conjunction with partition chromatography. The ultraviolet detector is capable of detecting components in the part-per-million (ppm) range. The refractive index detector, on the other hand, can only detect components down to the 2 to 4% range. It is referred to as a universal detector because it is not dependent on the sample components absorbing at a particular wavelength of light.

Typical applications include: surfactant evaluation, polymer characterization, additives in polymers, air and water pollution, raw material evaluation, multi-functional acrylates, plasticizers, coalescents, and cross-linking agents.

Ultraviolet and Visible Spectroscopy

Ultraviolet and visible spectroscopy (UV-VIS) examines the absorption of UV and visible wavelengths of light by a sample. This type of analysis is often used as a quantitative measure of a material. Materials which possess aromatic rings such as polystyrene, alkyd resins, and many paint additives will absorb UV light and can be examined. Materials which absorb in the visible region of the spectrum are those which possess color. Chemicals such as dyes can be examined in that region. UV-VIS is very sensitive for the species that absorb in these regions, and concentrations in the low parts-per-million range can usually be determined.

The visible region of the spectrum consists of wavelengths seen through the eye. In a visible instrument, a tungsten

filament light is used as a source of visible wavelengths. Wavelengths are separated by a grating and examined one at a time. A photocell detector is used to measure absorbance at each wavelength and a spectrum is recorded.

Ultraviolet wavelengths are shorter than visible wavelengths and occupy the region above the blue end of the visible spectrum. To observe ultraviolet absorbencies, a mercury lamp is used as a source of UV light. Wavelengths are separated by a grating and detected, again by a photocell. An ultraviolet spectrum looks similar to a visible spectrum. Modern instruments combine UV and visible detection, and as the spectrum is being scanned the instrument will automatically switch from one source to another. Observed absorbencies are directly proportional to concentration of the component of interest.

Materials which do not absorb in the UV or visible region can sometimes be measured by complexing them with an absorbing reagent, usually to develop a colored species. Very sensitive methods of this type are used for the determination of formaldehyde, phosphorous, and sulfate.

Solvent Identification

Gas Chromatography

Gas Chromatography (GC) is a technique for the separation of any species exhibiting a measurable vapor pressure at a temperature up to approximately 300°C, as well as any compounds for which a stable, volatile derivative may be formed. Both qualitative and quantitative information can be obtained.

Most GC samples are liquids or solutions at room temperature, although instrumentation may be adapted to analyze solid and gaseous samples. Liquid samples (approximately 0.001 mL) are introduced to the instrument using a syringe into a flash heating chamber called an injection port. There, the volatile sample components are quickly and evenly vaporized. In some cases, however, decomposition of sensitive components can occur when they come in contact with the hot metal surface. The analytical chemist may be able to minimize or circumvent this problem if proper precautions are taken. The vaporized components are then carried onto the column and through the gas chromatographic system using an inert gas, such as helium or nitrogen, flowing at a constant rate.

The column is the portion of the chromatograph where the actual separation of components is achieved. A packed column consists of narrow tubing made from stainless steel, nickel alloy, glass, or a number of other materials, filled with fine particles of a packing material. This packing material may consist of polymeric beads or an inert solid material supporting a thin film of a non-volatile liquid. It is the varying degree of interaction between each of the sample components with the packing material that causes the components to become separated in the column. A large number of packing materials of varying chemical composition are available. Columns containing other packing materials are easily interchanged so that different separations can be obtained.

Occasionally, samples will contain a number of components of similar volatility and/or chemical composition which are difficult to separate on packed columns. In these instances, capillary columns are used. Capillary columns are extremely long (100 to 300 ft, 30.48 to 91.44 m), narrow bore tubes made from glass, metals, or fused silica. They are internally coated with a thin film of a nonvolatile liquid to effect separation. A variety of detectors used alone or in combination can be strategically mounted at the end of the column to monitor the separated components as they exit the column. The detectors available in GC have varying sensitivity and specificity. If needed, some may be operated to detect materials in the sub parts-per-million level.

The response of the detector to an eluting component is electronically converted into a visual representation called a chromatogram. A chromatogram is a plot of detector response versus time elapsed since sample injection. Eluting components are represented as peaks in the chromatogram. The time needed for a component (peak) to elute can be used to help identify the component. The area produced under the peak is related to the concentration and is used in the quantitative determination of the component.

Typical applications include: qualitative and quantitative solvent analysis, odor analysis, pollution studies, purity determinations, determinations of residual monomers, and determination of airborne organic contaminants.

Additional information on gas chromatography may be obtained from ASTM Practice for Packed Column Gas Chromatography (E 260). ASTM Test Method for Direct Injection of Solvent- Reducible Paints into a Gas Chromatograph for Solvent Analysis (D 3271) describes the techniques used in many situations. Note should also be made of ASTM Test Method for Determination of Dichloromethane and 1,1,1-Trichloroethane in Paints and Coatings by Direct Injection into a Gas Chromatograph (D 4457) for exempt solvent analysis for VOC calculation purposes. ASTM Committee E19 on Chromatography is focused on chromatographic techniques. There are numerous ASTM gas chromatographic test methods for the determination of the purity of specific solvents and for the determination of specific impurities such as benzene.

Gas Chromatography—Mass Spectrometry

Gas chromatography has been well established as an excellent tool for the separation of volatile species in complex mixtures. A significant limitation of gas chromatography, however, is the relative inefficiency and lack of certainty in this technique when the identification of unknown components is required. Mass spectrometry is an excellent tool for qualitative analysis. However, if a complex mixture is introduced into the instrument, the resulting mass spectra of all components are superimposed on one another, making analysis difficult, if not impossible. These limitations are overcome by a combination of gas chromatography and mass spectrometry. Sample constituents are separated into pure components using the gas chromatograph; these pure components are then introduced into the ion source of the mass spectrometer for identification. Generally, samples are liquids; however, gases and solids can also be examined.

As the sample components enter the mass spectrometer, they are immediately ionized. Electrons are removed from the sample molecules resulting in the formation of positively charged ions. This is normally accomplished through electron impact or chemical ionization. Each of these ionization

techniques has unique properties for providing useful analytical information.

Electron impact ionization occurs when electrons emitted from a hot filament collide with sample molecules causing the loss of one or more electrons. This results in the formation of positive ions which contain excess energy. The excess energy causes many of the resulting ions to break apart or fragment, thus providing the fragmentation patterns used to determine chemical structure.

In chemical ionization, the mass spectrometer's ionization source is pressurized with a reagent gas such as methane, ammonia, or butane. Electrons from the filament collide with, and impart energy to, the reagent gas. The energetic reagent gas molecules subsequently collide with the sample molecules causing the sample molecules to become positively charged. Ions formed in this manner do not contain as much excess energy as ions formed via electron impact ionization. Consequently, very little fragmentation occurs and intact ions containing molecular weight information are obtained.

Following ionization, the sample and fragment ions are sorted according to their respective masses. Ion intensities at each mass are measured by an appropriate detector, and the corresponding signals are transmitted to a computer for further processing and data storage. Results can then be displayed in graphical or tabular form. Interpretation of the spectra and comparison with a library containing thousands of reference compounds allows sample composition to be determined by the analyst.

Typical problems examined using GC-MS include: the qualitative identification of volatile organic species and contaminants in coatings and coatings raw materials, quantitative analysis of volatiles at the parts-per-million and parts-per-billion level, evaluation of potential odor causing species, and determination of polymer composition following pyrolysis and chemical degradation. Other uses include: characterization of complex solvent systems; monitoring of waste streams and ground waters; characterization of polymer products, by-products, and intermediates; identification of odor problems; and monitoring of raw materials for potential contamination.

TRACE ANALYSIS

With the development of sophisticated instrumentation over the past two decades, the ability to increase sensitivity in lower detection limits for many materials has increased. This is particularly true in the areas of metals analysis. As a result, many regulatory and compliance agencies have changed their detection limits to reflect this increased capability. For EPA (Environmental Protection Agency), OSHA (Occupational Safety and Health Administration), and FDA (Food and Drug Administration) compliance, trace analysis is extremely important. Many manufacturers require trace analysis to identify contamination, to verify product purity, and so forth. Analysts must be prepared to provide data in the parts per billion (ppb) and sub ppb range when necessary, and this frequently involves good concentration techniques as well as good methodology and instrumentation.

Certainly techniques such as GC, MS, and HPLC are capable of measuring components in solution well below the ppm range. The specificity of mass spectrometry and its sensitivity for organic compounds has made it a common tool used in EPA protocols for pollutant-related analysis. Coupled techniques such as GC-MS, LS-MS, and ICAP-MS are also available today and can provide very low-level analysis. Commonly used trace element procedures such as AA, ICAP, ion selective electrode analysis, neutron activation analysis, and optical emission spectroscopy all offer low-level analysis. ICP-MS detection capabilities are comparable to those of graphite furnace atomic absorption spectrometry. For many elements ICP-MS provides quantitative analyses down to the parts per trillion level.

In addition, for inorganic compounds, scanning electron, microprobe, and transmission electron microscopy are useful for trace analysis. Surface techniques such as X-ray photoelectron, Auger, and SIMS are also useful as qualitative and quantitative measurement techniques.

At the very small concentrations that characterize trace and ultratrace analysis, and with the minute samples employed in microanalysis, the limit of detection, a new criterion of performance, becomes important. Because noise itself now becomes limiting, many questions arise. For example, how large must the reading from a sample be compared with that from a blank for a person to report that analyte is present?

At the detection limit, statistics and chemistry become intimately mixed and statistical procedures must be used to interpret chemical results. The detection limit is simply the smallest concentration of analyte that can be certified as statistically different from a blank. To determine the limit, two sets of measurements are necessary. In addition to a regular set, many measurements (10 to 20 are recommended) must be made on a blank under the same conditions. It must simulate regular samples but be without analyte.

To calculate the limit of detection, one begins by observing the limiting response. For a given measurement procedure, it is the smallest response that can indicate with reasonable probability that a particular analyte is present. To obtain the limit of detection from the limiting response requires a calibration curve or a standard addition curve. A usable curve will be one based on quite pure standard solutions of extremely low concentration. The alternative, a long extrapolation of a calibration curve beyond the lowest points for standards even in those favorable cases in which the curve is linear, will invite substantial error.

Actually, as quantitative measurements at the trace level have become more important than simple detection, a limit of quantification or *limit of determination* is recommended by IUPAC for comparison of the relative merits of different trace methods rather than the limit of detection.

The future of analysis will become more sophisticated with the development of more sensitive instrumentation and computer technology. Robotics and autosampling will also enhance the development of analysis and reduce the amount of error that is introduced in analysis. These changes tend to impose more sophisticated demands in analysis from customers and regulatory agencies. There is a tremendous burden on the analyst to be conscious of extraordinarily good laboratory techniques, the limitations of the instrumentation, and the reporting of sound data.

The Analysis of Coatings Failures

by George D. Mills[1]

THE TESTING OF COATINGS always has a relationship to coating failures, either directly or indirectly. Testing before failure helps to ascertain serviceability, establish the best formulation variables, maintain quality assurance of coating products during manufacture, develop storage and application parameters, ensure specification viability, and, in essence, prevent early failure. Testing after failure assists in determining cause, hopefully prevents future coating failures of a similar nature, and aids in placing liability.

Failure modes run the full gamut. Coating failure can originate from within, as with deficiencies in a coating's formulation or its manufacturer. Anomalies in the coating's film-forming chemistry from competing atmospheric side reactions are very common with some urethanes and epoxides. Failures can originate external to the coating material from improper specification, inappropriate or inadequate surface preparation, and application deficiencies.

The analysis of coating failures should follow a systematic program based on the "scientific method." Briefly this translates to: (1) investigate; (2) hypothesize; (3) test; and (4) conclude or reconsider. Test programs after failure are often a part of the failure analysis process and have the purpose of establishing viability of a proposed failure mechanism. Designing the test and evaluation program requires a knowledge of the total process from specification to paint manufacturing to paint application. In part, it requires a knowledge of the laws of physics and chemistry that are controlling what is happening at interfaces. The coating system contains many types of interfaces including the substrate/coating interface, emulsion resin particle/carrier surfaces, intercoat interfaces, and the interfaces between the pigments and binder in the coating formulation. The chemistry and physics of solutions controls apparent viscosity and can impact osmotic failure modes. Polymer curing and weathering reactions, corrosion, and dimensional stability are just a few of the other sources of coating failures often reported. As a preliminary to designing test programs to determine failure modes, the investigator must appreciate not only the processes of surface preparations, cleaning, and pretreatments, but coating application techniques as well. He must be knowledgeable about the different types of coatings and their typical degradation and stabilization mechanisms.

Coating failures may manifest themselves as a change in physical or chemical properties. Changes in gloss, color, extensibility, chemical resistance, and vapor/gas transmission coefficients are common problems. Failures associated with delamination of a coating from its substrate are usually classed as "adhesion" failures, although they are often a delamination through a weak boundary layer (WBL) near the interface. Osmotic activity from solvents or coating constituents within the film and salts beneath are common failure modes in some environments. Underfilm corrosion is often considered as a coating failure and may result in substrate damage.

Coating failure analysis is extremely important for various reasons. The most important is simply to "ensure" that the failure doesn't happen again. While this sounds noble, the experience of most investigators is to the contrary, for one sees the same problems occur repeatedly. Paints and coatings are very sophisticated chemical systems. Since all of the natural forces impacting the chemistry and physics of the system are operative, the total picture is seldom known. Most often, a very naive conception of the situation is developed and action is taken for one particular reason while failing to consider a multitude of other less familiar causations.

Truly successful investigations of coating failures necessitate knowledge of the coating system's chemistry and the many applicable evaluation and test procedures available. To appreciate which test regime would be appropriate for a specific failure situation, the investigator must understand much about the coating itself. This includes knowledge of the components of the coating, its curing chemistry, the chemistry and physics of its interfaces, and any interfering and competing atmospheric side reactions. Application equipment and procedures, with a host of related potential problems such as off-ratio mixing, use of thinners that are nonsolvents or contaminated with water from storage outside, as well as potential paint manufacturing problems are additional typical sources of coating failure problems.

Designing the proper test regime before a coating failure occurs is very important. It is difficult, if not impossible, to assess all of the variables that will be seen in the field after the coating is applied. Reconstruction of a failure situation is even more difficult, and it is usually impossible to match the original application situation totally. This is particularly true in off-ratio mixing problems. Advanced instrumental techniques using cryotrapping of pyrolized polymer fragments followed by gas chromatography using a mass spectrometer as a detector have proven extremely helpful [*1*].

The design of a test program to demonstrate feasibility of a particular failure mode is best accomplished by considering five basic questions. These questions guide the investigator

[1]President, George Mills and Associates International, Inc., P.O. Box 847, Humble, TX 77347.

Copyright© 1995 by ASTM International

through the logic that aides one in understanding the potential failure modes. These questions are as follows:

1. What is the actual coating failure?
2. What is the coating system?
3. What was the desired purpose of the coating?
4. How was the coating applied?
5. What evidence is presented by the failure?

WHAT IS THE ACTUAL COATING FAILURE?

A coating failure exists when a coating fails to accomplish all of its intended tasks during its engineered design life (EDL). Usually, a failure in a particular primary property prompts the investigation. The first step in analyzing a failure is to clearly define the problem. While this appears at first glance to be an easy and straightforward task, it is not. A typical example is the mistake of identifying a delaminated coating automatically as lost adhesion. Adhesion, by definition, is between two dissimilar surfaces. In contrast, cohesion is between two of the same surfaces. There can be numerous reasons for a coating to break away from its substrate. While adhesive loss is possible, cohesive delamination within a weak boundary layer is very common. A good example is a coating applied over improperly prepared zinc galvanizing where cohesive failure occurs in the zinc oxide-zinc carbonate layer and is automatically written off as a saponification problem, even though the coating may not be susceptible to (or capable of) saponification. Another very common cohesive failure is the apparent delamination of an amine-cured epoxy applied over an amine carbonate that has formed on (or exuded from) an earlier applied epoxy coating. This cannot usually be seen with the unaided eye. Splitting within a "transparent" layer near the interface will appear as if the problem is adhesive rather than cohesive failure. Interrogation of the coating interfaces by the proper instrumental technique is the only way to determine the locus of failure.

Many tests associated with coatings may be brought to bear in providing answers. While most of these tests are established ASTM procedures, some are related to task-specific, chemical analysis. These include auger spectroscopy, X-ray photoelectron spectroscopy (XPS), and other surface analysis techniques that are limited to "seeing" only the outer few angstroms of the surface. Ion bombardment, which ablates the surface, allows "seeing" an elemental analysis as a function of depth into the outer layer. Techniques such as energy dispersive X-ray (EDX) will evaluate the surface but are much more energetic, thus giving an average elemental analysis much deeper into the sample being evaluated [*7*].

Osmotic blister formation is another area often misunderstood. Osmosis requires one solvent (by definition, the specie present in the greatest concentration) and one or more solutes. Analysis of the blister fluid is required to determine the source of the driving force. While water is often the source of solvent with inorganic salts or organic solutes, other organic products are seen as the norm in some industrial tank-lining problems. Analysis of the blister fluid is best accomplished by GC/MS for organic solutes [*1*] and ion chromatography or EDX (after evaporation) for inorganic solutes [*7*]. To the contrary, "blister-like" formations in inorganic zinc-rich or flame-sprayed metallic coatings may look like osmotic blisters, but they are usually caused by the production of powdered corrosion products under or within the film [*2*]. It is safe to say that the problem cannot be solved and proper liability placed until the true coating failure problem has been identified.

WHAT IS THE COATING SYSTEM?

Failures are often related to the generic type of coating under investigation. As such, the failed coating should be identified as a preliminary step in understanding the potential failure modes that exist leading to the failure. Alkyds have failure modes different from acrylic latex systems. Epoxides will often fail differently from urethanes. Alkyds over vinyl primers are susceptible to water vapor transmission problems. Moisture-cured systems such as urethanes, epoxies, and ethyl silicate zinc-rich systems when applied in very dry atmospheres cannot cure properly. Urethanes and some latex systems present problems in wet atmospheres.

Although a coating is any material applied to another surface, each coatings practitioner will have a view of coating systems shaped by his/her experiences. While most coatings are paint-like in nature, many have strikingly different appearances and characteristics with correspondingly different failure modes and different required test regimes. The coatings manager at an automobile factory might work with inorganic metal pretreatments, electro-deposited primers, and robotically applied color coats with wet-on-wet UV-resistant clear topcoats followed by water-repellant surface modifications. The pipe corrosion specialists will encounter conventional liquid paints, fused powders, flame/arc-sprayed metallic powders such as zinc, aluminum, or high alloys, and plastic tapes wrapped around the pipe with or without primers for external protection. Internal pipe coatings may be the conventional liquid and powdered coatings as well as thin cement linings like those found in many potable water supply lines or fused polyethylene mixtures. Because of this great diversity, the coatings analyst will address coating failures of many generic types of films including organic, inorganic, and metallic.

Paints form the largest subgroup of coatings and, as such, will be the focus of this section. Analyzing coating systems before and after failure requires many different testing procedures. Many of these standardized procedures can be found in Volume 6.01 through 6.04 of the *Annual Book of ASTM Standards* [*3*]. To be efficient, the investigator must have knowledge of the paint formulations of many generic types. Knowledge of the polymer's typical failure mechanisms, individual polymer chemistries with their respective degradation mechanisms, and typical stabilization methods are also very helpful [*4*]. An efficient investigation requires an appreciation of the tools and instrumentation that can be brought to bear and is tremendously important in determining the testing regime best suited to a particular type of failure problem. This includes knowledge of the capabilities and limitations of the analytical instruments being used as well as the ability to interpret and challenge test data when necessary.

Typically, a paint may be considered as being composed of four "subsystems," any one of which may produce a coating failure. These are: (1) the resin or binder system; (2) the

pigment system; (3) the solvent or carrier system; and (4) the additives package. The resin or binder system holds the pigments together and provides physical characteristics such as electrical resistance, flexibility, water and gas permeability resistance, adhesion, etc. The pigment system serves to provide coating strength, vapor transmission resistance, anticorrosive properties at a metal interface, abrasion resistance, and other film property enhancements. For less than 100% solids systems, the carrier system is usually a solvent or dispersing media. For 100% solids liquid coatings, the dispersing media may be air or the pressure from an airless application system. For powder coatings, super dry air is the delivery system, transporting the fluidized powder through the delivery lines. The additive package is meant to produce specific effects to the coating system when included in low concentrations. Additives may address potential problems with the preapplied paint "in the can" or address potential film problems after application. Coating failures may originate from problems associated with quality control of the paint's manufacture as well as problems associated with long-term storage or application. Each type of coating will have some characteristic failure modes, although certain modes will be common to all.

Failure Modes Associated with a Generic Type of Coating

Failure modes tend to follow generic types of coatings. In a very broad sense, coatings may be grouped into three categories based on the final film. These are coatings with organic binders, those with inorganic binders, and those composed of metallic films. The largest category of coatings are those utilizing an organic binder. Organic binders use polymers based on carbon as the primary atomic makeup of their backbone. The paint film at application includes polymer precursors using functional groups such as epoxies, urethanes, vinyls, acrylics, and alkyds. These must polymerize to reach some high molecular weight at which they are capable of forming protective films. Generally, inorganic coatings are those that utilize elements other than carbon for forming a film. These may be silicates, sulfates, or cementitious coatings based on calcium. As a coating, each will have some typical failure modes. Metallics may be very thin films used on plastics for affecting gas molecule transmission and abrasion characteristics. They may be thick as from galvanizing or flame/arc-sprayed metallics used for corrosion protection.

Organic Resin Binders: Polymers Based on Carbon

Paints and coatings using organic binders are by far the largest category and will provide the greatest challenge to the failure analysis investigator. These will include binders derived from vegetable oils, petroleum, and cellulose. They can be separated further into groups based on their curing functionality or their polymer origination such as epoxies, urethanes, alkyds, acrylics, or vinyls. They may also be classed by their dispersion system such as solvent, emulsion, powder, waterborne, or 100% solids.

Organic resin binders will utilize some mechanism for producing the protective film. This film forming/curing mechanism is a potential source of failures. A failure may manifest itself as a film with poor flexibility, weatherability, chemical resistance, adhesion deficiency, or a host of other shortcomings.

The formation of a paint film may come about by various mechanisms, each having distinctive failure modes. Some typical examples include: (1) lacquers; (2) oxidative binders requiring oxygen from the atmosphere; (3) moisture-cured binders; (4) chemically reactive cross-linking binders; (5) heat-activated binders; and (6) nonthermal, high-energy cured binders.

Lacquers are coatings containing polymers dissolved in a suitable solvent system that evaporates to yield a film. While these coatings are called "lacquers" in the United States, in Europe and other parts of the world, the word "lacquer" is often used interchangeably with the word "paint." Film testing may address sanding characteristics, abrasion resistance, drying times, gas or water vapor permeability, gloss, and color retention, among other film properties. With essentially no chemical cross-linking occurring, the solids deposited on each coat will be determined by the maximum lacquer viscosity that allows application. Since this is related to the polymer's average molecular weight, which must be high for toughness and strength, films of low dry film thickness (DFT) are often seen, and the applied solids will be low. Lacquer film properties are strongly impacted by the solvent system, humidity and other ambient conditions, the application methodology used, and many other factors.

Common failure modes encountered are often associated with thin films and the water susceptibility of the "tailing solvents" used in the formulation, occluded water caused by the use of active solvents producing fogging and cloudiness at application, and others. In acid-modified solution-vinyl systems, reaction with basic pigments will cause viscosity increases and possibly gelation in the can. Other problem areas leading to failures include the "strength" of the solvent system, temperature of the coating solution at application, interaction of solute binder polymer with certain pigment particles, and interaction of some pigment particles with other pigment particles.

Typical failure modes for lacquers include production of cloudiness during application (blushing), use of improper (nonsolvent) thinner, "fisheyes" (a surface tension problem), lifting of solvent-sensitive undercoats, and delamination from overcoating sanding sealers containing excessive sterates, among others. Coating softness is often related to the inclusion of nonsolvents entrapped in the film if their evaporation or migration rate is less than the true solvents for the coating system. To address this problem, the coating formulation will often have a small "tailing" of slow-evaporating true solvent to allow the escape of these nonsolvent diluents.

Because of the large amounts of solvents required and the typically low solids content, this type of coating system is not considered to be environmentally friendly. As such, lacquers are not as popular as they were in the past. Most states have enacted laws that control the maximum value of the volatile organic content (VOC) of the paints, and this has greatly limited their use.

Oxidative binders are polymers that usually require the pressure of atmospheric oxygen to cross-link sufficiently to form a strong film. Paints based on unsaturated vegetable oils such as linseed, soya, tung, tall oil, and others as well as modified vegetable oils, such as alkyds, fall into this category.

These coatings require metal catalysts called dryers to be included in the formulation. These dryers assist in the curing mechanism by increasing the coating's ability to react with atmospheric oxygen. A common failure mode for some alkyd coatings containing organic pigment would be a slow or nondrying paint after application. This occurs when dryers are either left out at manufacture or prematurely bound. In-can aging will allow adsorption onto the organic pigment particles, causing a loss of activity before application. Some carbon blacks are particularly susceptible.

Increased viscosity within the can is often caused by reaction with the oxygen contained in the air space above the coating. Frequently, with highly reactive oxidative binders, a small amount of inert gas may be placed in the head space of the can prior to shipping. Skinning and gelling are problems frequently encountered with this type of system. Retardation is controlled by the use of additives such as volatile ketimines. These volatile inhibitors interfere with the cross-linking mechanism, thus extending the life of the coating material after the can has been opened. Often, upon reopening a can of an oxidative type of coating, one will notice that a vacuum has developed. This is due to the reaction with (and consumption of) the oxygen that was in the air in the head space of the can.

Moisture-cured binders constitute a class of organic polymeric materials that require water vapor from the air to cause polymerization. While the most common of these are the moisture-cured urethanes, epoxies cross-linked by ketimines form another important class of moisture-cured coatings. Inorganic silanol binders, found in many zinc-rich systems, must have water to complete the hydrolyzation required in forming the cured inorganic silicate binder. Typical failure modes include application of the coating in conditions providing insufficient moisture to complete the cure. Application to surfaces that are damp or excessively wet can create bubble formation in urethanes. Overcoating inorganic zincs before complete hydrolyzation interferes with curing by stopping the reaction with moisture. This produces a zinc-rich primer layer with low tensile strength. Such films will often fail by cohesive failure within the inorganic layer, especially after application of an epoxy that shrinks slightly on curing.

Failures associated with thinners that contain water as a contaminant present a different kind of problem. For urethane coatings, inclusion of excessive water in the coating matrix will generate gas bubbles of carbon dioxide caused by reaction with the isocyanate groups. In a worst case, the applied coating will be rough with bubbles through the film. In slight contamination cases, this will be evidenced by viewing a chip of the coating from the side through a microscope. Small bubbles will be seen through the coating thickness. When the bubbles are mostly located at or near the interface, there is probable cause to suspect application over a damp surface. Water picked up on the pigmented side of a two-part urethane during the pigment-grinding process during manufacture is a common problem. Water analysis of the polyol side may reveal the source of the problem.

Water contamination introduced into an ethyl silicate binder can cause premature gelation and shortening of the pot life. Water pickup in zinc and aluminum-metal-containing coatings often produces gas of sufficient pressure to explode the container.

Chemically reactive cross-linking binders include all two-part systems. This includes epoxies and urethanes that have appreciable reaction rates at room temperature as well as single-package, cross-linking systems that require heating or some other energy source to increase the reaction rate significantly and allow a cure to be attained. Some systems will contain all the reactive polymeric binder precursors that cross-link with each other to produce the final film. Some systems may generate the required energetic cross-linking specie by a reaction brought about by an outside energy source such as ultraviolet (UV) radiation, electrodeposition, or high-energy electron beams.

Ambient-cure, two-component, or catalyzed binders such as epoxies and urethanes require a proper mixing ratio to allow the finished film to have its desired properties. Improper ratio mixing can lead to a host of final film problems. These problems include inadequate curing, brittleness, loss of extensibility, loss of chemical resistance, early extensive chalking, and many more. Off-ratio coating systems may be investigated using GC/MS pyrolysis [*1*].

Epoxies are often cured by amine functional polyamides, amine adducts, or aliphatic amines. Polyamides, being manufactured from long-chain fatty acids, are very aliphatic in nature and, typically, not particularly soluble in the epoxy side. Because of this poor solubility, it is often necessary to allow extra time after mixing for the reaction products to gain solubility characteristics more closely related to each other. This extra time is called the "induction period" or "sweat-in time" and allows time for the two resins to partially co-react. The partially reacted resin solution eventually changes the solubility characteristics of the binder system sufficiently to completely solubilize all resin components. A failure to reach complete solubility will lead to "zone curing" with macro islands of unreacted polyamide and potentially unreacted epoxy resin. Additional failure modes include osmotic blister formation (where the low molecular weight amine is the solute, with condensed water being the solvent), increased amine carbonate formation and exudation to create intercoat delamination problems, film brittleness, poor weatherability, and others.

Application of amine and polyamide systems in cold weather can present future delamination problems. In cold weather, when the epoxy-amine reaction slows down, the amine reaction with carbon dioxide and water vapor from air does not slow very much. The formation of an amine carbonate "bloom" develops on the coating surface. Additional amine carbonate within the coating matrix formed during spray application exudes to the surface. This leaves a weak boundary layer on the surface. When overcoated, the insoluble "greasy" amine carbonate will not allow adhesion of the next coat and usually results in delamination in less than a year. The interface will be moisture sensitive and potentially provide the solute for osmotic blister formation. The author has found a simple test to evaluate for the presence of the amine carbonates. This is done by applying a drop of 6 *M* hydrochloric acid to a suspected surface while watching the edge of the drop under a microscope. The HCl will liberate the carbon dioxide at the edge of the "wetting front" as the droplet wets the surfaces. The bubbles of gas can be seen in

the edge of the drop of liquid. The experiment should be conducted under a microscope since the reaction is rather fast and because often only a small amount of gas is liberated. The gas may present itself as a tiny bubble within the drop of acid solution. To test the amine side of the curing agent for carbonate salts, add about 1 mL of the resin component to a test tube. Tilt the test tube at about 45°, add a drop of the 6 *N* HCl, allowing it to run down the inside of the tilted tube, and note the production of any foaming carbon dioxide at the acid solution/resin interface. The amount of foam produced is a quantitative indication of the amount of carbonate existing. Grinding pigment into the amine side, in open tanks, often introduces the carbonate.

Heat-activated binders have a cross-linking reaction rate that is too slow at room temperature to allow complete cure. These systems require heating to provide a forced cure. This is true for liquid systems as well as for most thermoset powder coating systems. Typical failure modes include abnormal brittleness, discoloration, lack of design physical properties, lower chemical resistance, and other problems. Causes may stem from formulation problems such as batch-to-batch variation in catalyst level or incorporation, as well as problems associated with variable temperatures within the pass-through ovens or heating equipment. Low temperatures caused by variations in metal heat capacity due to variations in metal mass of a coated part are seen often in powder coating systems as producing curing anomalies. Since the cured coatings will typically have elevated glass transition temperatures, T_g, the differential scanning calorimeter (DSC) is the instrument of choice in determining quality of cure [*8*].

Nonthermal, high-energy-cured binders require an energy source other than heat. These coating systems are typically employed on fast-moving, automated industrial lines. The coatings include both ultraviolet radiation curing systems as well as electron and other high-energy beam curing. Because the energy source must be "felt" through the polymer layer, UV-cured systems must be fairly transparent to the energy source and preferably have little or no pigmentation. However, UV-curable colored inks and coatings are commercially available. This usually necessitates that the films be of low DFT.

Inorganic Binders—Those Based on Noncarbon Polymers

Inorganic coatings are those that do not rely on carbon as the primary atomic composition of the polymer. These include those systems that ultimately end up with an inorganic binder after application. The most common include zinc-rich systems using alkali silicates as the binder. Generally speaking, inorganic coatings are formed from the oxides of specific elements. The silicates are formed from the oxides of silicon. Cement coatings and linings for water pipes rely on the oxides of calcium or variations thereof. Some high-temperature coatings used in flue gas desulfurization stacks are based on calcium sulfate.

A different class of inorganic coatings are those that are chemically reacted onto a metal surface. These include the colored anodized coatings commonly seen on aluminum window and door frames, precipitated zinc and iron phosphate coatings used as anticorrosives on pretreated steel, and acid phosphate treatments to zinc and galvanized surfaces, among

others. Typical failure modes with these types of coatings will include underfilm corrosion and spalling of the coating, especially with cement that has become carbonized from reaction with carbon dioxide and, therefore, lacks the higher pH required to disallow corrosion of embedded steel. Corrosion testing methods such as given in ASTM B 117 (see Table 1) are used often to determine coating quality.

Precipitation-type coatings are usually done from a water solution. Because of this, the surfaces must be able to be wet-out by the water solutions. A typical problem is "splotchiness" caused by incomplete thermodynamic wetting of the substrate. This lack of wetting disallows water-based chemical reactions that must occur at the metal interface. The reason for a lack of wetting is usually from oil or other low-energy contaminants on the surface. Investigation of the precleaning system is indicated in these cases. Surfactants are usually added to overcome this problem, but these may then cause an even worse problem if they are not totally removed. One must remember that surfactants are called "surfactants" because of their ability to displace, usually thermodynamically, most adsorbed species on the surface of the substrate. When overcoating a substrate that has been wet with surfactant, these surfactants must be displaced. This can often be difficult or impossible and often leads to eventual delamination or water sensitivity. A short-term test frequently used is the Hot Water Boil Test. This is also called the "Crock Pot Test" since a standard kitchen electric crock pot has been found to work very well. Samples are cut from coated specimens that have been through the cleaning system. These are placed in the crock pot under deionized water for 24 h (or less, depending on type of coating), and the coating is evaluated against a standard of known cleanliness.

Metallic Coatings

Metallic coatings are very thin layers of pure metal, usually applied to a substrate for appearance, modification of ware characteristics, corrosion protection, or to disallow the transport of migrating gas molecules through plastic film. They are important because of their ability to modify physical properties of the substrate such as stopping the migration of oxygen, carbon dioxide, and other small molecules through plastics. An example most are familiar with is the shiny metallized coatings seen on food wrappers containing oxidizable vegetable oils. It is usually assumed that these shiny packages are for "aesthetics only," however these thin metallized films serve to stop the migration of oxygen into the food package. With the trend to eat more unsaturated oils in our foods, the oxygen would react with the unsaturated bonds in the oils to produce a rancid taste. This is associated with the product being old and stale. The bad taste is due to the formation of aldehydes during the oxidation process.

Failure Modes Associated with the Pigment System, Carrier System, or Additive Package

Some common failure modes associated with the pigment system include: heavy settling; flocculation; lack of wet-out during manufacture; insufficient grind or dispersion development; adsorption of additives such as driers, UV stabilizers, and surface-active agents during storage; and poor color stability with some pigments. Improper use of the anatase titanium dioxide can lead to chalking. Accelerated ageing tests of the formulated coating usually include storage at elevated temperatures with intermediate observations of settling and grind measurements.

The carrier system assists the binder system in forming a film and in developing adhesion during application. For liquid coatings that are sprayed, rolled, brushed, flow coated, or dipped, the viscosity must be within certain limits dictated by the application equipment, final film build desired, and ambient conditions. Additionally, there must ultimately be intimate contact between the binder polymer and the substrate. While this may appear to occur automatically and instantaneously, it does not. Development of adhesion between binder polymer and the substrate is a time-dependent function. Thermodynamic wetting is controlled by the energetics in existence between the actual surface encountered on the substrate by the coating system. Thermodynamic wetting is a necessary, though not sufficient, condition for adhesion. Unfortunately, since adhesion development is a dynamic process requiring time for the many "molecular realignments and adjustments" to occur as well as the displacement of molecular species lightly bound to the substrate, high-solids coatings with little or no solvent have a formidable job before them. Displacement of surfactant-type molecules at the interface will usually present a severe challenge and frequently present delayed adhesion failures.

There are always adsorbed species on the surface. Depending on the "sticking" strength of the adsorbed surface species, the binder may not make intimate (molecular) contact with the substrate as its viscosity is increasing to a gel. Adsorbed species include such molecules as vapor-phase water, oxygen, and other gases from the air, oily contaminants, and surfactants from cutting oils or coolants. In thermodynamics, this sticking is related to the heat of wetting. Failure to displace these compounds often results in eventual adhesion problems. One of the roles of the solvent is to assist in wetting out the substrate by displacing the adsorbed species followed by deposition by the binder. The coatings formulator will design the solvent system to assist the polymeric binder in displacing any interfering adsorbed species. But, since desorption/adsorption is a time-dependent process, extremely fast solvents and viscous, high-solids systems may not be able to respond in the time during which the polymer system cures and approaches a gel state. Increases in viscosity after application also present additional problems. There must be sufficient time for adhesion to develop between the binder polymer and the substrate. In some instances, changes to the polymer backbone have been done to produce a more negative heat of wetting [5]. The use of additional mechanical energy as from brushing is always helpful. It is for this reason that brush striping of welds in tanks and critical areas is often required prior to spray application of the first coat.

Solvents are the most common of the paint system carriers. Typical problems encountered might include use of the wrong solvent, allowing water to contaminate proper thinners that have been stored outside, transfer of solvents to oily or contaminated containers, etc. Water, which has been drawn into a solvent container due to temperature changes, is a common work-site occurrence.

Air suspension of powders is an example of a nonliquid carrier system. Powder coatings are usually applied electro-

statically by fluidizing the powder with compressed air in a porous bottom chamber. The air-suspended particles are then drawn into an air stream via a venturi nozzle and transported to the point of application. Surfaces being powder coated may or may not be heated before application. With application to hot substrates, the powder melts and flows to produce a relatively thick coherent film. Depending on melt viscosity, flow characteristics, gel time, and thermal transfer characteristics of the melted polymer, air bubbles may be in evidence throughout the film. Due to the poor thermal transfer of the powder coating, the bubbles will be concentrated closer to the heat source, i.e., the substrate. These bubbles have not been a problem with fusion-bonded epoxy (FBE) pipe coatings other than to cause a decrease in lateral cohesive film strength. Failure modes common to powdered pipe coatings stem from the use of wet air, plugged ventures and spray nozzles, and irregular heating of the metal surfaces for various reasons. Long-term adhesion problems may develop when application to the steel surfaces occurs at too low temperatures. High steel temperatures favor enhanced thermodynamic wetting. Variations in adhesion often follow variations in steel surface temperature.

When powder coatings are applied to cold surfaces followed by heating through conveyor ovens, film build is usually limited to no more than 2 to 4 mils. Because of the short time allowed for flow and wet-out to occur, surfaces must be very clean and receptive to the applied coating. Typical failure modes are associated with surface pretreatments, poor adhesion over unclean surfaces, contamination with other noncompatible or off-color powders from the same application system, compatibility with specific surface pretreatments, "wet" air used as the carrier, as well as curing difficulties resulting from catalyst deactivation or poor incorporation during extrusion. Gel particles may result with some catalyst systems.

It is not practical to assume that the practitioner will have experience in all areas necessary to address the multitude of potential problems. Knowledge of application equipment, an in-depth chemical knowledge of the formulations and specific curing mechanisms and the physics of adhesion including the energetics controlling adsorbed molecular displacement, among other things, are required to thoroughly understand the potential problems one will encounter in the field. This should be developed through continued study, close observation, and by asking questions.

Tapes and extruded polyolefin thermoplastic coatings are popular pipe coatings. Sheeted rubbers find use on the risers of off-shore platforms and as acid tank linings. These will have specific failure modes. Rubber must be vulcanized in ovens after application to the tank wall or pipe. Failure modes usually will be associated with the improper cure of the polymer. This could stem from catalyst inactivation caused by the use of improper curing temperatures. Tapes of PVC with various types of adhesive binders are popular pipe coating materials. These may be applied in the cleanliness of a factory or as a "railhead operation" at the point of pipe construction or over the ditch. Extruded polyethylene and polypropylene pipe coatings are usually applied in a factory setting. Sheeted rubber coatings are frequently applied to the interior of carbon steel tanks that will see acid service. This is done both in the fabrication facility and in the field when it is possible to provide sufficient heat to cure the vulcanizable adhesives and coatings used. A common problem often encountered with these systems is the inadvertent inclusion of air bubbles or air pockets under the coating material. Bubble inclusion followed by eventual underfilm corrosion and perforation of the steel is a major failure mode for this type of coating.

Was the Specified Coating Material Used?

Often it is necessary to determine that the specified coating was used. Typically, Fourier transform infrared (FTIR) analysis of the binder is the analytical method of choice due to the widespread availability of the instrumentation. There is often considerable difficulty in gaining a positive identification of the coating due to interference from the pigments that produce an instrument response added to that of the polymer. The presence of silicates in paints is very common. A silicate peak often obliterates an informative section of the FTIR scan used to identify the polymer in question. Additional problems can stem from the specific technique used. The use of a "diamond anvil" attachment to a FTIR microscope has proven very beneficial in getting good polymer scans in the presence of interfering pigments but on rare occasions introduces some uncertainty when the binder is not totally homogeneous or well dispersed. An expected peak may appear to be missing. A good example is the presence of a crystalline, nonsoluble cross-linker containing the cyano functional group in a fusion-bonded epoxy powder coating that is not seen using the FTIR diamond anvil in microscopic transmission mode but that is seen using the typical FTIR attenuated total reflectance (ATR) mode of surface analysis. GC/MS techniques provide a definitive analytical technique for identifying the coating used years after an application [*1*].

Was the Coating Material Properly Formulated and Manufactured?

Determining the "as applied" quality of a coating years after application can be a difficult task in some respects. On the other hand, it is usually surprising to most that the solvents used in a coating typically remain in the applied coating material for many years. A good example is the trapping of alcohols in cured epoxy coating systems for years after application. Normal-butanol, a very common solvent used in epoxy-polyamides formulations, can be extracted three to five years after application. High-molecular-weight oxyalcohols and glycols are also present for long times and are often found as the solute in an osmotic coating failure. Gas chromatography using thermal extraction (TE) with liquid nitrogen "cryotrapping" before starting the GC run and a mass spectrometer (MS) for the detector (GC/MS) allows for a positive identification of trapped solvent molecules. The vapor transmission coefficient within the cured coating system dictates the rate of solvent loss after application. The technique is also very useful for identifying the generic type of coating used years after application by pyrolyzing a very small coating chip at a higher temperature. By doing this in a stream of helium and trapping the fragments with liquid nitrogen, an analysis of the fragments will allow one to identify the original polymer [*1*].

Quality in the manufacture of the coating products includes both the proper formulation for use in the environment intended as well as the eventual commercial manufacturer. There is usually a lengthy testing program required to evaluate the coating formulation before a product is commercialized. A few typical failures seen in the formulation and manufacture include systems formulated to contain low vapor pressure, water-soluble solvents in coatings to be used under water, formulation without required UV or thermal stabilizers for exterior coatings, gelation of acidic binders by reaction with basic pigments, loss of dryer catalysts from a oxidizable coating system, inclusion of carbon dioxide and water vapor into the amine side during the manufacturer of an adduct for a two-part catalyzed coating, and failure to exclude water contaminants during the manufacture of the nonisocyanate side of a urethane coating system.

WHAT WAS THE DESIRED PURPOSE OF THE COATING?

Before designing the test regime to evaluate a specification or starting the investigation of a failed coating, the analyst should ask why the coating was applied. Often it will be intuitive or would be stated in the specification. The design of the testing and evaluation program should include elements encompassing these objectives. Table 1 lists some of the ASTM standard test methods used to evaluate a coating's specific serviceability relative to a particular property. Table 2 lists some of ASTM's standard practices for accomplishing the objectives.

Coatings provide a renewable surface and allow the engineer to use materials that are more economical or provide a physical characteristic not attainable from the uncoated surface. While coatings frequently provide a variation in appearance, most coatings serve to protect more than to beautify. When the protection is not provided for the full design life of the coating, including the maintenance of all expected and desired protective properties, a coating failure has occurred. Frequently the coating will be evaluated for a particular service through a series of tests. These evaluation programs are designed to assist in predicting failure modes and to assist in the preparation of specifications. Problems often develop when the service does not match the initial testing program.

A major reason for applying coatings to many different types of substrates is to protect the substrate from deterioration. Coatings on steel, when applied properly, have the ability to stop corrosion in hostile environments for a period of time. Coatings applied to wood have the ability to prevent fungus growth and rotting, even in damp environments. Hard metallized coatings protect softer metals from wear. Highly active metallized coatings such as zinc and aluminum have the ability to prevent corrosion of steel in adverse conditions [2]. When coatings are applied to protect the substrate and the substrate sustains premature damage, a coating failure has occurred. Test regimes usually address the perceived problem. Sophisticated a-c impedance and d-c polarization techniques have the ability to measure actual corrosion currents and represent a very sensitive test method for metal substrates.

Coatings are often applied to the inside surfaces of pipes, tanks, plastic and paper food packages, food and beverage cans, and rail cars to protect the contents from contamination and/or spoilage. This contamination may originate from the metal container, which leads to discoloration of the product by allowing metal ions to enter. Contamination in the form of bacteria or degrading reactive gases are frequently a problem in food packaging. Tank coatings may fail by allowing components of the coating to migrate into the products carried within the tanks. Loss of coating components will then lead to coating shrinkage that will stress relieve in various ways leading to failures by cracking, increased osmotic activity, etc., depending on the products carried and the coating polymer fragments remaining. A coating failure that allows product contamination is usually very costly.

Coatings are frequently applied to enhance a substrate's appearance. Because of this, any undesired change in the coating's visual attributes will constitute a coating failure. This would include not only changes in color, gloss, and texture, but appearance failures due to growth of algae and mildew as well. Failure modes related to a loss in aesthetics are usually adverse reactions to the environment, often due to ultraviolet radiation or delamination of the coating.

Small molecules such as water and the acidic gases carbon dioxide, hydrogen sulfide, and sulfur dioxide have the ability to migrate through a polymer film. When this occurs, the possibility of corrosion of the substrate is great. Frequently, coatings are used to interfere with this process. The rate at which these small molecules can pass through a coating or polymer membrane is called the vapor transmission coefficient for that specie. Metal coatings applied to food wrappers inhibit or stop migration of oxygen, thereby maintaining freshness. A failure to prevent these molecular migrations in an amount based on the original design parameters constitutes a coating failure. Often this failure mode is closely related to cross-link density or changes in cross-link density after coating degradation.

Coatings are applied to stair treads and slick surfaces to provide nonslip characteristics. On the contrary, internal pipe coatings should be very smooth so as to provide decreased resistance to flow. This allows increased volumes of fluids with less pressure drop and lower power requirements for the pipeline. Many coatings provide abrasion resistance to a substrate, thereby increasing the substrate's life indefinitely since coatings are a renewable entity. Failure of the coating to accomplish any of these design goals constitutes a coating failure.

Coatings are frequently applied to metal substrates to modify electrical flow characteristics. Coatings are naturally dielectric, though conductive pigments and additives may decrease internal electrical resistance for special requirements. The electrical resistance becomes an important attribute in accomplishing a particular circuit requirement. A very good example are those coatings applied to metal surfaces that are placed under cathodic protection such as underground pipelines, metal bulkheads at a shoreline, ship bottoms, offshore underwater structures, as well as internal tank linings. ASTM G 8, G 42, and G 95 (see Table 1 and Ref *3*) are methods for evaluating the cathodic disbondment properties of coatings. Because of the generation of large concentrations of hydroxyl ion at coating defects, saponification of the coating or steel pretreatments can be a dominant failure mode with some coating systems.

Conductive coatings are used to dissipate electrical charge. These are found in laser printers and some copy machines. Conductive coatings are also applied to bags, plastic mats, and other articles used around electrical equipment sensitive to the discharge of static electricity. A failure to provide the desired low electrical resistance or conductivity over its planned lifetime constitutes a coating failure.

For materials that expand and contract extensively with changes in absorbed materials such as water and carbon dioxide, minimizing absorption will allow the substrate to remain dimensionally stable. Wood, when "dry," is about 10 to 15% water. Depending on the type of wood, absorption of water, especially through open-end grain, causes huge changes in the size of the piece of wood. Other characteristics such as flexibility, warping, and cracking are a common occurrence when wood coatings fail. The peeling of coatings on wood usually starts at some break in the film and slowly radiates from the site of moisture egress. As moisture enters the wood, it expands greatly and pulls the coating from the surface. As it dries out, the wood shrinks. This continual expansion and contraction is a major source of problems for wood coatings.

Paper products must be protected from moisture pickup to maintain strength and integrity. Paper cartons containing milk and other food products are usually protected by surface coatings of wax, polyethylene, or vinyl thermoplastics. Sizing or starch-type coatings are frequently applied to paper to provide a degree of stiffness.

While gloss is frequently considered an aesthetic property, coatings that have the ability to reflect or absorb specific wavelengths of light are functional coatings. Pigmented coatings engineered to reflect very little radiation are often applied to thermal adsorption devices such as solar heat exchangers. Coatings with adsorption efficiencies approaching 95% have been developed. Changes in reflection or adsorption characteristics over the coating's planned life span constitute a coating failure.

Coatings containing voids or small bubbles have the ability to adsorb mechanical wave energy such as sound. Changes with time in these adsorption or dampening abilities usually constitute a coating failure. Some of these unique physical properties are impacted by the adsorption of liquids such as water from condensation and may be the subject of test programs when evaluating this type of failure. Knowledge of the physics of wave energy transmission and point reflection through elastic media is necessary to design test programs evaluating these parameters.

HOW WAS THE COATING APPLIED?

Many coating failures can be traced to problems associated with the procedures surrounding the coating's application. For this reason, each step of the process must be considered. Getting a particular coating applied can be thought of as having been accomplished through a series of steps with multiple responsibilities. These broadly include the following:

1. Preparation and follow through of the specification.
2. Preparation of the surface/substrate.
3. Physical application techniques and equipment.
4. Third-party inspection.

The specification, type of coating being applied and its particular curing requirements, variations in ambient weather conditions, variations in the condition of the substrate, surface preparation techniques, pretreatments, equipment used during the application, the quality of third-party inspection as well as the applicator's knowledge and ability all play a major role in getting the coating properly applied.

Preparation and Follow Through of the Specification

The specification should serve as the "blue print" for getting the coating properly applied. Its existence implies that someone has surveyed the site to determine any abnormalities that might exist, evaluated the service requirements, reviewed the particular problems unique to the structure and service demands, identified a particular coating with the required service characteristics through prior testing, and provided an adequate application procedure that, theoretically, will meet the use requirements. The specification assists the applicator in knowing what is expected of him and serves as a legal document in times of dispute.

Frequently a coating will be specified by a specific manufacturer's product numbers. Failures in the specification, either in the type of recommended coating or the application procedures, can result in early failure. As such, the specification must be reviewed when investigating a coating failure. Coating materials may have been used that were not on the approved list. Most applicators are not in possession of proper knowledge to make substitutions and usually do not want that responsibility. Coating failures in many forms have resulted from attempts to circumvent the specification. Analysis of very small coating chips by FTIR or GC/MS and com-

pared with known samples can demonstrate compliance or lack thereof [7].

Before specifying a particular coating system, it is usual to evaluate specific candidates in a test program that closely simulates the use environment. This is accomplished either within the owner's organization or by subcontracted third part testing organizations. While most of the required test procedures are found in Volumes 6.01 through 6.04 of the *Annual Book of ASTM Standards*, specific custom-designed procedures may be desired.

Often a particular coating material will require specific application procedures dictated by its formulation. The coating manufacturer is in the best position to determine this since he is knowledgeable about the components of the coating. Requirements placed on the curing regime, mixing times with requisite induction periods, strainer mesh sizes, and other requirements will be specified by the manufacturer.

Preparation of the Surface/Substrate

The quality of the surface preparation done prior to coating application will strongly influence the life of the coating. Some contaminants are very harmful and lead to early failure in certain services. Some contaminants can be tolerated, and, while coating life may be somewhat adversely effected, long-term longevity can be realized. Displacement of some surface contaminants may be addressed by variations in the ability of the solvent system to affect coating wet-out. Contaminates that interfere with adhesion or promote underfilm corrosion are particularly troublesome to paints. There are potential problems with all types of surface preparations. The Steel Structures Painting Council (SSPC) has produced specifications addressing some of the most common surface preparations for steel [6]. These specifications will usually dictate the specific surface cleanliness required for service and should reflect that used during the original test sequences.

For coatings that have an extended design life, as with automobile bodies, the surface preps are extremely sophisticated. Unique electrodeposition coatings require a very clean and totally wet-out surface. Coating failures on this scale have resulted in multimillion dollar claims. Chemical pretreatments present potential failure problems as well. Cleanliness of the substrate and its impact on adhesion is the topic of many testing programs. But since one must be looking at the surface at a depth of no more than a few angstroms, the analytical techniques required include auger spectroscopy and X-ray photoelectron spectroscopy (XPS). The use of EDX to analyze a "surface" is not proper because the area being analyzed will include a depth well below the surface where "adhesion" will occur. While this technique is usually defined as a surface technique, it does penetrate well below the actual surface encountered by the coating as it attempts to "wet-out" the substrate.

Improperly operating equipment is a major source of coating failures. A very common problem is the abrasive-blast-cleaning air compressor that passes oil. Oil contamination can be a long-term, serious problem with certain coating systems. While pure aliphatic oil residues, being low-energy compounds, are usually displaced by the active solvents of the coating system such as ketones and esters, oils that contain surfactants present a serious problem. Adhesion between the binder of the coating and the substrate takes time to develop. It is highly probable that adhesion problems will develop with the egress of water vapor if the interface has been contaminated with strong surfactants and the solvent system does not have time to displace them before the coating gels and its glass transition temperature reaches ambient temperature. Analysis of the interface surfaces by XPS can allow a definitive identification of the structure of the molecules forming the interface and is required to identify the locus of failure.

Profile and surface conditions existing at the time of coating application are difficult to evaluate after a coating has been in service for a while. Frequently, though, it is necessary to inspect the substrate under a coating. Paint may be removed by using commercial paint stripper, allowing inspection of substrate profile and the current surface condition. This may include the presence of corrosion products, or mill-scale deposits may be found where the specification calls for complete removal. While the actual profile is not as critical as the original molecular contaminants that could interfere with the thermodynamic wetting process, one can gain insight into the history of the surface being inspected.

For submerged services, a "white metal" abrasive degree of cleanliness is usually specified. If a metal sample may be removed and is bendable, the sample may be subjected to extreme cold, as with liquid nitrogen or carbon dioxide followed by rapid bending. The coating will usually pop from the substrate if chemical bonding has not occurred, allowing a clear measure of the debris that remained at the time of application.

Physical Application Techniques and Equipment

The physical application techniques employed as well as the equipment used can lead to many types of coating failures. Coating defects can range from pinholes caused by small compressed air bubbles whipped in during high-speed stirring and applied by airless application systems, to curing problems originating from improper ambient field conditions, off-ratio mixing, or inclusion of water contaminants from "bad" solvent. Some defects such as orange peel, sags, and runs will be evident at the time of application, but improper curing of a coating may not become evident until a failure occurs months or years later. The analytical techniques useful in evaluating off-ratio mixing of catalyzed paints depends on the coating matrix, but typically include thermal methods such as differential scanning calorimetry (DSC), FTIR, gel permeation chromotography (GPC)/high-pressure liquid chromatography (HPLC) of solvent extracts from the failed coating, and GC/MS are typical analytical methods for evaluating cure.

The specific application technique will often present typical failure modes. Test programs that evaluate a particular coating before it is specified will usually utilize the expected application techniques. Application by spray, roller, brush, flow coater, dipping, or trowel requires that the coating material have certain physical properties. Ambient conditions expected at the time of application should be considered. Application may use electrostatics with some powders and liquid paints.

Was the coating properly cured? Was the temperature and relative humidity in the required range? Some moisture-cured ethyl-silicate, zinc-rich systems as well as moisture-cured epoxies and urethanes require that there be sufficient moisture available to allow binder-curing reactions to occur. Overcoating these coating systems before there has been sufficient water pickup can lead to premature coating failure due to insufficient coating strength development. Too much water can cause blushing with high flash lacquers.

The curing of a coating is usually by chemical reaction with the polymer precursors in the paint. All physical laws controlling chemical reactions will be in effect. This means that the reaction rate will be controlled by the substrate temperature since the heat capacity of the coating will usually be considerably less than the substrate. Potential side reactions with atmospheric constituents such as water and carbon dioxide may be a problem with some binders. For moisture-cured systems such as urethanes, epoxies, and ethyl silicate systems, air that is too dry will interfere with polymer curing. Excessive humidity may leave surfaces with a microscopic layer of water. With solvent-borne paint systems, this may not be as critical as with the super-high solids or 100% solids systems. The solvent system is usually engineered to assist in moisture removal by displacement, desolution, and selective azeotrope formation. Coatings that cannot displace these interfering surface-adsorbed species with properly engineered solvent systems may experience delamination shortly after application. With most coating systems, this may be demonstrated by the addition of thinners of varying "strengths" and noting the delamination sensitivity caused by water vapor. When a coating delamination problem exists with a particular coating system and the "adhesive" qualities may be enhanced by adding active thinner only, one may suspect problems with the thermodynamic wetting of the substrate.

Third Party Inspection

An important part of the professional application program will often include third party inspectors. These are usually required by the owner and serve as monitors and record keepers for the job. Should a failure occur in the future, the records frequently provide the only link to the daily happenings. Data will include paint batch numbers, weather data for each day, humidity and temperatures, wet- and dry-film builds, the thinners used, logging of equipment problems, names of operators, and a multitude of other data. Very important information useful to the solution of coating failures is often found in the inspection reports.

WHAT EVIDENCE IS PRESENTED BY THE FAILURE?

To successfully diagnose the causes of failures in coating systems, the investigator must be fully cognizant of all of the factors affecting the coating's longevity. This includes; (1) a thorough knowledge of the chemistry of the coating systems being used; (2) factors affecting the cross-linking, cure, or film-forming characteristics of the binder; (3) factors affecting adhesion and potential adverse chemical reactions between the substrate, binder, and environment; (4) corrosion fundamentals and protective techniques; (5) potential formulation problems; (6) potential application problems; (7) the suitability of the specified coating for the service; and (8) the instrumentation that can provide sophisticated answers to the complex questions that exist.

It is rare for all of these disciplines to be found in a single individual. New coating polymers are being developed routinely and are being incorporated into coating systems. Their reaction chemistries both with the cross-linkers used to produce the final film and the interfering side reactions with ambient, local, or solvent species may produce unexpected results. Because of this, the successful investigator must be aware of his/her limitations and be willing to seek knowledgeable assistance when necessary.

Those with experience in the formulation of paints and coatings will often have a distinct advantage over others. Understanding the potential shortcomings of the polymers used, the problems forced by the use of environmentally friendly solvent systems, the functions of the additives, the physics of adhesion, and the limitations of the analytical "tools-of-the-trade" will assist in understanding failure mechanisms. Even still, the challenge is tremendous and true solutions may be elusive. It is important to know when to ask for help.

While the investigation of a coating failure requires all of the knowledge discussed, a systematic approach offers the best chance for a successful conclusion. Before beginning the investigation, it is important to follow a preconceived procedure that will ensure that each phase of the investigation is addressed. Since each failure may be somewhat different, there will be opportunities to veer from the path as evidence is produced. The investigation should contain the follow elements as a minimum:

1. Gather background information.
2. Conduct the field investigation.
3. Conduct the laboratory investigation.
4. Consider potential failure modes and test the hypothesis.
5. Report the findings.

Gather Background Information

Inquire as to the nature of the problem. While the first reports coming in from the field will usually lack details necessary for a definitive conclusion, they do provide a picture of the problem. There is little standardization of the descriptions of failures. As an example, coating delamination can occur at the interface or within the coating or substrate. The observer usually will know only that "the coating fell off."

Obtain a copy of the specification. This will provide insight as to potential problems perceived at the initial documentation. The type of coatings and typical failure modes will prompt additional questions.

Obtain relevant daily inspection reports. These will provide data as to the current weather conditions at the time, equipment malfunctions, types of paints used, as well as any problems encountered out of the ordinary. Batch numbers of the coating material will allow queries to the manufacturer as to similar problems that may have been seen with the coating in other situations.

Conduct the Field Investigation

Talk to the applicator if possible, not just the foreman. Inquire as to any recollections about the application. Was the weather at the time of application cold, wet, dry? What was the time of day, direction of surfaces, surface preparation, blast medium used, condition of equipment?

Ensure that field test instruments are properly calibrated. The data must be reliable and relatable to other data available from original testing done prior to specification writing and the coating manufacture.

Gather all relevant samples. Representative paint chips from the "bad" area should be matched with representative samples from a "good" area. Fluid from under blisters may be withdrawn with hypodermic syringes and stored in glass bottles. Empty cans, samples of shot/grit from the automatic abrasive cleaning machines, sample debris from the dust collector, liquid samples from degreaser/phosphating baths, etc. will hold clues to problems.

Perform adhesion checks if indicated. ASTM D 3359 (Test Methods for Measuring Adhesion by Tape Test) describes methods for determining the degree of apparent adhesion of the coating. Frequently, poor or marginal adhesion causes other problems to surface although the coating appears to be intact. Underfilm corrosion is a common occurrence when contaminants remain on the steel interface after coating application.

Inspect surface profile and cleanliness of substrate. The depth and intensity of the abrasive cleaning will determine whether the surface contains "new metal." Profile depth alone is not sufficient to describe the surface. For high-solids coatings with limited active solvents, wet-out of the interface, a requirement for the development of adhesion, may not be possible as the coating increases its viscosity to a gel. As the coating cures to a film and internal stresses began to grow across the outer surface, some coatings can literally pull themselves from the surface. The inability of the coating to encapsulate debris encountered on the surface exacerbates the problem and decreases its total adhesion.

Field test for cure by MEK rubs. This test is useful for catalyzed coating systems such as epoxies and urethanes, though not suited for alkyds or latex systems. If the coating can be resolubilized, there is a high probability that there is a problem with the curing. Off-ratio catalyzation, severe zone curing from inadequate induction time, and deactivation of one reactive component are but a few of the reasons for failure of the MEK rub test.

Photo document observations. Include relevant data in each photo. This might include the observation number, test location, film build, highlight of suspect area (both good and bad), and some point of reference. The point of reference might be a pencil, coin, or even the investigator's finger. Cracks in a tank lining may be 1 cm long or 1 m long. A photograph without reference may be impossible to distinguish against a background (wall) of white paint.

Observe all activity in the area that may impact coating application or longevity. When inspecting the coating facility, look about to determine if other activities may present problems. Is the grit blast machine near the degreaser? Is metal shot and grit getting into the phosphating bath, increasing the chance for leaving loose iron phosphate on the surface to be overcoated? Is automatic welding equipment nearby using silicon sprays as a wire lubricant. These have been the reasons for coating failures in the past.

Conduct the Laboratory Investigation

After gathering the samples, the analysis may be planned depending on the nature of the problem. In answering those questions posed before, some analytical laboratory work is usually required. Some of the instrumentation and the answers they provide may be summarized in the following discussions about each instrument.

Infrared analysis of coating samples is sometimes useful in determining whether the specified coating was used. Operator technique is very important in obtaining totally definitive information, and results are often marginal. The method is very useful in testing the coatings prior to application when there is a desire to ensure compliance. Microscopic FTIR provides greater sensitivity when analyzing filled polymer solutions, as most paints are [*7*].

Gas chromatography is very useful for solvent identification. Solvent retention that leads to osmotic blister formation may be demonstrated by GC analysis of the blister liquid. Because of the migration of the solvent molecules into plastics such as polyethylene, glass collection bottles will provide a more accurate system for sample transportation.

A tremendously useful system of instruments is the "hyphenated" system made up of a pyrolysis/GC/FTIR/MS. In this "instrument," which is a laboratory on a bench, paint chips can be analyzed with little or no preparation. Positive identification of generic coating and polymer types, polymer degradation studies, solvent-retention analysis after years in the field, determination of catalysis levels in oil-free polyesters from field sample chips, and numerous other tasks are very easy with the instrument [*1*].

Ion chromatography is a very useful tool for the analysis of osmotic blister liquid when the problem stems from salts under the film. Analysis of soluble salts taken from a surface is also easy to accomplish by desolution followed by ion chromatography or after evaporation onto a selected substrate such as carbon by energy dispersive X-ray.

Thermal analysis techniques such as differential scanning calorimetry and thermal gravimetric analysis (TGA) are useful in determining some physical properties of coatings. DSC has been used to monitor curing profiles of powder coatings and other thermosets for many years [*8*]. TGA systems, set up to allow a flowing gas stream to sweep the escaping molecules through a heated gas cell of an infrared spectrophotometer, are now available. This system of instruments allows studies of the thermal stability of polymers used in coatings.

Surface analysis such as X-ray photoelectron spectroscopy (XPS), auger, scanning electron microscopy (SEM), and energy dispersive X-ray (EDX) are analytical techniques that look at the surface of the coating or substrate. Auger and XPS are tremendously important in determining the locus of failure when investigating coating delamination [*6*]. A major failure mode is the development of a weak boundary layer. These are not easy to identify with the naked eye. What may appear to be an adhesive failure could be the splitting of an organic layer very near the interface due to the loss of reaction caused by a rogue metal specie. Zinc is such a culprit

when overcoated with oil-free, polyester-based systems cured by a free radical mechanism. This has been seen when a zinc-rich coating had been applied by mistake and then removed by abrasive blasting. This left trace amounts of metallic zinc alloyed into the steel surface. The zinc interfered with the curing mechanism of the polyester.

Atomic absorption (AA) spectroscopy is useful in determining the concentration of metals in coating systems. While lead, chromium, and other metals are controlled to protect workers and the environment, low concentrations of catalytic levels may be determined as well.

Ultraviolet (UV) weathering characteristics are evaluated in simulated weathering cabinets. When failures are thought to have originated from UV degradation, test regimes may be designed to evaluate the coatings using UV of different wavelengths.

Physical and application characteristics such as percent solids, viscosity, pot life, and others are usually monitored as a quality assurance/quality control QA/QC procedure during or prior to application. The requirement to monitor these variables is often included in the specification, and the values can be found on the daily reports of the inspectors.

Liquid chromatography such as gel permeation chromatography (GPC) and high-pressure liquid chromatography (HPLC) are useful in evaluating a polymer used as a binder of coatings. Failures associated with the migration of the smaller-molecular-weight fraction to an interface, causing the development of a WBL, is a typical example. QA/QC of incoming resins for use in a coating is another typical use.

X-ray diffraction (XRD) is useful in the analysis of any crystalline material. Since most pigments found in paint are mineral in nature and possess crystalline structure, they may be identified using this technique. Even when a coating system may be lacking an identifying collection of crystalline materials, the "amorphous signature" of the XRD scan has been used to provide information about unknown coating specimens.

Consider Potential Failure Modes and Test the Hypothesis

At some time after starting the investigation, a hypothesis can be drawn. A testing program incorporating it may be developed that will assist in proving or disproving the possibility of a failure mode.

Report the Findings

After a conclusion has been reached, a full report should be written. This would include all of the data gathered including pictures. The report should contain, as a minimum, the following sections: (1) Introduction; (2) Executive Summary; (3) Background Information; (4) Discussion; and (5) Conclusions. Since a primary reason for failure analysis is to prevent similar problems in the future, the report should be written with that objective in mind. It should also serve as a teaching aid to others.

CONCLUSION

Coating failure analysis will draw from a multitude of disciplines. To increase effectiveness, one must be willing to have an open mind during observation and study the basic chemistry and physics controlling the processes. Do not enter an investigation with preconceived ideas so strongly set so as to be swayed from seeing the small details that will define the actual failure mode. Do not be afraid of the "heavy" chemistry associated with the sophisticated analytical instrumentation that can give one very powerful insight into the systems.

While there are some coating mistakes that are commonly made, the reasons for coating failures appear to be limitless. Just as a good mechanic must know how an engine works to diagnose its problems, so too must the coatings failure practitioner know how paints work and the tools available for use in any required investigation. This knowledge of potential failure mechanisms can be extremely helpful to others, as well, including the owner, specifier, paint manufacturer, and applicator. By appreciating potential coating problems, an awareness of many important details is naturally obtained. Learning the complex chemistry of urethanes may be beyond the average applicator, but the knowledge that bubbles in urethanes may be the result of painting over condensed water on the surface forces an awareness that is very helpful.

Part 15: Instrumental Analysis

Atomic Absorption, Emission, and Inductively Coupled Plasma Spectroscopy

70

by Dwight G. Weldon[1]

A PAINT, EVEN ONE AS SEEMINGLY SIMPLE as a red-lead alkyd, is actually a very complex system wherein a variety of components such as polymers that may or may not contain reactive functionality, pigments, plasticizers, additives, and solvents must interact in such a way that the dried film offers expected protection. In addition, quite often the film is expected to provide an aesthetic appeal. Because of this complexity, it not surprising that the complete chemical analysis of a coating can be a complicated and time-consuming task. Indeed, a complete analysis of all the components may require the use of several analytical techniques, many of which are discussed in this manual.

The intent of this chapter is somewhat more limited, as it pertains only to the analysis of coatings for metallic constituents and more specifically elements. Such compounds are widely used in the coating industry. Many pigments and extenders are inorganic compounds that may contain metals, and many driers, catalysts, and ultraviolet (UV) light absorbers are metal-containing compounds as, for example, cobalt naphthenate and dibutyltindilaurate. It should be pointed out that in theory inductively coupled plasma spectroscopy can be used to analyze all elements except argon. However, in actual practice, it applies to approximately 70 elements, many of which are not typically considered metallic by most paint chemists.

Classical wet chemical techniques are valuable in determining several of the above-mentioned paint-component compounds. However, a generally simpler, more efficient, and, in some cases, more sensitive way to achieve this involves the use of the related techniques of atomic absorption (AA), atomic emission (AE), and inductively coupled plasma (ICP) spectroscopy. It is the purpose of this chapter to briefly describe the underlying principles of these techniques and to discuss their usefulness within the coating industry.

ELECTROMAGNETIC RADIATION

A useful definition of spectroscopy is the study of the interaction of light, or more generally, electromagnetic radiation, with matter. Therefore, a logical starting place in the discussion of spectroscopic methods is a brief introduction into the nature of electromagnetic radiation.

Simply put, electromagnetic radiation is energy traveling through space at enormous velocities that are effectively the speed of light. The classical interpretation of this radiation ascribes to it a wave-like character with the propagation of the radiation likened to the ripples caused by tossing a pebble into a quiescent pond. However, certain electrical phenomena such as the photoelectric effect are more readily explained by the quantum mechanical interpretation of electromagnetic radiation which describes the radiation as small, discrete wave packets or bundles called "photons." These dual views of radiation as bundles and waves are complimentary and not mutually exclusive.

The classical, wave-like interpretation of electromagnetic radiation characterizes it by either the wavelength (λ) or the frequency (ν). Figure 1 is a simple representation of electromagnetic wave radiation wherein light is an oscillating vector with a wavelength, λ. From this, wavelength is defined as the length of a cycle, the distance between two successive maxima or minima, and the frequency as the number of cycles that take place per second. The relationship between wavelength and frequency is

$$\lambda = \frac{V}{\nu}$$

where V is the velocity of the wave front. In a vacuum, this velocity is equal to the speed of light, $c = 2.99 \times 10^{10}$ cm/s. Thus, for the radiation traveling in a vacuum, the equation is

$$\lambda = \frac{c}{\nu}$$

The electromagnetic spectrum is described in Fig. 2. The spectrum varies from high-frequency gamma rays, through the visible light region, all the way to low-frequency radio waves. The various regions of the spectrum have different energies, and therefore they interact differently with matter. The relationship between radiation frequency and its energy, E, that arose from quantum mechanics is given by the simple expression

$$E = h\nu$$

where h is Planck's constant, 6.624×10^{-27} erg-s. Thus, the higher the frequency or conversely the shorter the wavelength, the more energetic the radiation. As described in Fig. 2, the lower energy end of the electromagnetic spectrum involves low-energy processes such as rotation of molecules, whereas the higher-energy ultraviolet and visible light region involves higher-energy processes such as outer electron transitions. It is these transitions that form the basis of AA, AE, and ICP spectroscopy.

ATOMIC ABSORPTION SPECTROSCOPY (AA)

Atomic absorption spectroscopy probably is the most widely used of the three methods to be discussed. Basically, samples of coatings are chemically treated and introduced into a spectrometer that has been calibrated with known samples. For example, paint that is analyzed for lead is weighed, ashed at an elevated temperature to remove organic material, and then digested in hot nitric acid. The acid solution is diluted and fed into the spectrometer flame.

A simple, but not entirely accurate, picture of atomic structure involves negatively charged electrons rotating in orbits around a positively charged nucleus. The greatest population of atoms will reside in the lowest energy or ground state. If the atom is exposed to light of an energy exactly matching the difference between a ground-state orbital and an orbital of higher energy, a portion of this light can be absorbed and the electron can be excited such that it moves from the ground-state orbital to the higher-energy orbital. Thus, if a light source of appropriate frequency is available and is coupled with a detector capable of sensing attenuation of this light source, the concentration of a particular atomic species can be determined. This is the basis for AA spectroscopy.

Figure 3 is a simple block diagram of an AA spectrometer. It consists of an aspirator, which is used to deliver the liquid sample into a flame, and an appropriate light source that is usually a hollow cathode lamp. The cathode is made from the element of interest, encased in a glass sleeve, and maintained at a low pressure with an inert gas such as argon. The light source is positioned so that it can be focused through the flame into a monochromator (prism or grating) and onto a phototube or other suitable detector.

When an electric current is passed through the lamp, it excites the inert gas, which then impinges on the cathode and sputters off atoms of the metallic cathode material. Collisions between these neutral metal atoms and the gas ions result in promotion of the metal atoms to an excited state. When these

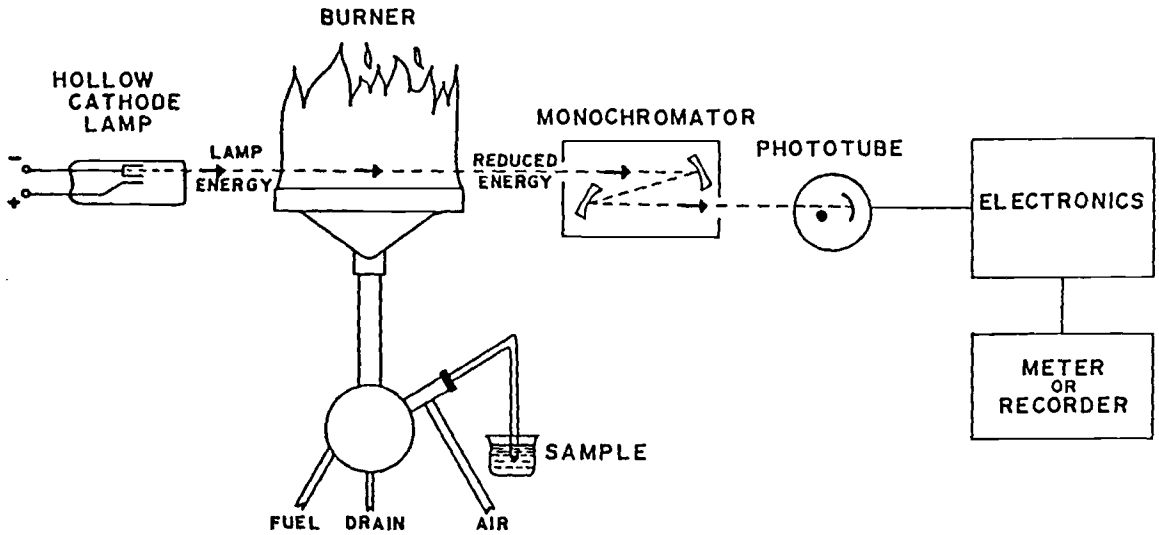

FIG. 3–Diagram of a simple atomic absorption spectrometer.

excited atoms relax back to the ground state, they emit light which is characteristic of the cathode element, and this light is then focused through the flame.

Intuitively, it would seem that there must be a relationship between the amount of light absorbed and the concentration of analyte atoms in the flame. Indeed, it has been found that if I_0 is the intensity of the incident beam originating from the source lamp and I is the intensity of the beam after it has passed through and been attenuated by the atoms in the flame of thickness or path length b, that the following relationship exists.

$$\text{Log}\,(I_0/I) = (k/2.303)b$$

where k is a constant. This relationship is known as Lambert's law. Beer found that increasing the concentration of analyte had the same effect as a proportional increase in path length. Therefore, the constant k is proportional to the concentration C of analyte and the relationship may be written as

$$\text{Log}\,(I_0/I) = abC$$

where a is the new proportionality constant. The expression is known as Beer's law.

The ratio I/I_0, which is dimensionless, is called the transmittance, T. In practical work, the terms "percent transmittance" [$\%T = (I/I_0)100$] and "absorbance" [$A = \log(I_0/I) = -\log T$] are the parameters most often used, and Beer's law is often expressed as

$$A = abC$$

Because the relationship between absorbance of an analyte and its concentration depends on the constant, a, and the path length, b, each instrument must be calibrated before a quantitative analysis can be performed. Methods of calibration are discussed in the references to this chapter and in many other analytical texts. Often calibration involves measuring the absorbance of a series of standards of known concentration and constructing a calibration cure, or the use of internal standards [*1*].

One of the inherent drawbacks to AA is the need to use a different lamp for each element to be detected, although some multi-element lamps that contain as many as five or six metals exist. Since specific cathode tubes are needed, AA is quantitative and not qualitative in nature.

Flame Characteristics

Although the processes taking place within a flame are very complex, the flame serves three basic functions:

- sample volatilization
- decomposition of molecular compounds to the elements of interest
- excitation of the individual atom (AE only)

The flame consists of three regions: an inner core, an interconal zone, and an outer cone. The analytical measurement is generally carried out in the interconal zone, which is the hottest part of the flame. The height of this zone above the burner varies with the type of gases being burned, their flow rate, and the burner type.

A very important property of the flame is its temperature, since thermal energy is responsible for decomposing samples into individual atoms and, in the case of AE, for exciting the atoms thus formed. The most common flame type is the air-acetylene flame, which achieves an interconal-zone temperature of approximately 2200°C. If a nitrous oxide-acetylene flame is used, the temperature is approximately 2900°C.

Hotter flames are usually more advantageous because they reduce the number of chemical interferences. One primary source of chemical interference is compound formation within the flame, resulting in broad-band absorption and emission. As flame temperature is increased, many of these compounds are decomposed into the free atoms and the problem is eliminated. Also, hot flames are desirable in AE since they will provide more energy for the excitation of an increased number of elements. Too high a temperature should be avoided since it is possible that a significant portion of the neutral atoms may become ionized rather than simply excited.

Graphite Furnace

A modification of AA involves the use of a graphite furnace rather than a flame to achieve excitation. Small graphite tubes or boats that have electrical contacts through which an electrical current can be passed are the basis of this technique. A small amount of sample is precisely measured into the graphite furnace, the current flow is begun, and a very high temperature is achieved, resulting in the production of an atomic vapor.

The graphite tubes are usually about 5 cm in length and about 1 cm in diameter. The sample is introduced with a micropipette through a hole in the top of the tube. The radiation from the hollow cathode lamp is focused through the axis of the tube. Heating is usually accomplished in stages. The first stage is a low-temperature step that has the purpose of volatilizing any water or solvent in the sample. The second, somewhat higher temperature, step is used to ash the sample, and this is followed by a rapid increase in current to achieve temperatures of 2000 to 3000°C and atomization of the unknown elements whose absorption is then measured.

The main advantage of the graphite furnace technique is improved detection limits due to greater sampling efficiency. Flames have low efficiency because flow down the drainage tube (see Fig. 3) results in most of the sample never getting to the flame, and also because the residence time of the atoms in the analytical portion of the flame is very brief. In contrast, graphite furnace atomizers utilize almost all of the sample and residence time is greatly increased.

Cold Vapor and Hydride Generation

Some elements, such as mercury, arsenic, tin, and antimony, are best analyzed in the vapor state. In this technique, the elements (except mercury) are converted to their gaseous hydrides with sodium borohydride in a reaction vessel. The gaseous hydrides are swept by an inert gas, such as argon, into a heated quartz cell that is located over the burner assembly area heated by the flame. A cold vapor technique is used for mercury.

An example where this technique might be useful is the case of tin. Organo-tin compounds are often used at very low levels as catalysts in certain urethane coatings. The typical detection limit for tin by conventional flame AA is 0.1 part per million (ppm), whereas the detection limit for the hydride method is 0.0002 ppm [*2*].

ATOMIC EMISSION SPECTROSCOPY (AE)

Instrumentation for atomic emission spectroscopy is very similar to that used for AA. In fact, the same instrument can usually be used for both methods. AE relies on detection of energy emitted from excited atoms as they relax to their ground state configuration as opposed to measuring the decrease in signal strength due to absorption of energy by ground state atoms being raised to an excited state. Since in AE the source of the measured light is the analyte itself, there is no need for an external light source such as the hollow cathode lamp used in AA. For this reason, the technique is more readily adaptable to multi-element analysis than AA. However, the number of elements readily analyzed by AE is considerably smaller than that detected by AA.

SOURCES OF INTERFERENCE

Spectral interference can affect AA and AE results. It can be caused by the overlapping of a line or band originating from an impurity element with the line being measured. For example, in emission analysis of sodium, the presence of calcium can give rise to spectral interference since thermally stable calcium hydroxide can form in the flame. This compound emits a band of radiation that overlaps the characteristic 590-nm line of sodium. This can be reduced to a certain degree if a monchromator of high resolution is used in AE.

Such spectral interferences are less common in AA than in AE. In AA the line source is the extremely narrow line produced by the hollow cathode lamp, and, therefore, monochromator resolution is less important in AA. However, there are still a few cases of spectral interference in AA. For example, both iron and platinum have absorption lines very near 272 nm, and manganese and gallium have lines near 403 nm.

Problems can be caused by chemical interference, which can decrease the population of free metal atoms and thereby yield an artificially low result. For example, many elements form stable oxides or hydroxides within a flame. Lithium is known to form a hydroxide in the flame. Such interferences can be minimized by increasing flame temperature.

Other types of interference include broad-band absorbance that is caused by molecules that have either formed or not been completely dissociated in the flame or by particulate matter in the flame.

Background Correction

Instrument manufacturers have devised a variety of instrumental methods for background correction. Background correction with a deuterium lamp relies on the fact that this lamp provides broadband continuous radiation in the ultraviolet region. By having a relatively wide slit width, the fraction of this radiation absorbed by the analyte is very small compared to the broadband absorbance due to molecular species in the flame or by scattering. Therefore, this type of interference can be corrected by simply subtracting the absorbance of the deuterium lamp from the absorbance of the hollow cathode lamp.

Another type of background correction utilizes the Zeeman effect. When vapor phase atoms are subjected to a strong magnetic field, a splitting of the electronic energy levels occurs. This produces, in the simplest case, three lines separated by a fraction of a nanometer and is termed the "Zeeman effect." The central, strongest line only absorbs radiation that is plane-polarized with the magnetic field, while the two weaker lines do not absorb radiation of this polarity. By mounting a rotating polarizer after the hollow cathode lamp, absorption by the analyte occurs only during the proper orientation of the polarizer. When the polarizer is in the opposite orientation, no analyte absorption occurs. Since background absorption and scattering occur during both cycles, it can now be subtracted to give only the absorbance due to the analyte.

The Smith-Hieftje technique relies on the observation that when hollow cathode lamps are briefly and cyclically pulsed at high currents, the emission band of the excited species is significantly broadened. The total absorbance from analyte plus background is obtained during the low current cycle, whereas the total absorbance during the high current pulse is primarily due to background. The signals can be subtracted from one another to obtain the corrected, analyte signal.

INDUCTIVELY COUPLED PLASMA SPECTROSCOPY (ICP)

Inductively coupled plasma spectroscopy is another technique for elemental analysis. As with conventional AE, the technique relies on measurement of light emitted when excited state atoms relax to their ground state. The major difference is that ICP accomplishes this through the use of a plasma rather than a flame. The plasma is formed as a result of argon gas being excited by an inductively coupled radio-frequency generator. One of the key elements in the instrument is the plasma torch into which the sample is carried by a rapid flow (~1 L/min) of argon.

The plasma is roughly 2 cm in diameter and is maintained within a water-cooled induction coil at the top of the torch. The torch consists of concentric quartz tubes through which argon flows. The plasma has a very intense, brilliant core. The temperatures in the plasma reach anywhere from 5000 to 7000°C, which is over twice that of most conventional flames used in AE. This higher temperature allows excitation of a greater number of elements than would be possible in a conventional flame, thereby extending the scope of the technique. Furthermore, it shares the advantage of AE over AA in that individual hollow cathode lamps are not required. Therefore, when coupled with either a rapid scanning or a multichannel monochromator, ICP is a very efficient technique for conducting simultaneous multi-element analyses.

The higher temperature of the plasma in comparison to the flames results in more complete atomization and reduction in chemical interference. Although it would seem that the higher temperature of the plasma would result in increased sample ionization and therefore poorer determination limits, this is not the case because of the suppression effect caused by the large amount of argon ions [*3*]. Detection limits are typically an order of magnitude better than AA, and the calibration curves are also linear over a much wider range.

Although the various instrument manufacturers have their own designs, there are basically two types of ICP spectrometers: sequential and simultaneous.

In most sequential spectrometers, the light dispersed by a movable diffraction grating is focused on a fixed detector, allowing emission intensities to be measured over a wide range of frequencies. Alternatively, the grating can be kept at a fixed position and the detector moved [*4*]. Since the scan speed is relatively fast and since there is no need to install and change hollow cathode lamps, the technique is much faster than AA when more than five or six elements per sample are being determined. Indeed, current instruments have throughputs ranging from 20 to 50 elemental determinations per minute [*5*].

In simultaneous spectrometers, a series or bank of detectors, such as photomultiplier types or diode arrays, are positioned at fixed points about the grating so that light at several, preselected frequencies is measured simultaneously. This is a much faster technique than the sequential method, especially if ten or more elements are being determined per sample. A disadvantage with the simultaneous instruments is their lack of flexibility. Since only a limited number of detectors can be used, only a limited number of preselected analytical lines can be measured. Typically, instruments can be set up to determine approximately 30 to 40 elements, although some can accommodate more than this.

Therefore, although able to detect more elements at somewhat better detection limits with an extended linear calibration curve compared to AA and AE, the biggest advantage of ICP spectroscopy is speed and especially so when multi-element analyses are performed. However, speed comes at a price. Conventional AA/AE spectrometers can be purchased for $15,000 to $30,000, whereas sequential ICP instruments are typically $50,000 to $75,000, and simultaneous instruments are well over $100,000. Therefore, if only a few samples are being analyzed per day for two or three elements, which is often the case in most coating laboratories, AA or AE is probably the most cost effective choice.

APPLICATIONS

Approximately 70 elements can be detected in a practical sense with either AA or AE. Detection limits are typically subpart per million. Thus, the techniques are both versatile and sensitive. Although several hours may be required for sample preparation, the actual analysis step is usually extremely rapid. Samples must be introduced into the instruments as liquids of low viscosity with the material to be analyzed in a dissolved state. Some limited work has been done on fine suspension samples.

One of the most common uses of AA spectroscopy in the coating industry is determination of lead. Lead had become a major health concern, and its presence can greatly impact the cost of removal and disposal of old paint from various structures. The commonly accepted method for lead determination is ASTM Test Method for Low Concentrations of Lead, Cadmium, and Cobalt in Paint by Atomic Absorption Spectroscopy (D 3335). In this method, the dried paint is ashed to burn off the organic materials and then digested in hot nitric acid. The method is also used to determine cadmium pigments and cobalt contained in some driers.

ASTM Test Method for Low Concentration of Mercury in Paint by Atomic Absorption Spectroscopy (D 3624) is used for the determination of mercury that is contained in many common fungicides used in paint. The sample is decomposed at elevated temperature, dissolved in sulfuric and nitric acids, diluted, and analyzed using a cold-vapor AA technique.

ASTM Test Method for Low Concentrations of Chromium in Paint by Atomic Absorption Spectroscopy (D 3718) involves ashing dried paint followed by digestion with potassium permanganate and sulfuric acid, dilution, and analysis.

ASTM Test Method for Low Concentrations of Antimony in Paint by Atomic Absorption Spectroscopy (D 3717) involves

ashing dried paint followed by refluxing with hydrochloric acid and stannous chloride.

Other ASTM atomic absorption and emission tests include:

- ASTM Test Method for Analysis of Aqueous Leachates from Nuclear Waste Materials Using Inductively Coupled Plasma-Atomic Emission Spectrometry (C 1109)
- ASTM Test Method for Determining Elements in Waste Streams by Inductively Coupled Plasma-Atomic Emission Spectrometry (C 1111)
- ASTM Test Method for Major and Minor Elements in Coal and Coke Ash by the Atomic Absorption Method (D 3682)
- ASTM Practice for Flame Atomic Absorption Analysis (E 663)
- ASTM Determination of Additive Elements in Lubricating Oils by Inductively Coupled Plasma Atomic Emission Spectrometry (D 4951)

A method for determination of zinc in cured films of inorganic zinc-rich primes that has been used in the author's laboratory involves digestion of the sample in 1:1 hydrochloric acid:water for 20 to 30 min followed by filtration and dilution. Results in good agreement with the manufacturer's published values have been obtained for a variety of coatings.

It should be pointed out that the usefulness of AA and AE spectroscopy is not limited to published ASTM test methods. The techniques are versatile, and in-house methods can often be devised to perform a variety of analyses. An excellent source of published test methods can be found in the journal *Analytical Chemistry*, "Application Reviews," usually published in the June 15 edition of every odd-numbered year since 1987 and in the April editions prior to 1987. For instance, the 1989 review [*6*] listed ten AA and AE methods for coatings and related products. These included determination of lead content in household paints, of nickel and cobalt in coatings for brass, of sodium and silicon in surfactants, and of metallic elements in poly(vinyl chloride). The 1993 review [*7*] lists 13 AA/ICP methods.

Chromatography

by Rolando C. Domingo[1]

CHROMATOGRAPHY IS A TERM THAT DENOTES a myriad of laboratory separation processes based on a differential migration phenomenon. It is particularly effective for the resolution of complex mixtures; hence, it can be used as a chemical preparatory method or, more importantly, as an analytical tool. This potent analytical technique has been widely used in the paint industry for a broad range of coating applications from everyday routine analysis to fundamental research into the nature of organic coating systems. Its use has been so extensive that virtually every type of material used in paint has been affected by chromatography.

Chromatography possesses certain inherent features that offer distinct advantages over conventional analytical techniques: complex mixtures, including isomers and homologs, can be separated; most of the equipment is relatively simple and inexpensive; chromatographic procedures are applicable to a broad spectrum of chemical types and are adaptable to both micro- and macro-size samples; and chromatography is capable of both qualitative and quantitative functions even when applied to multicomponent systems.

The term *chromatography* was coined by Tswett [*1*] who, in 1906, used powdered chalk and petroleum ether to separate plant pigments into colored zones of isolated pigment. As early as 1930 the technique was applied successfully to colorless materials, but the name remained unchanged. The term is currently used to signify a broad group of separation techniques, most of which are independent of color.

GENERAL PRINCIPLES

Considered simply, the chromatographic process involves the differential migration of sample components as they are moved through a chromatographic system. The rates of migration for various components are related to their unequal distribution between two phases, a moving phase and a stationary phase. Distributions are determined by driving and resisting forces that are exerted between the two phases and the components in the sample. These forces are influenced by the chemical structure and the size and shape of molecules present in the chromatographic system and in the sample. Generally, the stationary phase is a finely divided solid serving as an adsorbing surface or a liquid supported by some inactive porous media; the mobile phase is usually liquid or gas. The effectiveness of a chromatographic separation depends upon proper selection of phases, and, although the choice is often made on an empirical basis with heavy reliance on experience, the best results are obtained by the application of established theoretical principles. Phases are selected so as to take advantage of some functional incremental differences in the properties of the compounds to be separated; for the most part, these are differences in molecular size, solubility in the liquid phase, and adsorption to the solid phase. In today's capillary gas chromatographic columns, solid supports are no longer used. Instead, the liquid or stationary phase is coated onto the wall of the capillary tubing. To improve thermal stability, the stationary phases are oftentimes chemically bonded to the tubing wall.

In practice, there are certain basic fundamentals that apply to all differential migration techniques, regardless of the separation media used: flow rates must be slow enough to allow equilibrium to occur between phases; solute concentration must not exceed the adsorption capacity of the stationary phase; and the greater the difference in partition ratio between phases, the shorter the migration path required for resolution. Since the efficiency of all chromatographic processes is governed by the above factors, these concepts should be kept in mind when a system to be used for a given separation is being considered.

Chromatographic separations are conducted usually in columns of carefully graded sorptive powders, in sheets or strips of porous media such as paper, or in thin layers of powdered adsorbents spread on rigid surfaces. After a suitable system has been selected, a small quantity of the mixture is placed at one end of the chromatographic column and transported through the stationary phase with solvent or gas. Isolated compounds are detected "on column" if they are visible or "off column" by chemical or electronic means after leaving the column. A permanent record of the separation may be obtained by photographing the column, by plotting some property of the separated components against elution volume on graph paper, or by electronic recording. Such records are referred to as *chromatograms.*

GENERAL METHODS

Frontal, displacement, and elution analysis are the three basic methods for conducting chromatographic separations, and each has its own unique function. Separations are determined by adsorption or partition interplay between sample, stationary phase, and moving phase.

Frontal Analysis

Frontal analysis separations are made by the continuous addition of the sample onto a column containing an adsorbent. As the sample passes through the column, the component having the lowest adsorption affinity for the adsorbent emerges first. After the most strongly adsorbed component has saturated the column, the sample flows through the column unchanged. Only a limited portion of the least adsorbed component can be obtained in pure form. Frontal analysis is not an effective method for resolving mixtures, but it does provide a means of treating solutes having strong adsorption characteristics. This means of separation is seldom used in the coatings industry because of the advances in column technology for both liquid and gas chromatography.

Displacement Analysis

In this method, a concentrated portion of a sample is adsorbed onto a column, followed by the addition of a solvent (developer) that is adsorbed more strongly than any of the components in the sample. As the developer passes through the column, the components are displaced and forced ahead of it. Components will also displace one another so that the one least strongly adsorbed emerges from the column first, followed by the others in the order of increasing adsorption affinity. The component with the greatest adsorption affinity elutes last, immediately ahead of the displacing solvent. Under optimum conditions, each component will move through the column as a "belt" of pure material. A graph, obtained by plotting volume against some physical property of the effluent, will contain a series of steps. Under standardized conditions, the height of each step is used for identification, and the length of each plateau is used to determine relative amounts. When put to practice, all reversibly adsorbed components are moved through the column, but they are not resolved completely. The trailing edge of one component will overlap the leading edge of the following component, and, although it is not possible to completely separate each component in its pure form, normally a relatively pure fraction of each is attainable.

Elution Analysis

Elution processes are conducted by introducing a concentrate of the sample onto a column followed by the addition of an unadsorbed moving phase. As the sample mixture is washed through the column, components are selectively retarded and separated into discrete zones that are isolated by the presence of the moving phase between zones. This procedure contrasts with displacement and frontal methods by having the eluting solvent pass through the sample. Theoretically, complex mixtures can be completely resolved; hence, elution chromatography has the potential of being a good procedure for qualitative and quantitative analysis.

Of the three processes discussed, elution chromatography is the most efficient method for resolving mixtures, which accounts for its being the most widely used form of chromatography.

Adsorption Chromatography

Chromatography can be further classified as adsorption and partition chromatography. In adsorption chromatography, the stationary phase is a solid, most often a powder or granular adsorbent, and the mobile phase is either a liquid or gas. Sample components are separated according to their relative adsorption on active surfaces as they are percolated through an adsorbent bed. For any particular component, the degree of adsorption is related to the competitive attraction exhibited by the adsorbent and developing phase. Thus, if a component is attracted strongly by an adsorbent and attracted weakly by the moving phase, it shows little or no movement through the column. Conversely, if it shows a greater affinity for the moving phase than for the adsorbent, it will tend to move along with the moving phase. Hydrogen bonding, dielectric constants, and dipole moment of the sample and the two phases are factors that greatly influence adsorption separations. In general, strong adsorption is favored by the presence of highly polar compounds in weakly polar moving phases.

Liquid-solid chromatography (LSC) denotes the use of a liquid moving phase, whereas gas-solid chromatography (GSC) indicates a gaseous moving phase. Prior to the introduction of partition chromatography by Martin and Synge in 1941 [*2*], adsorption chromatography was used exclusively.

A vast selection of adsorbents and mobile phases are available, providing a great deal of flexibility for separating mixtures. Various aspects of adsorption chromatography, including technique and equipment, will be discussed in greater detail during the treatment of specific methods such as "classical column chromatography," thin layer chromatography, etc.

Partition Chromatography

Partition chromatography is distinguished from adsorption chromatography by the presence of a liquid that is positioned in the system by sorption to an inactive solid support. The liquid layer is the stationary phase, and the solid merely serves as a support. Separation of compounds is related to their differential solubility in two immiscible phases. Hence, a compound demonstrating a solubility preference for the stationary liquid phase will have its passage through the column retarded. Those that are less soluble in the stationary liquid phase, but readily soluble in the mobile phase, tend to move unimpeded through the column. In a static experiment with a given set of phases, a compound will be distributed between phases in a characteristic manner. This property is referred to as its partition coefficient, k, and may be defined as follows:

$$k = \frac{\left[\begin{array}{c}\text{concentration of compound in}\\ \text{stationary liquid phase (g/mL)}\end{array}\right]}{\left[\begin{array}{c}\text{concentration of compound in}\\ \text{moving phase (g/mL)}\end{array}\right]}$$

Since components are separated by virtue of differences in their partition coefficients, conditions of a test are adjusted so as to take advantage of some peculiar to each component that magnifies quality differences in k values. Fortunately, only slight differences are required for separation, and such differ-

ences can be achieved by proper selection of stationary liquid phase.

Although partition chromatography is historically more recent, it has surpassed adsorption chromatography as a method for separating complex mixtures. In partition chromatography there is a more rational relationship between the chemical character of materials and their chromatographic behavior, which accounts for its effectiveness when applied to the separation of closely related compounds such as isomers and members of a homologous series. Adsorption chromatography, however, is more limited in its applications; it will distinguish between classes of compounds, but there is little subfractionation within classes.

LIQUID CHROMATOGRAPHY

Of the various forms of chromatography, the form using a liquid eluent came first. Liquid chromatography (LC) is characterized by the employment of a liquid moving phase; the stationary phase may be either liquid or solid. The separation of molecules is based on their preference for a liquid or solid stationary phase relative to a liquid moving phase. LC encompasses established techniques such as paper, thin layer, "classical column," and gel permeation chromatography, all of which have been used extensively for routine and research purposes. For the purpose of clarity and continuity, the different chromatographic techniques will be discussed as separate entities, but, in some cases, there has been a fusion of techniques. For instance, papers have been impregnated with ion exchange materials; gels, the material commonly associated with gel permeation chromatography, have been spread on thin plates for thin-layer separations.

"Classical Column" Chromatography

The term "classical column" chromatography is used here to define procedures usually associated with older forms of chromatography. The method involves the introduction of a sample onto a column packed with adsorbent; separations are facilitated by the addition of a displacing or eluting solvent.

Apparatus and Technique—The essential equipment consists of container, adsorbent, and developing solvent. The container for the column of adsorbent is usually a glass tube, from about 5 to 50 mm in internal diameter, with a working height of from 5 to 25 times the diameter. Columns prepared from plastic and metal tubes have been also used. Fritted glass disk, perforated plastic, cotton, or glass wool may be used at the base of the column to support adsorbents such as silica, magnesium and aluminum oxides, calcium phosphate, charcoal, and cellulose. Adsorbents vary in their capacity and activity, with activity increasing with decreasing particle size and water content. If practical flow rates are to be realized, it is necessary to use relatively large particles, but not so large as to reduce the capacity below reasonable limits. In addition, narrow mesh ranges provide more uniformly packed columns and columns of higher efficiency. Adsorbents may be packed in two ways, as a dry powder or as a slurry. To ensure uniformity, the tube should be vibrated frequently and a vacuum or pressure applied during addition of packing material.

Although the activity and capacity of different adsorbents are not the same, the sequence of eluting power for different solvents is the same for any given adsorbent. In order for separation to occur, the eluting solvent must be appropriate to the packing material and sample. For example, a very polar solvent will displace the sample completely with little or no separation of components; on the other hand, a very nonpolar solvent may cause all of the components to adsorb on one section of the column with little migration or separation of components. A general practice is to start the analysis with the most nonpolar solvent and gradually change to solvents of increasing polarity. The process of systematically changing the composition of eluting media during a chromatographic analysis is referred to as gradient elution [2]. Strain [3,4] lists absorbents according to their absorptive strength and solvents in the order of their eluting power.

An analysis is conducted by introducing a sample in a few milliliters of nonpolar solvent and allowing it to flow onto the column. The eluting solvent is added, in small increments at first, and then in large quantities. At no time during the analysis is air drawn through the column. If colored compounds are chromatographed, they are detected visually on the column or in the effluent. Certain colorless compounds may be examined by fluorescence when exposed to ultraviolet radiation, or the packing may be extruded and the components detected after treatment with reagents. Eluted components are identified by dividing the effluent into aliquots and determining such properties as refractive index, nonvolatile content, pH, optical density, etc. Automatic fraction collectors, actuated by weight of fraction or a timing device, can be used to avoid manual collection of effluent.

Classical chromatography, as it is commonly used, is relatively simple but lacks detector sensitivity and is time consuming. The latter is particularly true when a fresh column is required for each analysis. Nevertheless, this type of chromatography has contributed to the general knowledge of organic coatings and to paint analysis.

Applications—ASTM Test Method for Hydrocarbon Types in Liquid Petroleum Products by Fluorescent Indicator Adsorption (D 1319) describes the determination of hydrocarbon types in petroleum products. A column is packed with activated silica gel containing a mixture of fluorescent dyes. A hydrocarbon mixture is introduced onto the gel, and isopropyl alcohol is added to desorb the sample down the column. The hydrocarbons are separated according to their adsorption affinities; aromatics are retained the most tenaciously, immediately followed by olefins, and finally by saturated hydrocarbons. The fluorescent dyes are also separated selectively with the hydrocarbon types and make the boundaries of the aromatic olefin and saturate zones visible under ultraviolet radiation. The volume percent of each type of hydrocarbon is calculated from the length of each zone. A separation of this type is an example of adsorption chromatography by displacement; the developing solvent in this case is isopropyl alcohol. Hydrocarbon types in mineral spirits and VM&P naphtha have been determined using this method.

Loeblich and Lawrence [5] used partition chromatography for the qualitative and quantitative analysis of rosin and modified rosin products. The column is packed with 2-aminopyridine-furfuryl alcohol on silicic acid. The alcohol serves as the stationary liquid phase; isooctane is the eluting solvent.

Fractions are collected and titrated with 0.01 *N* sodium hydroxide solution.

Swann et al. [*6*] used carbon black and asbestos to separate phthalate plasticizers from phthalate resins. Phthalate resins were retained selectively on the column, and phthalate plasticizers were detected and measured by saponification of the effluent.

HIGH PRESSURE LIQUID CHROMATOGRAPHY

In recent years the term liquid chromatography has acquired new significance by being used to denote a completely integrated column-detector-recorder system. New developments in instrumentation make use of the principles and practices commonly associated with gas chromatography, the object being the attainment of rapid and high-efficiency separations. Traditional methods, out of necessity, employ large samples, slow flow rates, and short columns, conditions that are not conducive to rapid, efficient analysis. With the advent of high-pressure flow systems and highly sensitive continuous flow detectors, operating conditions closely approaching those used in gas chromatography may now be used. The total unit consists of thermostated columns, solvent reservoir, degasser, metering pump, detector, and strip-chart recorder/electronic integrator.

The resurgent interest in liquid chromatography has prompted an ever-increasing number of instrument manufacturers to produce highly sophisticated instruments that are capable of multiple modes of operation including adsorption, partition, and gel permeation separations. The term *high pressure liquid chromatography* (HPLC) will be used in this section to designate adsorption and partition separations based on advanced liquid chromatography technology. Descriptions of liquid chromatographs have been presented by Lambert [*7*], Stouffer et al. [*8*], and Jentoft and Gouw [*9*], the principal differences being in the techniques used to monitor the sample stream.

HPLC has already reached the level of acceptance enjoyed by many other chromatographic techniques. Its potential as an analytical tool is still creating an enormous amount of interest. In the past, most publications were concerned with the refinement of instruments with less emphasis on applications. Presently, publications are now focusing on the applications of HPLC in the paint and coatings industry. HPLC complements other forms of chromatography. For example, HPLC can be used for the analysis of compounds having a broad range of molecular weight, whereas thin-layer and paper chromatography are limited to nonvolatile compounds and GC is limited to those that can be vaporized. HPLC is usually regarded as a relatively slow method when compared to other chromatographic techniques. However, the time necessary to produce a separation is related directly to the resolution required. HPLC can make separations of simple mixtures at speeds comparable with GC; complex samples may still require several hours. Readers are encouraged to read ASTM Practice for Liquid Chromatography Terms and Relationships (E 682-79).

Apparatus and Technique—Figure 1 shows the pertinent components of a liquid chromatograph. Solvent from one of the reservoirs is moved through a degasser by a pulse-free pump that is capable of delivering flow over a wide range of pressures. The flow is split into two streams; one is directed to the reference side of a differential detector, the other is allowed to pass through a sample injector, fractionating column, and finally to the sample side of the same detector. The sample is introduced with a syringe, or sample loop, located at the entrance to the column, and the effluent from the column is generally monitored by a continuous flow differential detector.

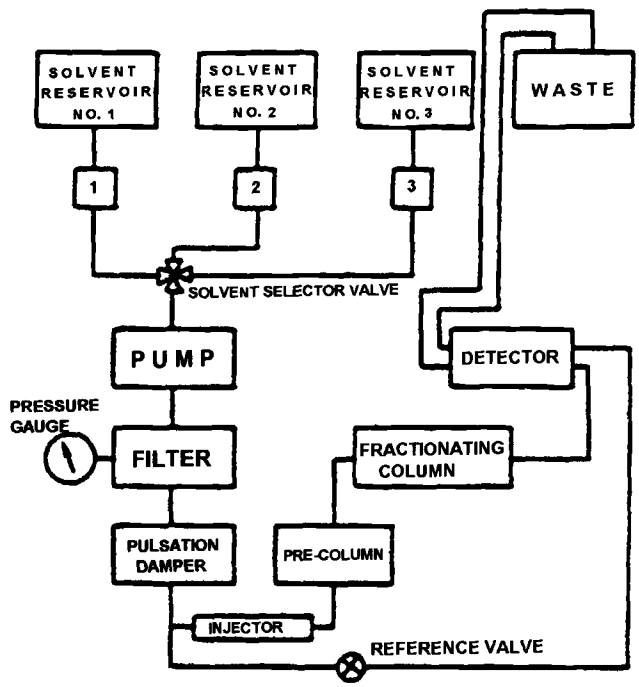

FIG. 1–Schematic diagram of a high-pressure liquid chromatograph.

Most column packings used in traditional methods for both adsorption and partition separations may be used for HPLC, for example, silica gel, alumina, diatomaceous earth, etc. There have been, however, newly developed packings that greatly extend and enhance the use of HPLC.

In the past, the development of LC was impeded by hydraulic difficulties and detector problems, but with the advent of improved solvent transport equipment and high-performance continuous flow detectors, HPLC has been elevated to a position of new prominence. At this point, it is needless to belabor the importance of each of these two factors. However, the performance characteristics of the various detectors should be carefully considered since the type used directly influences the effectiveness of the total system. Some detectors are selective, responding to only certain classes of compounds, while others are applicable to a wide range of classes and have broader application. For this reason best use is made of detectors in the context of the complete system and sample to be analyzed. Photometric, refractometric, calorimetric, radiometric, polarographic, and ionization detectors have been evaluated by Huber [*10*]. He concluded that all of them can be used for HPLC, but that a universal, all-purpose detector is not yet available. Some of the more conspicuous detectors will be discussed briefly so as to provide background regarding principle of operation and area of usefulness.

At the present time, refractive index comes closest to being the universal detector for liquid chromatography. Detection depends on the difference in the refractive indexes of pure solvent flowing through the reference side of the detector and of the effluent from the analytical column; measurement is nondestructive to the sample, the level of sensitivity is good, and operation is simple. Use of the refractive index detector in liquid chromatography is discussed in ASTM Practice for Refractive Index Detectors Used in Liquid Chromatography (E 1303-89). As with other nondestructive detectors, when used in conjunction with an automated fraction collector, the sample can be isolated and subjected to further treatment.

The heat of adsorption detector is also applicable to a wide range of materials since it responds to an almost universal property of materials, heat of adsorption. Thermal changes, induced by the adsorption and desorption of the sample, are sensed, amplified, and recorded as positive and negative peaks on a chromatogram.

The flame ionization detector, also called chain, cord, and belt detectors, combines high sensitivity and quantitative analysis with wide dynamic range. In flame ionization detection, all of the carrier leaving the column can not be directed through the detector; instead, a small wire or belt is passed continuously through the eluting stream collecting a portion of the sample. The carrier solvent is flash evaporated in one chamber, and the sample residue is then moved into a pyrolysis zone where the sample is decomposed thermally and detected with a flame ionization detector. Since the carrier solvent is removed completely, this type of detector is not affected by gradient analysis, but at the same time, its use is restricted to nonvolatile compounds. Obviously, this type of detector is well suited for the analysis of resins, polymers, and oils.

Photometric detectors measure the difference in ultraviolet light adsorption between a sample and reference stream. Since ultraviolet adsorption is parameter-specific, this type of detector is limited to chromophores. This property, of course, can be advantageous when nonultraviolet and ultraviolet adsorbing compounds emerge from a fractionating column together.

Applications—Bombaugh et al. [*11*] were able to separate ethylene glycol, diethylene glycol, and triethylene glycol using a column packed with porous silica beads; the eluting solvent was water in methyl ethyl ketone, and the eluted compounds were detected using a differential refractive index detector. Poulson and Jensen [*12*] used an adsorption column composed of 100 to 200-mesh silica gel for the separation of alkene-alkane hydrocarbons. Diatomaceous earth coated with various liquids was used to separate and determine aromatic hydrocarbons [*13*]. The compounds were sensed with a differential photometric detector. ASTM Practice for Testing Fixed-Wavelength Photometric Detectors Used in Liquid Chromatography (E 685-79) discussed the use of the fixed wavelength photometric detectors in liquid chromatography.

PAPER CHROMATOGRAPHY

Paper chromatography, as the name implies, uses paper as the separation media. A strip of filter paper is spotted with the sample near one edge and is arranged so that developing solvent can move by capillary action through the sample. The differential distribution of components between phases (paper and developing solvent) causes them to migrate at characteristic rates. If compounds are colorless, reagents may be applied to reveal them as circular or elliptical spots.

The popularity of paper chromatography can be attributed to several desirable qualities. The method is extremely versatile and simple, it allows for simultaneous analysis of several samples on one paper, and optimization of the developing solvent is easily controlled. On the other hand, one should be cognizant of certain disadvantages. The sample must be nonvolatile or be capable of conversion to a nonvolatile derivative before analysis, the length of the migration path is limited, and quantitative analysis is moderate. Most important, extraordinary precautions must be taken to reproduce conditions of test in order for retention data to be reproducible and significant.

Apparatus and Technique—The equipment necessary to conduct paper chromatography involves materials common to most laboratories. Whatman No. 1 filter paper has been the type most widely used, but for many analyses, other types of filter papers are adequate and sometimes preferred. A large assortment of containers has been employed as developing chambers: glass jars, test tubes, graduated cylinders, specimen tanks, and pipes can all be used if they are provided with tight-fitting lids. An unlimited number of liquid mobile phases are available; the type used is dictated normally by the polarity of the sample.

Capillary action is the principal dynamic force involved in ascending, lateral, or radial paper chromatography. However, in the case of descending chromatography, the movement of solvent is initiated by capillary action and finished by gravity. Occasionally, particularly when complex mixtures are encountered, it may be necessary to employ a two-dimensional technique. In this type of analysis the separation is carried out using one solvent in one direction, drying the sheets, and finishing the separation at right angles with another solvent. In all paper chromatographic separations, it is essential that the internal volume of the developing chamber be saturated with vapors from the eluting solvent.

If cellulose papers are exposed to water vapor, they will adsorb about 22% of water that may serve as the immobile liquid phase for reverse phase chromatography. Where water is impractical as an immobile phase because of sample insolubility, papers can be impregnated with other liquids such as kerosene, silicone oil, and olive oil. It is sometimes necessary, for the solution of special problems, to alter the composition of the paper. This can be done by direct chemical treatment or by the addition of a material having special properties, such as an ion exchanger. Papers of this type represent a departure from conventional paper chromatography since principles based on other techniques are involved.

Under stringently controlled conditions, compounds may be identified by their R_f values. The R_f value is the ratio of distances traveled by a compound and the solvent front, expressed as follows:

$$R_f = \frac{\text{distance moved by compound}}{\text{distance moved by solvent front}}$$

Although the use of R_f values is well documented in the literature, they are often difficult to reproduce and should be used with caution. When R_f values are reported, detailed in-

formation concerning all of the operating parameters must be stated.

Since it is possible to conduct multiple analyses on one sheet, an unknown mixture can be identified by analyzing it in parallel with standard compounds; direct comparison can be made with respect to the retention characteristics of both the sample and standard. If standards of known concentration are run simultaneously with the unknown, the amounts of each isolated component can be estimated from their relative intensities.

For additional information regarding the theory and practice of paper chromatography, the reader is referred to books by Hais and Macek [*14*] and Block et al. [*15*].

Applications—Dicarboxylic acids and polyols have been identified in polyesters [*16*] by paper chromatography. Following dissolution of the resin with alcoholic potassium hydroxide, isolated dipotassium salts were converted to their corresponding acids and separation was accomplished by ascending technique. Polyols recovered from the saponification filtrate were separated by a two-dimensional technique; chloroform-ethanol mixture, used first in one direction, was followed by elution at right angle with ether saturated with water. Dicarboxylic acids were visualized with bromcresol purple, and polyols were detected by spraying with ammoniacal silver nitrate. Tawn and May [*17*] identified dicarboxylic acids and polyols in alkyd resins using a similar procedure.

Mills and Werner [*18*] identified various types of natural resins using reverse phase chromatography. Papers were wet with kerosene and were blotted to remove excess kerosene. Samples were chromatographed with a liquid moving phase consisting of isopropanol-water-kerosene. The papers were dried, sprayed with a carbon tetrachloride solution of phenol, and exposed to bromine vapor. Colors varied according to the type and amount of resin.

THIN-LAYER CHROMATOGRAPHY

In thin-layer chromatography (TLC) an aqueous slurry of a finely divided adsorbent mixed with a binder is spread on a glass plate so that a uniform, coherent film adheres to the glass. Coated plates are dried and activated by baking in an oven for a prescribed length of time. An analysis is conducted in much the same manner as in paper chromatography. A plate is spotted with a sample and placed in a chamber containing solvent. After the developing solvent has irrigated the TLC plate, the plate is removed from the tank, dried, and compounds are detected with appropriate reagents. As in paper chromatography, the vital driving force exhibited by the mobile phase is that supplied by capillary action; separation is due to adsorption or partition processes.

Paper chromatography and TLC are similar, and both share some of the same advantages such as high sensitivity, selectivity, and low cost. TLC, however, provides sharper zone separation and increased speed, 20 or 30 min for most TLC analyses as opposed to several hours for paper chromatography. TLC is subject to most of the disadvantages described for paper chromatography, for example, compounds must be nonvolatile, have a limited elution path, etc.

Apparatus and Technique—Equipment requirements for TLC are minimal. The basic materials, as shown in Fig. 2, consist of a tank, plate, adsorbent, visualization reagent, rack, and adsorbent applicator. Relatively inexpensive equipment can be purchased from distributors of chromatographic supplies; if necessary, however, apparatus can be usually improvised from material found in most laboratories.

A developing tank must have a tight-fitting lid, and it should be large enough to receive 2 by 8-in. (5.08 by 20.32 cm) or 8 by 8-in. (20.32 by 20.32 cm) plates, but not so large as to require a large solvent reservoir. A "tankless" system can be arranged by sandwiching the thin layer between two plates and placing the sandwiched layer in a shallow trough containing solvent.

The nature of the adsorbent plays a major role in determining the type of separation that will be obtained. In a broad sense, any of the adsorbents used in column chromatography can be used to prepare thin films provided they are available as powders of uniform particle size. Silica gel and aluminum oxide are used most frequently. The homogeneity and quality of adsorbent powders are important factors to be considered if well-defined results are to be obtained.

For a given adsorbent, the migration of components in a mixture is determined by the choice of mobile liquid phase;

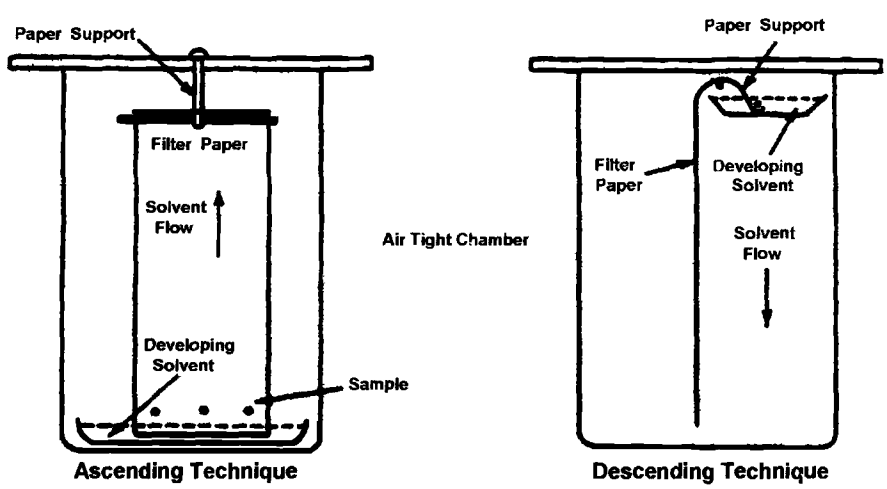

FIG. 2–Apparatus for paper chromatography.

its polarity can be altered to enhance or suppress the movement of the components. For example, if a sample moves with the solvent front, the polarity of the mobile phase should be reduced by choosing a solvent of lower polarity or by mixing solvents of different polarity. Conversely, if a sample shows little tendency to move, the polarity of the eluting solvent is increased by selecting a solvent occurring lower in the eluotropic series or by changing the ratio of polar and nonpolar solvents, favoring the polar solvent. The eluotropic series, solvents arranged in order of polarity, and other solvent activity have been described in books [*19,20*].

The preparation of chromatoplates is relatively easy and can be accomplished by using several techniques: pouring, dipping, spreading, or spraying. The first two methods require no special equipment, but they lack the refinement needed to provide uniform films. The spray technique is messy and does not always yield films of uniform thickness. By far the most popular technique is that which uses a draw bar.

Films are prepared by mixing adsorbent, binder, and water until a homogeneous slurry is obtained. Glass plates, usually 2 by 8-in. (5.08 by 20.32 cm) or 8 by 8-in. (20.32 by 20.32 cm), are aligned on a perfectly flat surface. A spreader is positioned on the end plate, charged with the slurry, and drawn across the plates with constant pressure and speed. For analytical purposes, film thickness should be in the range of 0.2 to 0.5 mm. Chromatoplates are air dried and, if desired, activated by heating at elevated temperatures. Although glass is the most common substrate, plastic and fiber glass sheets have been used successfully. TLC sheets from plastic and fiber glass can be cut and shaped with scissors. Precoated glass plates and plastic sheets can be purchased from several commercial sources, and, although the price per plate is increased substantially, the cost is still within the budget of most laboratories.

A solution of the sample may be transferred to the chromatoplate with a micropipette or syringe. After the diluting solvent has evaporated, the plate is transferred to a developing chamber where it is irrigated with the developer solvent. If a two-dimensional technique is necessary, the plate is turned 90° and treated with another solvent. The plates are dried and then sprayed with an appropriate visualization reagent.

Methods of identification are similar to paper chromatography; R_f values or "parallel analysis" are standard techniques for TLC. Additional information may be obtained by removing spots with a spatula and subjecting them to chemical or instrumental analysis.

Visual comparison with standards of known concentrations run simultaneously is often sufficient for estimating the amount of a component. If more precise quantitative information is required, instrumental methods are used. Densitometric techniques measure the density of color or acid char on the plate and relate this property to the amount of sample present. With all quantitative TLC procedures, it is important to rigidly control sample application, adsorbent quantity, and solvent composition. For an in-depth treatment of TLC theory and practice, the reader is referred to books by Truter [*19*], Bobbitt [*20*], Randerath [*21*], and Stahl [*22*].

Applications—The utilization of TLC for paint research and routine applications has been ably illustrated by Privett and Blank [*23*] and Rybicka [*24*]. The former dwells on the many general applications to fats and oils that are important to the paint chemist. For example, Fig. 3 shows the separation of various oils on a 20 by 20-cm plate coated with silicic acid (250 mils) using petroleum ether containing 15% diethyl

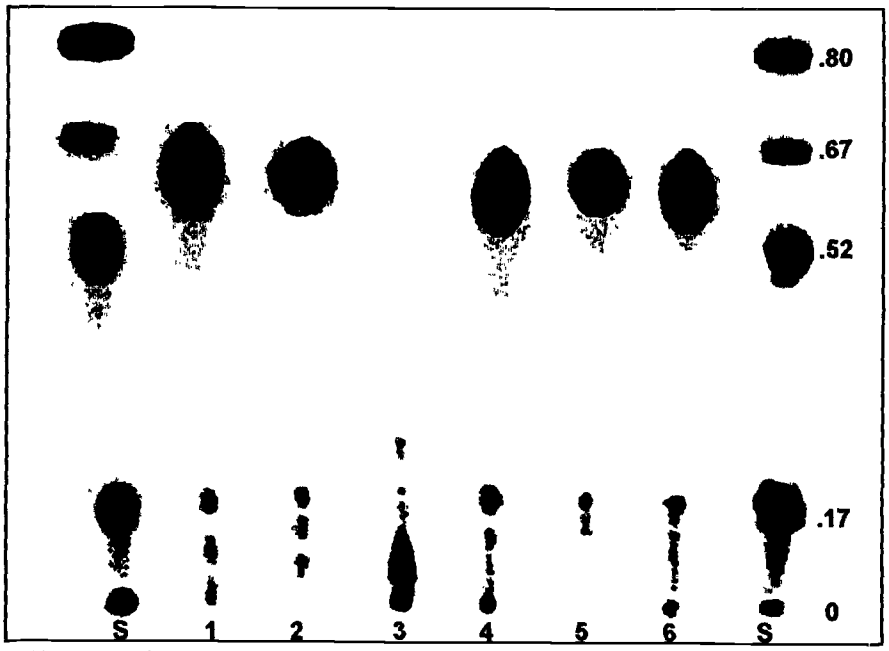

FIG. 3–TLC analysis of oils on silicic acid with 15% diethyl ether in petroleum ether containing 1% glacial acetic acid. (Courtesy of *Official Digest.*) S—Hormel Institute standards: lecithin (R_f = 0), cholesterol (R_f = 0.17), oleic acid (R_f = 0.52), triolein (R_f = 0.67), cholesteryl oleate (R_f = 0.80). 1—linseed oil, 2—safflower seed oil, 3—castor oil, 4—tuna oil, 5—olive oil, and 6—menhaden oil.

ether and 1% glacial acetic acid as the developing solvent. Zones were made visible by treating the chromatoplate with a solution of sulfuric acid and potassium dichromate. Privett and Blank also demonstrated the use of TLC for the determination of total saturated fatty acids in oils, and an investigation of a more basic nature illustrated the usefulness of thin films for elucidating mechanisms involved in the auto-oxidation of oils.

An interesting application, as described by Rybicka, illustrates the utility of TLC for monitoring glycerolysis reactions. Periodic sampling and TLC analysis on silicic-acid-coated plates were used to show how triglyceride content is decreased, accompanied by an increase in mono- and diglycerides. Similar studies with other polyols and oils were described.

A very comprehensive survey of TLC methods as applied to lipids has been made by Mangold [*25*]. Included are details for the separation of glycerides, fatty acids as methyl esters, and cis- and transisomers along with other facets of lipid analysis. Many of the methods are capable of yielding information relevant to the analysis of organic coating materials.

Knappe [*26*] demonstrated the application of TLC to a broad spectrum of coating materials including polyols, dicarboxylic acids, fatty acids, and hydrolysis products from nitrogen resins. Numerous chromatograms and comprehensive retention data were presented to illustrate applications.

Techniques for the fractionation of materials used by the plastic industry, but of importance to the paint chemist, have been described [*27–29*]. These data include tables of R_f values of polyhydric alcohols, dicarboxylic acids, and plasticizers. An impressive list of 40 plasticizers is presented in Ref *29*. Separations were performed on silica gel layers using methylene chloride as the mobile phase. Antimony pentachloride was the primary visualizing agent.

Potentially, TLC promises to be an extremely valuable tool for research and quality control problems, and wider acceptance by the paint industry should be seen in the near future. The commercialization of precoated TLC plates from several manufacturers should alleviate some of reproducibility problems associated with "home-made" TLC plates prepared in the past. Used to its fullest potential, TLC techniques can be used to screen and/or separate a wide variety of relatively nonvolatile materials prior to HPLC analyses.

GAS CHROMATOGRAPHY

Of the various forms of chromatography, that using a gaseous moving phase has proved to be the most effective for the analysis of organic coating materials. As in most chromatographic processes, the separation of compounds may occur by partition or adsorption activity—GLC and GSC, respectively. The equipment for, and the execution of, both forms are similar; however, due to its versatility and effectiveness, GLC has made a much greater impact on paint analysis, and for that reason it will be emphasized and discussed at considerably greater length. A glossary of GC terms can be found at the end of this chapter.

The primary object of this discussion is to impart to the reader a basic concept of GC processes and to focus attention on the many applications to paint analysis. Within the scope of the discussion, it will be only possible to etch the surface of present GC knowledge. If the references appear to be numerous, it is because the technique has such broad application and not because it has been exhaustively investigated.

GC is a separation technique that uses a gaseous moving phase to transport volatilized components of a sample through a small diameter tube containing a solid adsorbent or a liquid fixed to an inert porous solid. As the components advance through the column, they are retarded selectively by sequential adsorption on a solid stationary phase or by solubilization in a liquid stationary phase. A sensing device, located at the exit of the column, detects the various components by responding electronically to some physical or chemical property. From the time of appearance and the magnitude of the signal furnished by the detector, information regarding the number, type, and concentration of components can be usually ascertained.

Since the advent of GC, many time consuming and laborious test procedures have been reduced to routine methods of short duration. In addition, the unique responsive capability of GC permits the accumulation of analytical information, much of which can not be obtained by conventional techniques. In short, GC is characterized by versatility, reliability, and speed.

The outstanding popularity and performance of GC can be attributed to features that are inherent in this type of analysis. Any material that is volatile or can be converted to a volatile derivative will respond to GC. GC is extremely sensitive—as little as one nanogram of some materials can be detected. Rapid and efficient analysis is made possible by the low density and viscosity of carrier gases, which permits rapid mass transfer between phases, thereby allowing rapid flow rates. Columns can be used repeatedly; several hundred analyses on one column are not unusual. The production and interpretation of data are relatively uninvolved. On the other hand, GC has certain disadvantages. Materials remaining on a column are not detected. Owing to the empirical nature of the technique, chemical or instrumental confirmatory tests may be necessary to verify the presence of a compound, particularly when background information concerning the sample is lacking.

Ever since its introduction by James and Martin [*30*] in 1952, a wealth of GC information has appeared in the literature that has swelled to mammoth proportions. The retrieval of such information is readily made possible through the use of compiled classified indices such as bibliographies [*31,32*] and annual volumes of *Gas Chromatography Abstracts* [*33,34*]. In addition, for current developments, Preston Technical Abstract Company [*35*] offers a weekly abstract service consisting of titles of papers and abstracts. Reviews [*36–41,44,46*] reflecting specific application to organic coatings have been also published. ASTM Committee E-19 on Chromatography's *Chromatographic data compilations* [*49,50*] are arranged according to compound and liquid phase; data include relative indices for a vast number of compounds obtained on different columns. Committee E-19 has been also responsible for the publication of two general methods, ASTM Practice for Packed Column Gas Chromatography (E 260) and ASTM Practice for Gas Chromatography Terms and Relationships (E 355). ASTM Committee D-1 on Paint and Related Coatings, Materials, and Applications also pub-

also published Practice for Direct Injection of Solvent-Reducible Paints Into a Gas Chromatograph for Solvent Analysis (D 3271-87) and ASTM Test Method for Analysis of Dichloromethane and 1,1,1-Trichloromethane in Paints and Coatings by Direct Injection Into a Gas Chromatograph (D 4457-85).

Gas-Liquid Chromatography

Various terms such as gas-partition, vapor-phase-partition, gas-liquid-partition chromatography, and vapor fractometry have been used interchangeably when referring to GLC. However, the name GC, which stands for gas chromatography, is probably the most commonly used.

GLC is characterized by the presence of a stationary liquid phase, usually a nonvolatile liquid or solid that is liquid at the operating temperature, supported by the wall of a tube or by sorption to an inert porous material such as diatomaceous earth. In GLC, the components to be separated are vaporized at the entrance of a partition column and moved through the column by a continuous flow of inert gas. For the most part, the rate of migration exhibited by components is dependent upon their degree of solubility in the immobile liquid phase. Very soluble molecules are dissolved readily by the stationary phase, and their passage through the column is retarded. Compounds that have poor or moderate solubility in the liquid phase spend more time in the carrier gas and move through the column rapidly. Ideally, the multiplicity of variable conditions can be regulated so that each compound will reach the end of the column at different times where they are detected electronically as they leave the column.

The distribution of a compound between phases is referred to as its partition coefficient. Although the partition coefficient difference may be very small in a static experiment where only one equilibrium occurs, separation is possible through magnification of that difference by a continuous series of equilibria that is the normal occurrence during chromatographic separation. Since the partition coefficient is affected directly by the solubility characteristics of the liquid phase, the equilibrium for a given compound can be shifted by using stationary phases at different chemical structures. Liquid phases of varying polarity are available in great number, and it is the exploitation of their different selectivities that accounts for the tremendous flexibility and effectiveness of GLC.

Apparatus and Technique—The essential components of a gas chromatograph are shown schematically in Fig. 4. In the following discussion of equipment, it will be convenient to explain the process under its operational stages, which may be briefly summarized as follows. The flow of gas, usually from a compressed gas cylinder, is adjusted to desired levels with a series of pressure and flow regulators and split into two streams; one is allowed to flow through the reference side of a differential detector and the other is directed to the injection system, which is located immediately ahead of the column. This segment of the chromatograph, the injection port or flash vaporizer, is maintained at a temperature sufficiently high to cause instantaneous vaporization of the sample in the flowing carrier gas. Introduction of liquids and solids in solution is accomplished most often by injection through a self-sealing silicone rubber septum with a hypodermic syringe. The sample is carried immediately onto the column where the various components are separated by virtue of their different partition coefficients. As the components emerge from the partition column, they pass through a sensing device that transmits an electronic signal proportional to the concentration of the sample to a potentiometric strip recorder or an electronic integrator.

To provide maximum performance and flexibility, the injection port, column oven, and detector should all be individually thermostated. A rule of thumb is that the temperature of the injection system and detector should be at least 25°C higher than that of the column.

The choice of carrier gas is limited to a few inert gases, and this is restricted even more by the type of detector used. The most widely used carrier gases are helium, nitrogen, hydrogen, and argon.

A GC detector must be capable of sensing minute changes in the composition of the carrier gas in a reproducible and precise manner. In order to perform effectively, GC detectors must have high sensitivity, linear response, and low noise level. Secondary factors such as low cost, simplicity, and ruggedness are also desirable. The two most prominent detectors are thermal conductivity (TC) and flame ionization (FID). TC detectors, also called katharometers, consist of two filaments heated electrically and arranged in a Wheatstone bridge circuit; one filament is exposed to pure carrier gas and the other is located in the carrier gas stream emerging from the analytical column. When the carrier gas from the column

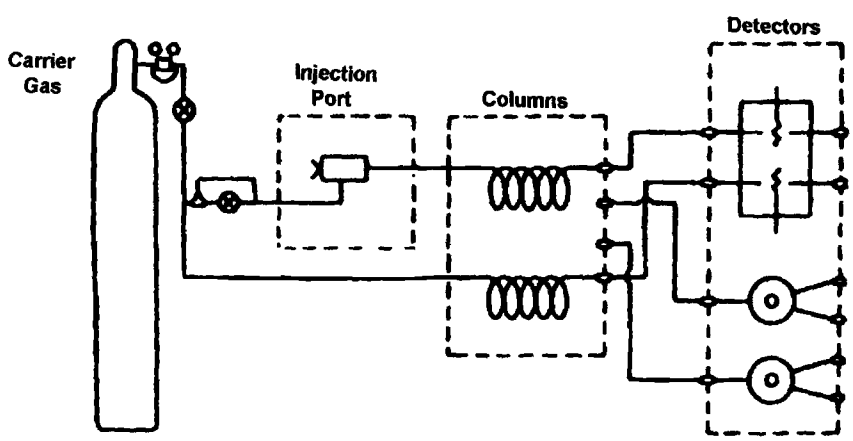

FIG. 4–Schematic diagram of a gas chromatograph.

is diluted with the sample, the temperature and resistance of the sensing filament increases, thereby causing a voltage drop across the bridge, which is shown as a peak on the chromatogram. FID detectors operate on the principle that relatively few ions are formed when hydrogen is burned in air; but when organic compounds are present, ions proportional to the carbon concentration are formed. By applying a potential across two electrodes surrounding the flame, the ion current produced from the sample molecules is fed to an electrometer amplifier, the output of which is sent to a recorder. TC and FID detectors are both durable and relatively trouble free. TC detectors will respond to virtually all compounds, whereas FID detectors are sensitive to organic compounds only. One of the principal virtues of FID detectors is its high sensitivity, about 1000 times that of thermal conductivity. Testing of thermal conductivity and flame ionization detectors used in gas chromatography are discussed in ASTM Practice for Testing Thermal Conductivity Detectors Used in Gas Chromatography (E 516-91) and ASTM Practice for Testing Flame Ionization Detectors Used in Gas Chromatography (E 594-77), respectively.

There are other high-performance detectors that are used in conjunction with GC. Beta-ray ionization detectors use a radioactive source to ionize the argon carrier effluent from the column. Metastable argon ions collide with sample molecules, inducing a current flow that is amplified and measured. Glow discharge detectors operate on the principle that the composition of the effluent can be measured in terms of voltage across a gaseous discharge. In an electron capture detector, nitrogen is passed through an ionization chamber containing tritium as the source of ionizing radiation. All ions formed by the ionizing radiation can be collected by applying a small potential across the chamber. When the effluent from a gas chromatograph contains electron-attracting compounds, a decrease in current flow proportional to the electron affinity of the compound is observed. The detector is highly selective for compounds containing halogen, conjugated carbonyl, nitriles, nitrates, and organometal compounds. The function and performance of various detectors have been discussed in detail [*53,54*]. The use of electron capture detectors in GC is covered in ASTM Practice for Use of Electron-Capture Detectors in Gas Chromatography (E 697-91). Testing of nitrogen/phosphorous thermionic detectors for use in gas chromatography is discussed in ASTM Practice for Testing Nitrogen/Phosphorus Thermionic Ionization Detectors for Use in Gas Chromatography (E 1140-86).

Most modern instruments are equipped for linear programmed temperature operation, which consists of increasing the column temperature at a uniform rate throughout an analysis. Programmed temperature gas chromatography (PTGC) is particularly useful for the examination of complex mixtures and wide-boiling-range samples, where a single analysis of high and low boiling components at constant-temperature isothermal analysis is not practical. Generally, when the range of boiling points in a mixture is 100°C or more, temperature programming is recommended. If low-temperature isothermal analysis is used, low boiling compounds will be usually separated effectively but high boiling compounds emerge as broad peaks. At high isothermal temperatures, light components emerge rapidly, causing peaks to be crowded; high boiling compounds produce favorably shaped peaks. when temperature-programmed operation is employed, a low initial temperature can be used for the separation of low boiling materials, and, by steadily increasing the column temperature, intermediate and high boiling components can be eluted in a reasonable length of time as sharp, well-defined peaks.

Although PTGC has greatly enhanced the usefulness of gas chromatography, its practice is somewhat restricted by the type of liquid phase employed. During temperature programming, a temperature is reached at which volatilization or decomposition of the liquid phase occurs, thereby causing a positive deviation of the recorder pen from the baseline. This effect is referred to as column bleeding, and in the event of severe bleeding the recorder pen may travel off-scale, obscuring any component peaks that may be present. Column bleed may be suppressed by favoring thermally stable liquid phases and through the use of short and low-loaded columns. These remedies are not always practical since a specific problem may dictate the use of conditions contrary to those described above. A more direct way to compensate for column bleed is through the use of a dual column gas chromatograph. In this type of system, a column matching the one used for analysis is mounted in the oven compartment and connected to the reference side of the detector. As the temperature is increased, a signal is generated in the reference cell equivalent to that in the sample cell, thereby cancelling out any signal due to substrate bleeding.

Columns

The successful practice of GLC depends primarily on the proper selection and preparation of a suitable column. The availability of hundreds of liquid phases and numerous solid supports in addition to parameters such as length, diameter, amount of liquid phase, and mesh size offers an almost infinite number of possibilities. Fortunately, most separations can be performed on relatively few columns involving only a few liquid phases. Columns are divided into two major classes, packed and open tubular. Packed columns consist of tubing filled with size-graded support material impregnated with a nonvolatile liquid. Generally, higher-column performance is obtained with small-column-diameter and light-stationary-phase loading. Four to ten-foot (1.22 to 3.048 m) columns of ⅛ or ¼ in. (3.175 or 6.350 mm) outside diameter containing 10 to 20% liquid phase are common.

With Golay's development of the capillary column or open tubular column [*55*], the separations possible in GLC were greatly increased. These columns are prepared by coating the inside surface of small-diameter tubing with a thin layer of nonvolatile liquid. Capillary columns are generally much more efficient than packed columns, but, owing to their low capacity, high-sensitivity detectors and special sampling techniques are necessary to accommodate the small samples used. Fortunately, the split/splitless injector ports introduced by GC manufacturers the late 1980s and early 1990s are able to handle normal-sample-size injections without much difficulty.

The readers may find the chemically cross-linked and surface-bonded stationary phases made using fused silica capillary tubing (30 m by 0.25 mm ID) quite useful to have in their gas chromatography laboratory (see Table 1).

Tubing

Tubing materials should be stable with respect to the sample, packing, and carrier gas, and be of uniform diameter. Tubing made of copper, stainless steel, monel, glass, and plastic have all been used for the construction of packed columns. The two most widely used materials are stainless steel and copper—stainless steel for its inertness and copper for its low cost. The most common tubing material used in capillary column gas chromatography is fused silica, primarily due to its flexibility and inertness. Special attention was given to the wide-bore, 0.53-mm inside-diameter columns because they have been reported [*47*] as a packed column alternative. Readers are also referred to a 1990 review covering the fundamentals, characteristics, and selection of open tubular columns in gas chromatography [*48*].

Solid Support

The function of the support material is to provide a large surface area for holding the liquid phase; it should be chemically inert to the sample and partition liquid and have good handling characteristics. The principal support materials are those derived from diatomaceous earth (Table 2). They are relatively inert, have adequate mechanical strength, and will adsorb up to 40% of the liquid phase without losing their free-flowing character. Diatomaceous earth supports can be broadly classified as to color: white or pink. White supports contain fewer active sites and therefore are considered superior for the analysis of polar compounds. Pink supports, on the other hand, are less fragile and have a greater capacity for holding the liquid phase. Schuppe and Lewis [*49*] group the

various commercial diatomaceous earth supports according to color and ASTM code.

Ideally, a support should be completely inert, but unfortunately diatomites exhibit a certain amount of surface activity. The interaction with polar compounds, usually hydrogen bonding, is attributed mainly to the presence of silanol (—Si—OH) groups located at the surface of the support. Attempts to deactivate supports have been practiced in several ways: washing with acid and alkali, saturating with polar liquids, and reacting silanol groups with reagents. Although acid and base washing have been widely practiced, both techniques are of questionable value. In fact, acid treatment has sometimes proved deleterious by promoting isomerization of certain compounds and the decomposition of the liquid phase. By far the most effective way to reduce support reactivity is by reacting the silanol groups with a silylating reagent. This treatment is more effective with white supports; the degree of deactivation varies with the type of reagent and the technique employed.

Other support materials of notable importance are glass beads, Teflon®, and porous polymers. Since porous polymers are used generally without a liquid phase, they will be discussed in detail under gas solid chromatography. Teflon® has found its greatest use in the separation of very polar compounds such as water, acids, alcohols, and amines, but Teflon® has poor handling properties and produces columns that are much less efficient as compared to columns from diatomaceous earth. Because of their low surface area, glass beads can not hold much liquid phase, less than 0.5%; it is this low volume of liquid phase that is responsible for some of its advantages, namely, speed of analysis and low operating temperatures. They are, on the other hand, substantially less efficient than diatomite columns. For information concerning support technology, such as types, physical properties, chemical structure, pore structure, treatment, etc., the reader is referred to detailed articles [*56–58*] on the subject.

Stationary Liquid Phase

The selection of liquid phase is one of the most vital judgments made in selecting a chromatographic system, for it is the degree of selectivity of the partitioning liquid that most strongly influences the separating capability of a GLC column. Theoretically, any liquid can be used as a liquid phase, but there are some limiting factors. A liquid phase must be nonreactive to the system and sample, have reasonable thermal stability, and be liquid at the operating temperature. Although materials of low vapor pressure are favored, the main criterion regarding volatility is that the liquid phase be relatively nonvolatile (vapor pressures 0.01 to 0.10 mm) at operating temperature. Finally, a liquid phase must be soluble in some volatile solvent to allow coating of the support. Terms such as substrate, partition liquid, stationary phase, and solvent are synonymous with liquid phase.

Considerable effort has been expended in an attempt to permit advance prediction of the most suitable liquid phase for a given problem, but most often the analyst must rely on experience, published procedures, and certain generalizations. Although solute-liquid phase activity such as chemical interaction, hydrogen bonding, and other cohesion forces all affect the selectivity of the liquid phase, in practice the most distinguishing characteristic is polarity. The polarity of the liquid phase is determined by the ratio of polar or polarizable groups to nonpolar groups, with the retention of solutes depending on the relative polarities of solutes and liquid phase. The greater the polarity of the stationary phase, the greater is the solubility (retention) of polar solutes relative to nonpolar solutes. The solubility or lack of solubility of sample components in the liquid phase can be used to make group separations or to accelerate or retard components with respect to others in the sample. In general, nonpolar liquid phases separate nonpolar solutes by order of volatility and polar solutes by structural type; whereas, polar phases separate polar solutes by order of relative volatility and polarity and nonpolar solutes by structural type.

An enormous number of liquids, semisolids, and solids have been recommended for use as liquid phases. Schupp [*54*] listed over 300 materials along with their maximum temperatures, chemical names, and trade names. The seventh edition of *Guide to Stationary Phases for Gas Chromatography* [*59*] contains over 700 literature references to liquid phase use in order of application to different classes of compounds. Lists of liquid phases, arranged alphabetically in chemical classes, are available from suppliers of chromatographic equipment, and they usually include maximum temperatures and solvency. Although there are a vast number of liquid phases available, the majority of problems encountered in most laboratories can be resolved with five or six stationary liquid phases provided they represent a wide range of polarities. The following list, arranged in order of descending polarity, is representative of such a group: N,N bis(2-cyanoethyl)formamide; diethylene glycol succinate; dodecyl phthalate; polyethylene glycol (molecular weight 20 000); and apiezon grease. Books on GLC generally contain chapters devoted specifically to the discussion of partition liquids, and it is recommended that the reader consult the previously mentioned books [*54,65*] for a more complete study of liquid phase technology.

Column Efficiency

Column efficiency may be defined by considering the narrowness of a peak relative to time spent in the column. Provided there are no instrumental deficiencies, column efficiency is a function of packing type, packing technique, and operating conditions and is usually expressed in terms of the number of theoretical plates. The plate concept, a carryover from countercurrent extractions, implies a series of complete equilibria or "theoretical plates." The better the performance of a column, the higher is its number of theoretical plates. Inasmuch as distinct stages are not observed in chromatographic separations, the number of theoretical plates for a column is calculated from the relative peak sharpness shown on the chromatogram. A good packed column should have an efficiency of at least 400 plates, and it is not uncommon for a well-prepared column to have over 1000 plates. The number of theoretical plates, N, equals $16(x/y)^2$, where x is the distance in millimeters from injection to peak maximum, and y is the baseline in millimeters cut by the two tangents as shown in Fig. 5.

Column efficiency can be expressed per unit of column length. The height equivalent to a theoretical plate (HETP) is calculated by dividing L, the length of the column in centimeters, by N; thus, HETP = L/N. High HETP indicates that the

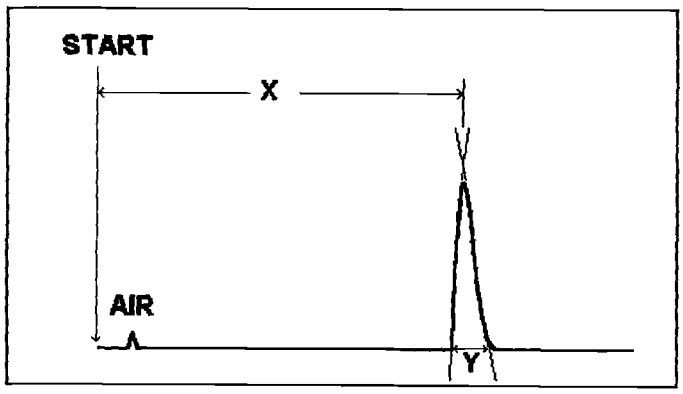

FIG. 5–Graphic calculation of column efficiency.

column has been poorly prepared or is not being operated under ideal conditions.

Theories [*60–62*] have been developed to elucidate mechanisms that cause spreading of the component molecules as they pass through the column, and an understanding of such processes is important to efficient operation of a chromatograph. Such theories take into account the interrelated multiple effects of parameters such as column diameter, column length, carrier gas, temperature, gas velocity, support size and shape, and sample size, and their ultimate effect on N. A summary and comparison of these theories have been presented [*63*]. A brief discussion to shorten analysis time while maintaining or improving resolution was published in 1993 [*64*].

Interpretation of Chromatograms

Fundamentally, the object of a chromatographic analysis is the resolution of sample components for identification and quantitative measurement. Fortunately, GC has tremendous capacity for resolving mixtures, but, unlike many other instrumental techniques, the record of an analytical run tells very little about the chemical nature of separated compounds. In addition, components in a sample mixture may not completely separate on a given column; consequently, the number of peaks on a chromatogram is not always an indication of the number of compounds in a sample.

When background information concerning the sample is available and when sample components are few, the interpretation of GC data is fairly simple. However, the interpretation of a chromatogram from a multicomponent sample, where background information is limited, is a formidable task. In this section, qualitative and quantitative analysis will be briefly discussed; for a more complete treatment of the subject, the reader is referred to the work of others [*65,66*].

Qualitative Analysis

For a given set of operating conditions, the amount of carrier gas required to elute a compound from a column is characteristic for that compound and is not influenced by the presence of other compounds. Accordingly, the time from injection to peak maximum is a property peculiar to a compound. This type of information, represented as retention volume (V_R) and retention time (t_R), has been the basis for most schemes of qualitative analysis. The use of such information may be greatly assisted by the considerable amount of published retention data such as ASTM compilations [*49,50*].

One of the weaknesses of gas chromatography is in the identification of unknown compounds. J. C. Dutoit [*51*] examined the retention indices of 135 solutes representing most chemical families on pure polar phase and pure nonpolar phase. This 1991 publication should aid the readers in the qualitative identification of GLC peaks. Another recent study regarding qualitative analysis by GLC using retention indexing was completed by Y. Sun et al. [*52*]. The programmed temperature retention value databases compiled in various laboratories are listed along with reproducibility data under different chromatographic conditions.

For the purpose of illustration, the description of retention parameters will be confined to retention times; this does not, however, imply the use of retention volume to be inferior. Retention time measurements are shown on the chromatogram presented in Fig. 6. The adjusted retention time (t'_R), time measured from air peak to peak maximum, corrects for instrument dead volume.

The first impulse would be to conclude that absolute retention times are adequate for identification purposes, but absolute retentions are comparable only when obtained on the same column using identical operating conditions. Instead, most retention times are calculated relative to some other compound that is used for reference. Relative retention time (r) is obtained as follows:

$$r_{c,s} = t'_{R,c}/t'_{R,s}$$

where c refers to component in the sample, and s indicates the reference standard. Relative retention times are independent of column length, liquid loading, and flow rate, but they are dependent on the type of liquid phase. The reference material may be one that is known to be in the original sample, or it can be mixed prior to the chromatographic analysis. In practice, relative retentions are obtained usually by computing the ratio of the distance from air peak to standard and air peak to component.

Once a peak has been tentatively identified from its retention time, the sample may be "spiked" with the suspected compound to see if it superimposes and shows up as one peak. If the two materials emerge together, this is good evidence of its presence in the original sample, but this does not constitute positive identification since more than one com-

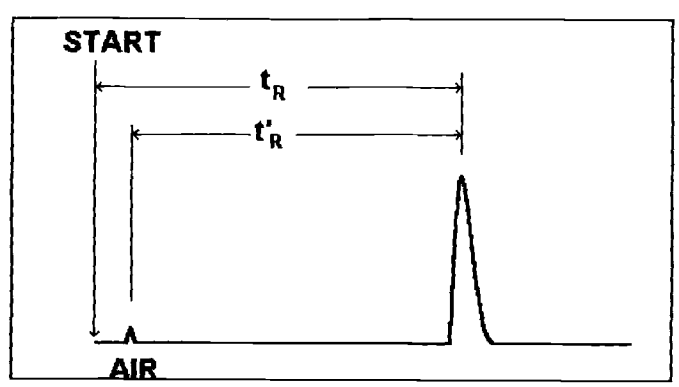

FIG. 6–Retention time (t_R) and adjusted retention time (t'_R).

pound may have the same retention time for a given column. The next step is to go through the same procedure using a different column having a packing of completely different polarity. It is not likely that two materials will have the same retention time on widely different columns, but, if doubt still persists, the compounds can be trapped at the exit of the GC unit, and the isolated materials can be subjected to instrumental or chemical analysis. Walsh and Merritt [*67*] trapped eluted materials in a neutral solvent and applied a battery of chemical tests to determine chemical functionality. Methods have been described for direct trapping of fractions on a disk of potassium bromide and fraction trapping with subsequent transfer to a microcell; the isolated components were then subjected to infrared (IR) analysis. Although somewhat limited in versatility and flexibility, table top GC-mass-spectroscopic and GC-FTIR units do an outstanding job of routine identification and for quality control purposes. Prices of these integrated instruments vary from 60,000 to approximately $100,000.

Success in any research laboratory is highly dependent on the timing upon which unknown chromatographic peaks are identified. While infrared (IR) and mass spectroscopy (MS) have been proven to be important qualitative tools, each has its inherent weaknesses. When used together, these techniques reinforce each other, producing a richer body of useful information than either technique used alone [*68*]. The use of mass spectrometers as detectors for capillary column gas chromatography has also been discussed by Clement [*69*] in his 1992 publication. Another 1992 review [*70*] with several references is given on gas chromatography, including column types, injection methods, detection means, data systems, supplementary apparatus, and future prospects.

Quantitative Analysis

The analog signal generated by the presence of a compound in the carrier gas is proportional to its concentration, and quantitative analysis is obtained by conversion of this signal to some form of digital data. For the most part, quantitative data are obtained from peak area measurements, but significant use has been made of peak heights.

Peak areas can be measured by: (1) use of a planimeter, (2) cutting and weighing chart paper, (3) triangulation ($A = WH/2$), (4) height times width at half height ($H \times W$ at $H/2$), (5) ball-and-disk type of integrator, and (6) electronic digital integrator. The planimeter yields good results, but its use is tedious, and accuracy is dependent on the shape of the peak and the skill of the operator. Cutting and weighing peaks from chart paper is time consuming, and it is practically impossible to accurately cut and weigh cutouts of narrow peaks. Triangulation and height times width at half height are both relatively simple methods, and each will yield satisfactory results with symmetrical peaks, but the methods are unsuitable with asymmetric or very narrow peaks. The ball-and-disk type of integrator, which is attached to the drive mechanism of the recorder pen, has found widespread application. Since peak areas are integrated as they are recorded, the operator need only count the integrator units under the appropriate peak. With an electronic integrator, the output from a gas chromatograph is fed to the measuring unit that converts the analog signal to digital, which is eventually converted to peak areas using appropriate algorithm. The integrated peak areas are read directly from the printer/plotters of most electronic integrators. Of the various methods for integrating peak areas, ball-and-disk and electronic integration provide the best results for applications requiring reasonable speed and precision of quantitative data. However, ball-and-disk integrators are extremely difficult to find because of the popularity of electronic digital integrators. Where cost permits, particularly in the case of routine analyses, the electronic digital integrator is preferred. Most electronic integrators made in the late 1980s and early 1990s have the capability of plotting the chromatograms in real time. Thus, a separate strip chart is no longer necessary to monitor the progress of the analysis.

Area normalization and internal standardization are methods used for converting digital data to percent composition. In the normalization procedure, the area of the component being measured is divided by the total area of all other peaks. This method assumes that all of the sample is eluted from the column.

$$\text{percent component } C = \frac{\text{area of } C}{\text{total of peak areas}} \cdot 100$$

If a portion of the sample remains on the column, error proportional to the amount of material remaining on the column will be conferred on all the compounds measured.

The internal standard method is used more widely for the quantitative interpretation of a chromatogram. In this method, peaks of interest are calculated relative to a known amount of internal standard that has been added prior to chromatography. It is not necessary to determine all peaks as in the normalization method, and this can be advantageous particularly when one compound is to be determined in a complex mixture. The following calculation is used with internal standardization determinations:

$$\text{percent component } C = \frac{C \cdot W}{B \cdot S} \cdot 100$$

where

C = peak area of component,
B = peak area of internal standard,
W = weight of internal standard, and
S = weight of sample.

If the determination is to be calculated on a volume basis, simply substitute volume for weight in W and S. Complete elution of all components is not necessary; in fact, the percent of sample hangup can be determined by calculating the total percent represented by all the peaks eluted and subtracting the total from 100.

A direct weight-to-area relationship does not exist for all compounds. Detector response is a function of structure and molecular weight; the detector response for a given compound is not the same with all detectors since various detector types operate on different principles. Once determined, however, response factors are generally interchangeable between instruments having the same type of detector. Messner et al. [*71*] published thermal conductivity factors for a large variety of compounds and also provided a formula for calculating factors. Deitz [*72*] tabulated a lengthy list of TC and FID detector response factors for various classes of compounds. For certain applications, peak height measurements

are more convenient and reliable than peak area. Such is the case when peaks are tall and narrow and where errors in area measurements are likely to be maximized. Peak height determinations are affected to a greater extent by variations of operating conditions than are peak area determinations. This effect is greatly diminished through the use of an internal standard.

To increase accuracy and precision of peak area measurements, the use of electronic integrators is highly recommended. The initial cost for such an investment can easily be recovered within a short period of time primarily through labor cost savings. Current integrators are so versatile that they can perform difficult peak integration that normally would take a less experienced analyst a lot of time to perform. Some can perform reintegration and recalculation using a variety of methods. In the 1990s, most integrators are capable of being interfaced to a personal computer to enhance data crunching and for information storage and retrieval purposes. This is especially useful where data documentation is critical.

Applications—Applications for GLC in the paint industry exist at almost every level of manufacture and product development. Its rapid acceptance by the industry is due to several inherent features, principally, versatility and speed. Initially, analyses were solvent oriented, but applications to virtually every class of material used in surface coatings have been reported in the literature. At present, GLC is used for a variety of analytical operations including both routine and research functions. It is unexcelled as a routine quality control tool for defining raw materials to be used for the manufacture of paint products. Batches of solvent, plasticizers, polyols, fatty acids, and other materials can be examined simply and rapidly to determine conformance to acceptable standards. Information regarding vehicle composition of a whole paint can be obtained in great detail and with reasonable accuracy. Moreover, GLC can be used to monitor drying processes, solvent release from films, and the chemical curing of polymeric materials. In a 1991 publication, K. Takahashi [*42*] described a simple and sensitive method for the measurement of the leaching rate of tributyltin and triphenyltin compounds from antifouling paint by gas chromatography using flame photometric detection. Static headspace analysis by combined gas chromatography–mass spectrometry for the analysis of organic solvents in printing inks was recently studied [*43*].

Because of the multiplicity of published papers relevant to GC coatings analysis (well over 1000), complete coverage of all applications is beyond the scope of this chapter. A review [*46*] describing basic GC processes and applications includes approximately 150 references to coatings analysis. In his monograph on GC application to polymer analysis, Stevens [*44*] refers to several hundred analytical procedures and, in many cases, presents operating conditions, tables of retention times, and chromatograms. Readers are directed to the second part of a 1992 article by Ettre [*45*] on the evolution of chromatography since the development of GLC by Martin and James 40 years ago and HPLC by Moore and Horvath 25 years ago.

A partial list of references is shown in Table 3; examples were selected to illustrate the variety of coating problems amenable to GLC analysis. Methods directed to the analysis of oils and fats are listed separately, but most are also applicable to fatty acids isolated from alkyd resins. A compilation of ASTM methods that have been evaluated and accepted as standard or tentative procedures is presented in Table 4. Other GLC procedures are currently being evaluated for ASTM acceptability.

One facet of GLC that often goes unrecognized is the pretreatment of substances to alter their structure, thereby permitting the examination of materials that would not respond normally to GLC analysis. Such is the case with the analysis of paint binders and very polar materials such as polyols and dicarboxylic acids. Many of the methods of sampling and techniques for preparing derivatives described by Cavagnol and Betker [*73*] and Schupp [*74*] have application to the analysis of surface coatings. Beroza and Coad [*75*] attack the same general problem but in a different way; for the most part, samples are altered within the instrument and not externally.

In the following discussion of analytical methods, special emphasis will be directed to the broad range of usefulness within the paint field, and, wherever possible, basic principles and equipment will be stressed.

Solvents

A major consideration in GLC is sample volatility. Materials to be analyzed must possess sufficient vapor pressure to permit vaporization at the point of sample introduction. Since enamel and lacquer solvents fulfill this requirement, it is only natural that GLC would be rapidly utilized in this area. Solvents may be encountered in two forms: as raw material to be formulated into a surface coating or as an ingredient of a coating. In the latter event, the analysis is complicated by the presence of pigment and binder, which usually necessitates the isolation of solvent through distillation. To alleviate problems associated with solids or nonvolatile components of the paint or coating, a removable glass liner or glass insert can be installed in the injection port of the gas chromatograph. Such glass liners can be occasionally solvent-cleaned or oven-cleaned overnight at 400°C. Another, but less desirable alternative, is through the use of a precolumn. The precolumn should be made from the same stationary phase as the analytical column.

An important aspect of production control is the analysis of individual solvents for impurities. Relatively small amounts of impurity may seriously affect the performance characteristics of a paint, and such impurities can be easily detected and determined using GLC. Batches of solvent can be rapidly screened by subjecting them to GLC analyses and comparing the resulting chromatograms to those obtained from reference materials of acceptable quality. Relative amounts of each solvent can be quickly ascertained from ratios of peak heights or peak areas. If significant deviation from the reference material is observed, a more thorough and precise GLC analysis can be then conducted. In 1993, Vonk [*78*] described the use of wide-bore fused silica columns for the analysis of solvents.

Petroleum fractions, such as mineral spirits and VM&P naphtha, are extremely complex mixtures of hydrocarbons, and it is virtually impossible to completely separate all the components. Nevertheless, valuable information regarding

[a]*Annual Book of ASTM Standards,* Volume 06.01.

the nature and identity of such solvent systems may be obtained by comparison with reference chromatograms obtained using identical operating conditions. No attempt is made to identify the individual peaks; instead, observations are made to determine if the unknown and control have similar distillation ranges and if peaks are proportional. Chromatograms of this type are referred to as "fingerprints" and will often suffice for quality control purposes.

The percentage of aromatic species in mineral spirits may be determined by using columns prepared from highly selective liquid phases such as N,N-bis(2-cyanoethyl) formamide (CEF) and 1,2,3-tris(2-cyanoethoxy) propane. These very polar liquid phases are capable of eluting high boiling aliphatic solvents well in advance of low boiling aromatics, thereby providing the means for aliphatic-aromatic group separation. Such columns provide the basis for the analysis of aromatics in enamel thinners and solvents [*79,80*] yielding information that relates to the photochemical reactivity of hydrocarbon solvents, a factor of importance in air pollution studies.

The problem of determining solvents in whole paints and lacquers by GLC is compounded by the presence of nonvolatiles, and special provisions must be made for sampling. No universal method for isolating solvent from paint and lacquer is available. Vacuum distillation and collection in a cold trap [*86*] works well in many cases, but this scheme is time-consuming and difficulties arise when very light or very heavy solvents are present. Introduction of a coating from a syringe onto an adsorbent pad [*36*] in the injection port has been used, but viscous samples require dilution, and thermally unstable resins are decomposed in the injection port, resulting in the appearance of extraneous peaks on the chromatogram. To avoid or significantly minimize thermal degradation of certain resins, it is advisable to decrease the injection port temperature below its decomposition temperature. A good injection port temperature for most solvent analysis is 200°C. As previously indicated, use of a removable glass liner or insert is a must if direct injection of the whole paint is to be performed. Again, the glass insert can be occasionally cleaned using an appropriate solvent or by overnight oven cleaning at 400°C. Precipitation of lacquer resins with pentane and subsequent analysis of the supernatant liquid by GLC works well with most automotive lacquers [*77*], but the nonuniform occlusion of certain solvents has been reported. For the most part, the means of sample handling will be determined by the type of material encountered and the extent of analytical information desired.

Several comprehensive schemes have been proposed that are particularly useful for the analysis of unknown samples. Haken and McKay [*87*] used GLC in conjunction with solubility tests in various media along with functional group analysis for the characterization of solvent systems. The New York Society for Paint Technology published a paper [*81*] on the subject of solvent analysis that included a comprehensive tabulation of retention data for a broad spectrum of solvents. A procedure for the identification of plastic and lacquer solvents was described by Haslam et al. [*86*]. The solvents were isolated by vacuum distillation in a sealed "H-tube" and subsequently separated on tritolyl phosphate and paraffin wax columns. Chromatographic data were supplemented by infrared spectroscopy where necessary.

Since no single column will separate all solvents, separation on one liquid phase can be very misleading. When examining an unknown solvent mixture, it is best to conduct the analysis on at least two liquid phases of different polarity, and in some cases supplementary chemical or instrumental testing will be also necessary.

GLC has been also used to study the retention of solvents in paint films during drying processes [*88,89*]. It has been demonstrated that solvent retention is related to the chemical structure of the film and solvent, as well as the boiling point of solvents. Perrone [*90*] also described a GC method for the determination of residual solvents in pressure sensitive tapes as a quality control step in the manufacturing process.

Oils

The drying and nondrying oils used in the production of paints and varnishes can be identified through the application of GLC. The GLC analysis is preceded by the saponification of sample and isolation of the fatty acids. Free fatty acids may be examined directly [*100*], but they are generally analyzed as their methyl esters, which are more volatile, less polar, and less susceptible to isomerization. Any of several acid-catalyzed esterification techniques, for example, hydrochloric acid (HCL), sulfuric acid (H_2SO_4), or boron trifluoride (BF_3) in methanol, will provide adequate conversion to the ester; the BF_3-methanol reagent, however, offers the advantages of a high yield combined with rapid ester conversion. The difficulty in handling BF_3 gas can be circumvented by using boron trifluoride etherate in methanol. The reagent is easy to prepare, stable, and will convert fatty acids to their corresponding methyl esters within a few minutes.

Many of the fatty acids found in oils are of the same carbon chain length, differing only in position and number of double bonds. Most polyester liquid phases will differentiate between C_{18} fatty acids, but polyesters having the highest oxygen-to-carbon ratio provide the best separations. Of the polyester liquid phases, diethylene glycol succinate has received the most attention. Six-to-eight-foot (1.83 to 2.44 m) columns containing 10 to 20% polyester on white diatomaceous earth supports are most common.

Zielinski et al. [*105*] considered the analysis of reacted and unreacted oils and made provisions for their complete analysis. Fatty acids were identified from the relative retention time ratio (RTR) values. RTR values were defined as the numerical ratio of the corrected retention time of a given methyl ester peak to that of the methyl palmitate peak. With the exception of licanic and eleostearic acids, all the fatty acids can be readily separated and identified.

Linseed, soybean, tall, safflower, and cottonseed oils can be identified from their characteristic fatty acids distributions. With other oils, identification may be achieved from an inspection of only one or two acids. For example, marine oils contain respectable amounts of palmitoleic and myristic acids, castor oil consists mostly of ricinoleic acid, coconut oil is rich in lauric acids, and oiticica and tung oils contain appreciable amounts of licanic and eleostearic acids, respectively.

Complete details for the identification of oils in organic coatings by GLC may be found in ASTM Test Method for Fatty Acid Content of Alkyd Resins and Resin Solutions

(D 1398), ASTM Test Method for Fatty Acid Composition by Gas-Liquid Chromatography of Methyl Esters (D 1983), and ASTM Test Method for Identification of Oils and Oil Acids in Solvent-Reducible Paints (D 2245). The first provides a means of isolating fatty acids from an alkyd resin, and the other two give details for preparing methyl esters, chromatographic analysis, and interpretation of data.

A further extension of GLC to fatty acid analysis is demonstrated in a method for dimer acids [*107*]. Dimer acids are relatively nonvolatile, but their elution as methyl esters is made possible by using a short column composed of a thermally stable liquid phase, silicone grease, on silanized Chromosorb W. Monomeric fatty acids are eluted as one peak, while dimer acids emerge further along the column as a well-defined gaussian peak.

Resins

The GLC analysis of resins constitutes a special problem inasmuch as the analyst must rely on some means of forming volatile products, either by derivative formation or through thermal decomposition. Thermal decomposition techniques will be discussed in greater detail in the following section; this section will be concerned with methods for converting nonvolatile resinous materials to volatile derivatives.

Alkyd and polyester resins account for a large portion of polymeric material used in organic coatings. The identification of the oil component in alkyd resins by GLC has been already described. The remaining classes of material, dicarboxylic acids and polyols, can be analyzed by chemically degrading the resin so as to regenerate the acids and alcohols, which are then derivatized and subsequently analyzed by GLC. If butylamine is used to degrade the resin, polyols may be analyzed qualitatively [*115*] as their acetates or qualitatively and quantitatively as trimethylsilyl ethers [*117*]. The latter method involves a minimum of sample manipulation, and it is applicable to all of the polyols normally found in alkyd resin. Both procedures are relatively uninvolved and capable of analyzing more than one polyol simultaneously.

When alkyd or polyester resins are subjected to a catalyzed equilibrium reaction in a large excess or methanol, methyl esters of mono- and dicarboxylic acids are formed in good yield.

$$\text{MeOH (large excess)} + \text{alkyd or polyester} \longrightarrow \text{methyl ester} + \text{glycol}$$

A method [*111*] has been developed for the identification of mono- and dicarboxylic acids in alkyd and polyester resins where lithium methoxide was employed as the transesterification catalyst. Two columns, one polar and the other nonpolar, were used to obtain retention data. Identification was made possible by comparing the relative retention times of peaks from a sample to those obtained from pure compounds. Percival [*108*] reported a similar method using sodium methoxide as the catalyst; semiquantitative results for polyols and dicarboxylic acids were presented.

Pyrolysis

Thermal degradation, when used in conjunction with GLC, can be applied to the analysis of a wide range of polymeric materials. This technique, commonly referred to as pyrolysis, has been the subject of numerous papers. One of the most recent reviews regarding pyrolysis gas chromatography, their advantages and problems in polymer characterization, was published in 1992 by Ahmadi et al. [*109*]. Pyrolytic GLC is a most convenient way of analyzing small quantities of high-molecular-weight material without the necessity of resorting to chemical pretreatment. Under proper conditions the products of thermal degradation are unique for the material being analyzed, and if conditions are controlled carefully, highly reproducible results are obtained. Data, however, are sometimes difficult to interpret, and reproducibility between laboratories is not always good.

Early pyrolysis work was conducted in a system external to the gas chromatograph, with the pyrolyzate being collected in a cold trap. Pyrolysis products were introduced into a gas chromatograph and chromatographed by conventional means. Ever since its inception, pyrolytic GLC has undergone a series of refinements with the ultimate development of integrated pyrolytic-GLC systems. Curie point pyrolysis coupled with gas chromatography–mass spectrometry (GC-MS), headspace GC-MS, and preparative HPLC were used to determine the compounds of an uncured polyester resin containing a cross-linking accelerator, an acrylate copolymer, surfactants, additives, and marble powder [*110*]. Of the many techniques described in the literature, two are most prominent.

In one method, a filament of high-resistance wire is coated with the sample resin, and the sample is pyrolyzed by energizing the filament with a predetermined amount of current. In a modification of the "filament technique," a quartz or ceramic sample holder is placed inside the heating coil to prevent catalysis, which may occur at the surface of the wire. In both variations, pyrolysis products are carried onto the column as they are formed, thus preventing the occurrence of secondary reactions between highly reactive chemical species. Pyrolysis temperature can be controlled by calibrating various settings of a variable voltage source with a thermocouple.

The second type of pyrolysis [*119*] employs a microoven to decompose the sample. In this technique the oven is preheated to the desired reaction temperature and the sample is then introduced by means of a moveable boat or cup. The unit can be designed so that several samples can be readied for analysis and introduced one at a time by external sample manipulation. Generally, the carrier gas is not allowed to flow over the sample until pyrolysis is complete, at which time valves are positioned so as to direct the carrier gas flow over the boats, thereby carrying the pyrolysis products onto the column.

As compared to the filament technique, the microoven offers better reaction temperature control and a means of weighing the sample and residue, but it is more susceptible to secondary reaction of pyrolysis products.

Since polymer composition may vary over a wide range, it is difficult to choose column and chromatography conditions to cover all substances. Some polymers yield highly polar species (for example, acetic acid from polyvinyl acetate or amines from nitrogenous resins) that may be lost by adsorption on the column. Columns that perform well with polar substances are not always suitable for the separation of less

polar materials. Therefore, optimum conditions should be determined for different classes of polymers. When samples are completely unknown, best use is made of pyrolysis when the general type of resin is determined by prior chemical or instrumental testing. Kim [*120*] reviewed the fundamentals of gas chromatography and pyrolysis and their applications in the analysis of fibers and polymers. Generally, the fragmentation of polymers will proceed by three basic pyrolytic reactions. Cross-linked polymers tend to carbonize, and as a result they produce pyrograms that are very difficult to relate back to the starting material. Such is the condition with alkyd resins. Secondly, some linear polymers will rupture between the side chain and the polymer backbone. This type of pyrolysis can be useful if the decomposition products are characteristic of the side chain. Pyrolysis of polyvinyl acetate typifies this type of bond schism; acetic acid is the principal decomposition product. The final and most useful type of pyrolysis occurs when the polymer backbone ruptures, producing monomers of the polymer. This type of decomposition is favored by quaternary-substituted carbons on the polymer backbone. For instance, good yields of methacrylate monomer are formed from the pyrolysis of polymethacrylate polymers, whereas polyacrylate polymers give low yields of acrylate monomer.

If experimental conditions are controlled carefully, the reproducibility of pyrolysis patterns is good. Thus, if sufficient reference chromatograms are developed, an unknown resin can be identified by matching the sample pyrogram with one from a reference library. Since, in many cases, decomposition produces a pattern of peaks that are not individually identified, the resulting chromatogram is employed as a "fingerprint." Jain et al. [*121*] demonstrated the use of pyrolytic GLC for the identification of small samples of paint. Characteristic pyrograms were obtained from different types of paint vehicles and those with the same vehicles but different pigments. The method was recommended for use in the forensic field where, very often, chips or traces of paint are the only physical evidence. Groten [*122*] investigated a broad spectrum of polymeric materials and found that they all produced characteristic pyrograms. McKinney [*123*] compiled a bibliography on pyrolysis gas chromatography for the period 1960 to 1963 that includes a subject and author index. A comprehensive treatment of pyrolysis chromatography, with special reference to paint resins, was presented by Hillman [*124*]. The study included 22 pyrograms of various types of coating materials in addition to a discussion of the effects of operating conditions and polymer structure on the resulting chromatograms.

As mentioned before, alkyd resins do not yield well-defined pyrograms that can be used for compositional analysis. Pyrolysis of alkyd resins is most useful for the examination of minute chips or flakes of paint. If an adequate amount of wet sample is available, alkyd resins may be examined best by gas chromatography of the fatty and dibasic acid methyl esters [*105,111*] and the trimethylsilyl ethers of the polyhydric alcohols [*117*]. Styrenated and acrylated alkyds, however, give good yields of monomer from the modifying resin, and with proper calibration the concentration of modifying resin can be ascertained.

When the pyrolysis is limited to certain classes of resins, for example, methacrylate and polystyrene, high yields of monomer are obtained that can be equated with the copolymer composition of the polymer through the use of calibration mixtures. Since copolymers do not give the same pyrograms as physical mixtures of the same composition, physical mixtures cannot be used for the quantitative analysis of copolymers. A random rupture of bonds occurs when acrylate is pyrolyzed; yields of monomer are low, accompanied by the esterification alcohol and gases. A scheme for the identification of copolymer composition of thermosetting acrylic resins has been presented [*108*]. In this method, a filament was coated with the resin solution and dried prior to decomposition. Twelve monomers were identified by combined analysis on polar and nonpolar columns.

Plasticizers

One of the most desirable properties of a plasticizer is low volatility, and for this reason it would be expected that the analysis of such materials by GLC would not be easy. Indeed, the vapor pressures of many plasticizers are so low that they have been recommended as stationary liquid phases for GLC analysis where moderate operating temperatures are adequate. However, by a suitable choice of operating conditions, most nonpolymeric plasticizers may be chromatographed without great difficulty.

In general, reasonable emergence times of high boiling compounds may be achieved by the use of short columns, rapid flow of carrier gas, high operating temperatures, or low-liquid-phase concentration. Since each of these operating conditions can produce undesirable effects such as poor resolution, reduced column longevity, and tailing, a compromise must be reached that will allow the resolution of high boiling mixtures within a reasonable time span. A 9-in. (22.86-cm) silicone grease column [*127*] was found to be adequate for the quality control of incoming stocks of butyl benzyl phthalate. Differences in the manufacturing processes of this plasticizer leads to products of variable composition, and, although a high yield is the desired end product, appreciable amounts of dibutyl and dibenzyl phthalate are sometimes encountered. When incorporated with acrylic resins, dibutyl phthalate tends to distill out of a lacquer on exposure, a condition that may ultimately lead to resin embrittlement.

A method for the analysis of plasticizers was presented [*128*] in which a 6-ft (1.82-m) silicone grease column was used to separate a broad range of plasticizers. A rapid flow of carrier gas, 120 mL/min, and a high terminal column temperature, 290°C, were used in conjunction with temperature programming for the separation of low, medium, and high boiling plasticizers.

Miscellany

Ghanayem and Swann [*135*] separated glycols on polar columns without resorting to derivative formation. A method of this type is useful where the purity of low-boiling, uncombined polyol is under consideration. High-boiling polyols, however, normally require derivatization prior to the chromatographic step. The ever-increasing popularity of aerosol packaging has generated considerable interest in methods for the chemical analysis of aerosol propellants. The performance characteristics of various propellants may vary

over a broad range; flammability, toxicity, vapor pressure, and solvency are some of the factors that determine their usefulness. It is practically impossible to identify propellants using conventional methods; they are, however, susceptible to GLC analysis. A two-column method [*136*] has been devised for the identification of propellants in aerosol-packaged paint. In this method, a 22-ft (6.70-m) silicone grease column is used at ambient temperature for the separation of fluorinated compounds, chlorinated hydrocarbons, and aliphatic hydrocarbons. A 6-ft (1.82-m) porous polymer column is used for the separation and identification of carbon dioxide. The concentration of each propellant may be approximated from the ratios of peak heights or peak areas. Obtaining a representative sample from an aerosol can could, prior to solvent analysis, present some difficulties to inexperienced analysts. Rastogi [*137*] suggested freezing the aerosol can in liquid nitrogen, puncturing the can, and allowing the propellant to evaporate as a sample preparation method.

The many applications of GLC to paint analysis are too numerous to mention; indeed, the number is vast and continues to grow. Eiceman et al. [*138*] reviewed the fundamental developments in gas chromatography for the period 1990 and 1991 and noted the attention given to the characterization of liquid phases and prediction of retention behavior. A review of the usual methods of quantification by headspace gas chromatography for liquid samples was presented by Nagai [*139*] in 1991.

In today's laboratory environment where analysts are required to multitask, autosamplers are helpful not only for productivity reasons but also for increasing accuracy and precision. The design, operation, and troubleshooting of GC autosamplers was discussed by Hinshaw [*140*]. Moreover, the labor cost associated with troubleshooting could be prohibitive when the analytical laboratory relies solely on the GC instrument manufacturer. It is critical for the analysts to be fully informed and educated about all aspects of problem solving, including the chromatographic hardware. A paper [*141*] covering trace-level sampling, principles of splitless injection, post-injection effects, and troubleshooting splitless injection was published in 1991.

Gas-Solid Chromatography

Gas-solid chromatography (GSC) represents a gas chromatographic technique where components are separated on a solid rather than on a liquid phase. Its application to the analysis of coating materials has been extremely limited, and for this reason only a very brief description of GSC processes will be presented with special emphasis being directed to new developments and potential applications to paint analysis.

Instrumentation and interpretation of data are basically the same as in GLC, the only departure from GLC convention being the absence of a liquid stationary phase. Initially, GSC methods were used primarily for the analysis of very volatile, inert materials, but with the introduction of new packing, the technique has been extended to the analysis of a much broader spectrum of chemical types. Alumina, silica gel, molecular sieve, organoclay, and porous polymers are the most widely used GSC packing materials. GSC with silica gel, alumina, or organoclay preclude the analysis of polar solutes since polar solutes are irreversibly adsorbed on surface-active groups. Of the GSC packings mentioned, porous polymers are the most recent, and, owing to their versatility, they offer the best potential for GSC analysis of coating materials.

Porous Polymer Packings—Porous polymer beads represent a unique advance in column technology by making use of polymer synthesis to produce columns for specific applications. Porous polymer beads are derived from the same family of polymers used in gel-permeation chromatography; they were first introduced as a GC packing by Hollis [*146*], who demonstrated their application to various chemical species.

The porous polymer beads used by Hollis were prepared from styrene, *t*-butylstyrene, and ethylvinylbenzene cross-linked with divinylbenzene. By varying the monomer ratios and polymerization conditions, the properties of the polyaromatic beads can be varied with regard to chemical structure, pore structure, particle size, and surface area. Consequently, beads of different performance characteristics can be synthesized. Porous polymer beads from different sources have been studied [*147*]; their physical properties and performance characteristics have been described in great detail.

Technically, the use of porous polymer beads packings should not be classed exclusively as GSC since partition and diffusion, as well as adsorption, all contribute to their effectiveness. Most likely, adsorption predominates at low temperatures and partition at high temperatures. Porous polymer beads have good mechanical strength, which permits their being packed by conventional vibration techniques. Most beads can be used up to 250°C with little or no bleeding, and this characteristic is particularly important when high-sensitivity detectors are used in conjunction with temperature programming. Unlike diatomaceous earth packings, porous polymer beads are hydrophobic, eluting water very rapidly with little or no adsorption. The potential uses of such packings are still being explored, but excellent results have been already achieved for the analysis of polar compounds [*148*], these chemical types being difficult to chromatograph on conventional GLC columns.

Finally, the readers may find the list of ASTM practices relevant to chromatography shown in Table 5 useful in their practice of chromatography.

GAS CHROMATOGRAPHY GLOSSARY

The following definitions of terms used in GC were compiled by Brenner and Olson [*149*] and the International Union of Pure and Applied Chemistry under the Chairmanship of Dr. Ambrose [*150*].

adsorbent (active solid)—Solid, granular material used to pack columns and on the surface of which sample components are held by adsorptive forces.

adsorption chromatography—*See* **gas-solid chromatography.**

adsorption column—Column used in gas-solid adsorption chromatography. The column material consists of an active solid (adsorbent).

E 1303-89	Practice for Refractive Index Detectors Used in Liquid Chromatography

air peak—The peak of a substance that is not retarded by the column material, thus indicating the time necessary for the carrier gas to travel from the injection point to the detector.

attenuator—An electrical element containing a series of resistances that may be selected by a switch to produce the reduction of input voltage to a recorder by a fixed factor.

band—*See* **peak.**

band area—*See* **peak area.**

baseline—The line drawn by the recorder pen when no sample is being measured in the detector.

capillary column (open tubular column)—Tubing of small diameter, usually 0.25 to 1.0 mm inside diameter, in which the inner walls of the tube are used to support the stationary liquid.

carrier gas—The gas, usually inert, that constantly flows from a pressurized source through the chromatograph, impelling the sample through the system.

chromatogram—The graphic recording of the detector response versus time or volume of carrier gas.

column—A metal or glass tube packed or internally coated with the column material through which the sample and carrier gas flow and in which the chromatographic separation is performed.

column material—The material contained in the column. In adsorption chromatography, the column material is the adsorbent itself; in partition chromatography, the column material consists of a stationary phase distributed on an inert solid support or coated on the inside wall of the column.

component—A pure compound contained in the sample mixture.

detector—A measurement device, usually electrical, that emits a signal in the presence of a component that is eluted from a chromatographic column.

elution—The "washing" of a component through and out of the column by the carrier gas.

filament element—A type of thermal conductivity device in which a fine tungsten or similar wire is used as the variable resistance element in the cell chamber.

flow programming—A technique in which the carrier gas flow rate is gradually increased in order to expedite the elution of the higher boiling components.

gas chromatography (GC)—Collective noun for all chromatographic methods in which the moving phase is a gas. The term "chromatography" implies that a stationary phase is present in addition to the moving phase. These methods are also called *vapor-phase chromatography* (VPC).

gas-liquid chromatography (GLC)—Chromatographic method in which the stationary phase is a liquid distributed on a solid support. The separation is achieved by partition of the components of a sample between the phases. This method is also called *gas-liquid partition chromatography* (GLPC).

gas-solid chromatography (GSC)—Chromatographic method in which the stationary phase is an active solid (adsorbent). The separation is achieved by adsorption of the components of a sample. This method is also called *gas-solid adsorption chromatography.*

integrator—A mechanical or electromechanical device for producing a continuous summation of detector output with respect to time, yielding a measurement of included area of a chromatographic band.

ionization detectors—Chromatographic detectors in which the measurement of a sample is derived from the current produced by the ionization of sample molecules induced by thermal, radioactive, or other excitation sources.

katharometer (catharometer)—*See* **thermal conductivity cell.**

Liquid phase—A liquid that is relatively nonvolatile at the column temperature and is sorbed on the solid support where it acts as a solvent for the sample. The separation achieved differs with differences in solubility of the various components of the sample in the liquid phase. This is also called the *stationary phase* or *substrate.*

moving phase (mobile phase)—The carrier gas within the column, in which sample component molecules progress down the length of the column.

partition chromatography—*See* **gas-liquid chromatography.**

peak—The portion of the chromatogram recording the detector response while a single component emerges from the column. (If the separation of a mixed sample is incomplete, two or more components may appear as one peak.)

peak area—The included area formed by the ascending and descending arms of a chromatographic-recorded band and the baseline of the chart.

potentiometric recorder—A readout device in which a pen, whose deflection is proportional to the voltage output of the chromatographic detector, writes on a paper chart that is moving at a constant speed.

pyrolysis—A technique in which nonvolatile samples are thermally decomposed in the absence of oxygen in the inlet

system and the volatile products are admitted to the chromatographic column.

relative retention—The ratio of the retention time of a component to the retention time of a second component chosen as a standard.

resolution—The degree of separation between peaks.

retention index—The number of carbon atoms (multiplied by 100) of a hypothetical normal paraffin which under the given conditions would have a retention time identical to that of the substance of interest.

retention volume—The product of the retention time of a component and the volumetric flow rate of the carrier gas.

retention time—The elapsed time from injection of the sample to recording of the peak maximum of a component band.

sample—The gas or liquid mixture injected into the chromatograph for analysis.

sample injector—A device by which a liquid or gaseous sample is introduced into the apparatus. The sample can be introduced directly into the carrier gas stream or into a chamber temporarily isolated from the system by valves that can be changed so as to instantaneously switch the gas stream through the chamber.

separation—The elapsed time between elution of two successive components, measured on the chromatogram as the distance between the recorded bands.

solid support—The granular material upon which the thin layer of liquid in a partition column is held.

solute—The individual fractions of the sample dissolved in the liquid phase during their travel through the column. This is also used as another term for the sample itself.

solvent—Synonym for the liquid phase.

span of a recorder—The signal level (number of millivolts) required to produce a change in the deflection of the recorder pen from zero to 100% on the chart scale.

splitter—A T-fitting attached to the column to divert a portion of the flow. An *inlet splitter* allows introduction of very small samples to a capillary column. An *effluent splitter* may be used to permit parallel operation of two detectors.

stationary phase—*See* **liquid phase.**

substrate—*See* **liquid phase.**

tailing—A form of band distortion in a chromatogram in which the trailing edge returns to the baseline relatively slowly, producing an asymmetrical band.

temperature programming—A technique in which the column temperature is gradually increased in order to expedite the elution of the higher boiling components.

thermal conductivity—A physical property of materials that is the ability to conduct heat from a warmer to a cooler object.

thermal conductivity cell—A chamber in which an electrically heated element is contained that, by its change in resistance, will reflect changes in thermal conductivity within the chamber atmosphere.

thermistor bead element—A type of thermal conductivity detection device in which a small glass-coated semiconductor sphere is used as the variable resistive element in the cell chamber.

vapor-phase chromatography (VPC)—*See* **gas chromatography.**

Electron Microscopy

by John G. Sheehan[1]

THERE ARE TWO MAIN TYPES of electron microscopes, the scanning electron microscope (SEM) and the transmission electron microscope (TEM). Today both SEM and TEM are used for microstructural examination in nearly all disciplines of science and engineering. The resolving power of electron microscopes is three orders of magnitude greater then light-optical microscopes. Modern SEMs with field-emission electron guns resolve better than 1 nm, and modern TEMs resolve better than 0.2 nm [*1*]. Contrast develops in SEM by electrons emitted at or near the surfaces of bulk specimens and therefore topography and composition are examined. Contrast develops in TEM by electrons transmitted through thin specimens and therefore variations in structure and composition are examined.

Types of signals generated in a sample of varying thickness by incident electron beam are illustrated in Fig. 1. The SEM collects secondary electrons (SE), backscatter electrons (BE), and X-rays from surfaces of bulk specimens. The TEM collects X-rays, elastically scattered electrons, and inelastically scattered electrons from thin and ultra-thin specimens. Hybrid TEMs have SEM capabilities: they collect BE that exit the incident-beam side of thin specimens, and they collect SE and X-rays from both sides. These are known as scanning transmission electron microscopes (STEM) or analytical electron microscopes (AEM).

SEM and TEM were both invented in the 1930s in Germany. TEM quickly became widely used to image replicas of surfaces at resolution far better than was possible with the first SEM and therefore further attempts to develop SEM were regarded as a waste of time. SEM did not become available commercially until 1965, when Cambridge Instrument Company marketed the "Stereoscan" [*2*]. Immediately SEM became widely used to examine coatings, as seen in American Chemical Society Symposia on SEM of coatings in 1968 [*3*] and again in 1972 [*4*]. Today the higher resolution available from SEMs has mostly replaced TEM of surface replicas, since TEM is no longer needed to see sub-micrometer pigment and latex particles. Therefore SEM will receive most of the attention in this chapter.

This chapter has three main parts: SEM, TEM, and applications to coatings. The SEM section begins with a discussion of image formation and signal collection; these must be understood to correctly interpret SEM images. Then, the electron-optical column that includes the electron gun, the condenser lens system, the scan coils, and the objective lens are discussed. The function of each must be understood in order to create ideal conditions for SEM imaging. Also included is a discussion of X-ray microanalysis, used to identify qualitatively or quantitatively the elements present in a sample. The SEM section ends with a discussion of metal coating, needed to prevent charge buildup on nonelectrically conductive samples during SEM imaging. As resolution of SEM has improved, it has become critical to coat samples with ultra-thin films (1 to 5 nm) that do not blanket surface details to be imaged.

The TEM section has a brief discussion of contrast and electron optics. The last section discusses some of the wide range of applications of electron microscopy to coatings, from practical problems of identifying contaminants, to fundamental research of latex coalescence and adhesion.

SCANNING ELECTRON MICROSCOPY

The scanning electron microscope (SEM) images surfaces at magnifications from about ×10 to ×200 000. Depth of focus is large, so rough surfaces can be imaged. The types of signals that can be collected include secondary electrons (SE), backscatter electrons (BE), and characteristic X-rays. An image of a sample in the SEM is formed on a cathode ray tube (CRT) by a dot-mapping process. As the electron beam scans the sample, the signal from each spot is collected, amplified, and synchronously displayed on the CRT with an intensity proportional to the collected signal. The same scan generator deflects the electron beam across both the sample and the CRT and therefore the signal displayed on the CRT is a magnified image of the scanned area.

A schematic diagram of the SEM is shown in Fig. 2. Electrons are pulled out of the gun by the electric field between the gun and the anode. The condenser lenses form the beam into a finely focused probe. The scan coils cause the probe to scan across the sample in a raster. The objective lens focuses the beam on the sample. Any combination of BE, SE, and characteristic X-rays can be detected. Details of the function of each component in the SEM are discussed below.

Image Formation

Most SEMs are equipped to detect secondary electrons (SE), backscatter electrons (BE), and characteristic X-rays as the electron beam scans across sample surfaces. The SE signal is produced when bound electrons are removed as a result of inelastic scattering of the electron beam. The intensity of

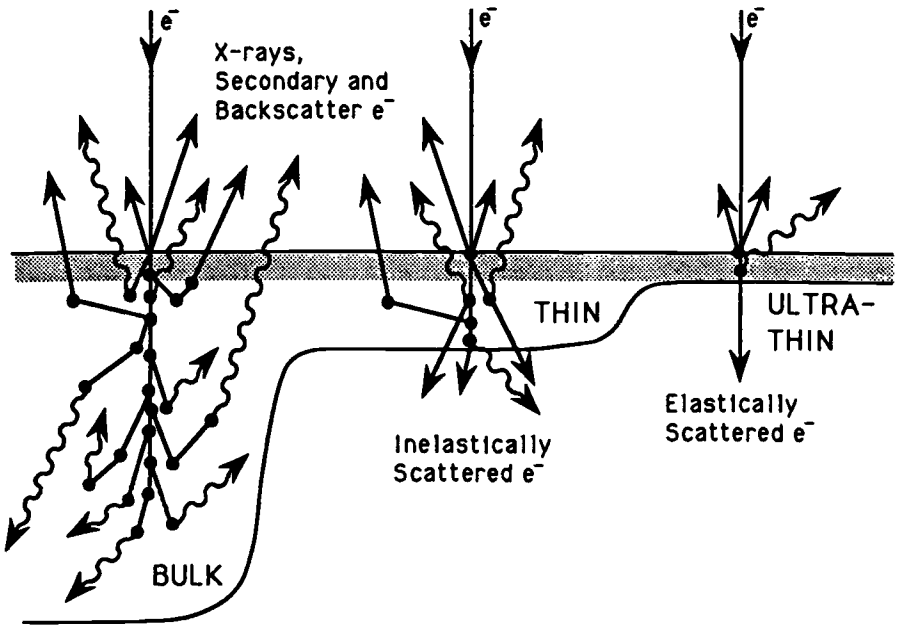

FIG. 1–Signal types generated by electron beams impinging on a sample of varying thickness. Adapted from Thomas [*1*].

the SE signal depends partly on the orientation of the sample with respect to the electron beam, which is why SE images are topographical.

Backscatter electrons (BE) result from elastic scattering. Electrons are elastically scattered when they penetrate the electron clouds of atoms and change direction, a result of coulombic interaction with the positively charged nuclei, known as Rutherford scattering. An electron is backscattered after a series of direction-changing elastic events that cause the electron to exit the sample. The probability of a backscatter event depends on the size of the nuclei and therefore backscatter contrast depends on the distribution of average atomic number in the sample. The depth in a sample from which BE information emerges ranges from about 80 nm for gold to about 600 nm for aluminum with an accelerating potential of 20 kV [*6*]. The yield of BE varies by only about 10% over an accelerating-potential range of 10 to 50 kV [*5*].

Most SEM images are collected with the Everhart-Thornley (ET) detector, shown in Fig. 3. The ET detector collects mostly SE and some BE. The main components of the ET detector are a collector grid, a scintillator, and a photomultiplier. SEs, whose average energy is about 3 to 5 eV [*5*], are pulled toward the scintillator by a 300-V potential on the collector grid. A 10-kV bias on the scintillator accelerates SEs enough to cause photon emission in the light pipe. The collection grid also protects the electron beam from deflection by the 10-kV bias on the scintillator.

Secondary electrons are classified into four types, shown schematically in Fig. 3. SE-1 are generated by direct interaction with the primary beam and therefore carry the highest resolution information. SE-2 are generated by backscatter electrons as they exit the sample surface and therefore generate sub-surface atomic number contrast. In 1940, before the first SEM images were collected, von Ardenne correctly predicted that SE-2 would limit resolution: SE-2 cannot be detected separately from SE-1. McMullan [*2*] wrote an historical account.

SE-3 are generated by backscatter electrons that strike the objective lens pole piece and the specimen chamber walls. SE-4 are generated when the primary beam strikes pole pieces and apertures. SE-3 generated at the objective lens pole piece can be reduced with a shield made of low SE-emitting material, such as carbon-coated aluminum, placed just below the objective lens. A +50-V bias, applied to the shield, also prevents escape from the shield of any SE-3. To increase atomic number contrast, BEs that strike the shield can be converted into SEs when the shield is positively biased or covered with a material that emits a large number of secondary electrons. Reimer [*6*] discussed signal types in detail. Peters [*7*] discussed high-resolution SE image formation.

There are two main types of BE detectors. One is the ET detector described above, an inefficient way to collect BE: the geometric collection efficiency of BE in an ET detector is only about 1 to 10% [*5*]. The efficiency is low because most BEs travel away from the sample in the beam direction, and ET detectors are usually mounted away from the beam axis. Collection efficiency is improved if a disk-shaped detector is placed at the bottom of the objective lens, with a hole in the middle for the electron beam. Both solid-state and scintillation-type detectors are used in this way.

To demonstrate the importance of understanding how SE1, SE2, SE3, and BE generate contrast in the SEM, three micrographs of the same area of a 1:6 styrene-butadiene latex:calcium carbonate coating formulation, air-dried from 80 wt%, are shown in Fig. 4. Micrographs in Figs. 4A and 4B were recorded at 20 and 5 kV, respectively, with an ET detector. In Fig. 4A, the calcium carbonate particles are visible from beneath the latex-film surface from a combination of SE-2, SE-3, and BE.

This is possible because the exit depth of BE from a latex film is about 1 μm at 20 kV. In Fig. 4B, the calcium carbonate

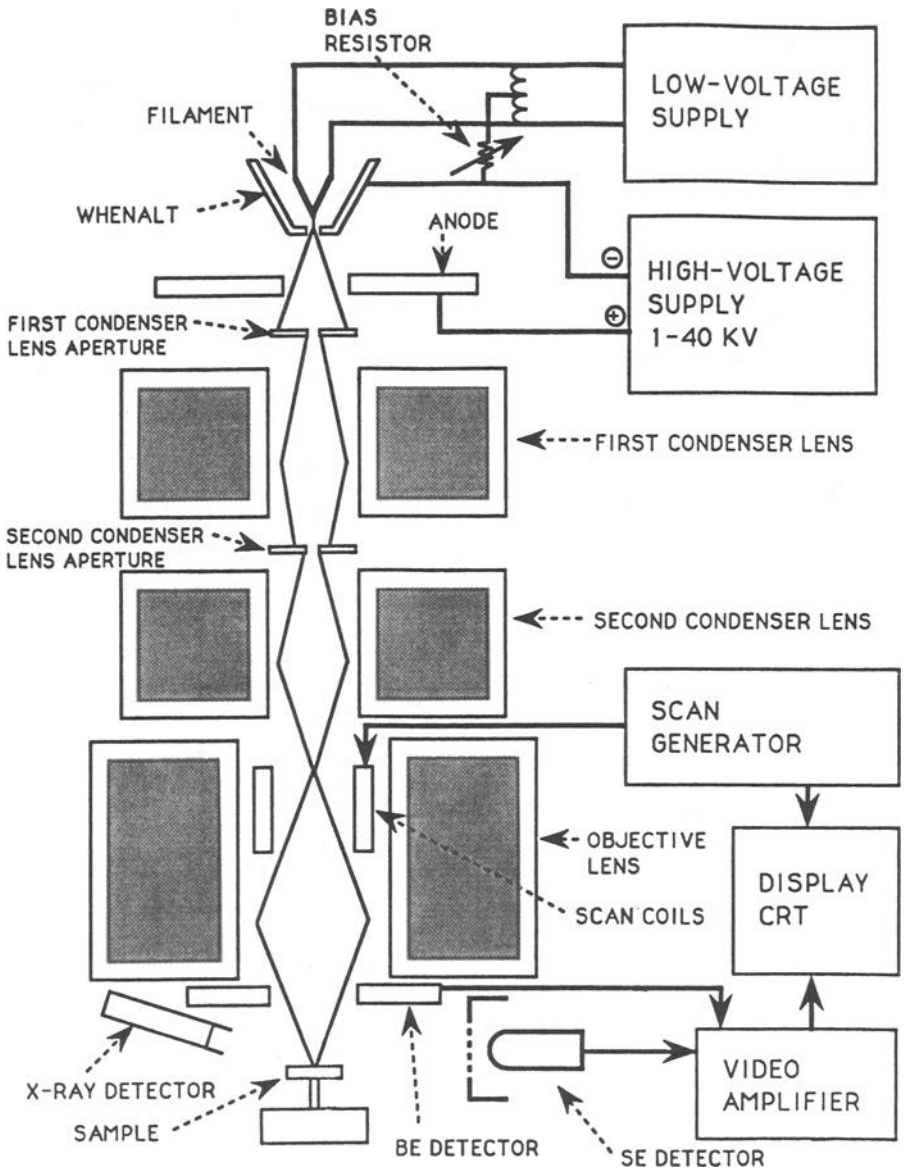

FIG. 2–Schematic diagram of an SEM with a thermionic electron gun. Adapted from Thomas [1].

particles are barely visible because the exit depth of BE, and therefore contrast from SE-2 and SE-3, is less than 100 nm at 5 kV. Comparison of Figs. 4A and 4B demonstrates the strong dependence of accelerating voltage on the appearance of SEM images: sometimes more than one accelerating voltage is needed for correct interpretation. Also, SE images at lower accelerating voltage better represent topography because the exit depth of BE is smaller.

The micrograph in Fig. 4C shows the same area as Figs. 4A and 4B, this time recorded with an annular solid-state BE detector that was attached to the bottom of the objective lens. Because no SEs were detected, the latex binder at the sample surface generated no contrast. Instead, contrast was generated by the distribution of calcium carbonate particles beneath the latex-film surface. This example illustrates the importance of understanding image formation in the SEM in order to correctly interpret images. Observation of only Fig. 4A would lead one to the false conclusion that the latex film does not cover all of the calcium carbonate particles.

X-Ray Microanalysis

Inner shell ionization is the event that triggers characteristic X-ray production. An X-ray photon is produced when an electron from an adjacent shell drops to an inner shell to replace the ionized electron. Each element has its own set of characteristic X-rays and therefore elements present in a sample can be identified qualitatively or quantitatively if a spectrum of emitted X-rays is collected.

There are two types of X-ray detectors, the wavelength dispersive spectrometer (WDS) and the energy dispersive spectrometer (EDS). In WDS, a small portion of the emitted X-rays hit a crystal. X-rays that satisfy Bragg's law for the crystal are diffracted to a proportional counter. X-ray spectra

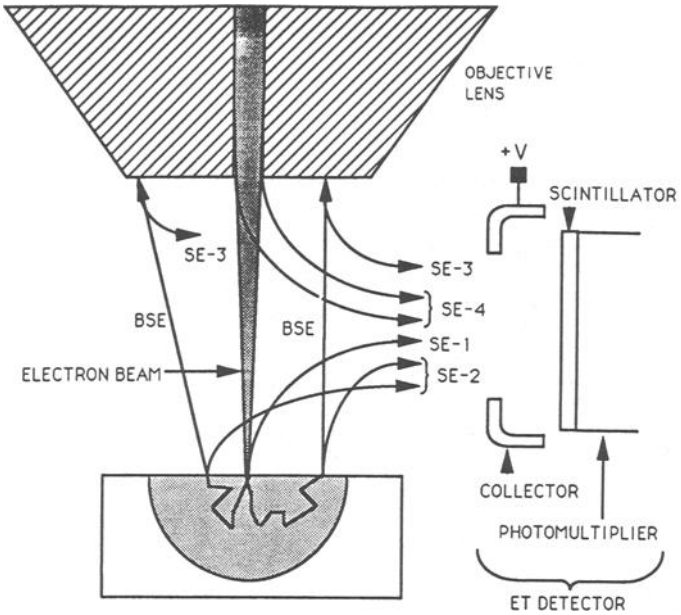

FIG. 3–Types of secondary electrons collected by the Everhart-Thornley detector. SE-1 carries high-resolution information, but it cannot be separated from SE-2. Adapted from Reimer [*6*].

are collected by varying the crystal angle. The advantage of WDS is high-energy resolution, 6 to 30 eV.

Before 1968, when EDS was introduced, all X-ray microanalysis was done with wavelength-dispersive spectrometers. Today, EDS is installed on most SEMs. In EDS, X-rays pass through a thin (ca 8-μm) beryllium window into a lithium-doped silicon detector. The energy of incoming X-rays is measured from the number of electron-hole pairs generated in the silicon detector. The beryllium window separates the vacuum in the microscope from the crystal. The crystal is cooled with liquid nitrogen to reduce the leakage current. Low energy resolution (about 150 eV) is the disadvantage of EDS compared to WDS. However, the whole energy spectrum in EDS can be recorded simultaneously and therefore elements in a sample can be quickly identified. The detection limit of an Si(Li) detector with a beryllium window is down to $Z = 11$ (Na). Windowless and ultra-thin window detectors extend the detection range down to $Z = 4$ (Be).

In quantitative X-ray analysis with EDS, the X-ray intensities of each element in a sample are measured and compared to the measured intensities of pure-element standards. The concentration of each element in the sample is the ratio of the X-ray intensity of each element in the sample to that in the standard. However, corrections are needed to account for the different ways X-rays are generated in the sample compared to the standard. These include backscattering and the stopping power (Z), X-ray absorption (A), and fluorescence (F). Together, these corrections are known as the ZAF correction. All EDS spectrometers available from commercial vendors have computer programs that calculate ZAF corrections. More on quantitative X-ray microanalysis is found in Refs *5* and *6*.

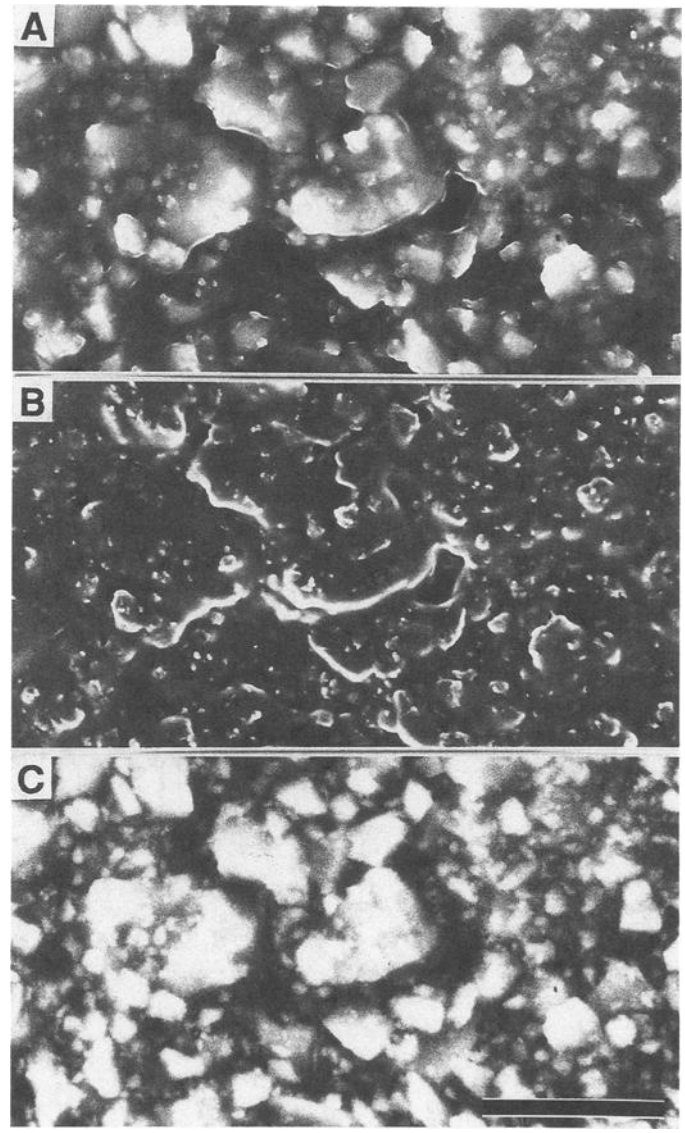

FIG. 4–Three SEM images of the same area of a coating formulation with 1:6 latex:calcium carbonate, air dried from 80 wt% aqueous suspension. (A) SE image at 20 kV; (B) SE image at 5 kV; (C) BE image at 20 kV. Bar = 10 μm.

Electron Guns

The ultimate resolution of an SEM is determined by the type of cathode in its electron gun. The main measures of electron gun performance are current density and diameter of the first crossover. High current density and a small first crossover are needed for high-resolution imaging.

There are two types of cathodes, thermionic and field emission (FE). Thermionic excitation occurs when a filament is heated to near its melting point, allowing electrons to overcome their work function and eject themselves into the vacuum. Tungsten and lanthanum hexaboride (LaB_6) are the most common thermionic cathode materials. Tungsten cathodes consist of a wire bent like a hairpin. They are easy to operate, and moderate vacuum prevents oxidation (1 to 5 $\times$ 10^{-3} Pa). However, they require frequent replacement: every 2 to 40 h. LaB_6 cathodes consist of a crystal of the material,

usually soldered to refractory metal strips. One advantage of LaB_6 over tungsten is its higher current density, 20 to 50 A/cm^2, compared to tungsten at about 3 A/cm^2. Another is the smaller diameter of the first crossover, about 10 μm for LaB_6 and 50 μm for a tungsten hairpin. Together, these make the resolution of LaB_6-equipped SEMs higher. Another advantage of LaB_6 cathodes is their longer lifetimes, 200 h or more. However, LaB_6 guns require more frequent and more precise alignment than tungsten guns. Better vacuum ($<10^{-4}$ Pa) is required to slow evaporation that results from reactions of LaB_6 material with oxygen-containing residual gases [*6*].

Field emission occurs when a huge potential gradient ($>10^7$ V/m) is applied to a tungsten tip of about 0.1 μm in diameter, causing electrons to tunnel through their potential barrier. No thermal energy is needed to lift the electrons over the barrier. The combination of high current density and small diameter of the first crossover in FE guns makes possible ultra-high resolution (<1 nm) SEM imaging, not possible with thermionic cathodes. The current density is around 10^6 A/cm^2, three orders of magnitude greater than LaB_6 cathodes. The diameter of the first crossover from a field emitter is only about 10 nm and therefore only one condenser lens is needed to demagnify the probe enough for high-resolution imaging. Gas molecules that strike the tip cause the work function to rise and the emission to fall. Field emitters that operate at room temperature (known as "cold-field" emitters) require vacuum better than 10^{-8} Pa. Even in a clean vacuum, gas molecules eventually cover the tip. The tip is cleaned by rapid heating to around 2300 K. Field emitters that operate at around 1200 K are less susceptible to gas molecules, and field-emission is stable at pressures up to 10^{-7} Pa [*6*].

SEM at low accelerating voltages (1 to 5 kV) has advantages of high topographic contrast, less specimen damage, and less surface-charge buildup. Until recently, low-voltage SEM was limited in resolution mainly by large chromatic aberrations in objective lenses, which arise from the large energy spread of electron beams from thermionic cathodes. This problem has been overcome by FE cathodes, whose energy spread is more than ten times smaller than in thermionic cathodes. The merits of low-voltage SEM with FE cathodes were discussed by Pawley [*8*].

Condenser Lenses, Scan Coils, and Objective Lenses

The purpose of the condenser lens system in the SEM is to deliver electrons from the first crossover to the specimen plane in a small-diameter, high-intensity beam. SEMs with thermionic electron guns have two condenser lenses, as shown in Fig. 2. Each condenser lens and spray aperture demagnifies the probe. The first condenser is placed halfway between the second condenser and the electron gun, and the second is placed halfway between the gun and the specimen. Two condenser lenses instead of one are advantageous because more electrons are collected and focused into the probe, and the probe diameter is smaller. The spray aperture in each condenser lens intercepts scattered electrons and decreases spherical aberrations. The first spray aperture is usually fixed, and the second is selectable to varying diameters. A small final probe diameter is not always advantageous because it makes small both the probe current and the signal-to-noise ratio. Higher probe currents are needed for EDS and some backscatter detectors. The operator must decide which combination of aperture and condenser lens currents fits the requirements of resolution and signal detection. Many modern SEMs do not have an aperture in the objective lens, and therefore the second condenser aperture is often called an "objective" aperture because it is the aperture closest to the sample. This can be a source of confusion because textbooks on SEM call the final aperture in the objective lens the "objective" aperture.

The scan coils deflect the electron beam across the sample in a raster. Magnification is the ratio of the CRT width to the raster width. The probe is focused at the sample surface by the objective lens. The distance between the objective aperture and the sample is known as the "working distance." The depth of focus is inversely proportional to the working distance. But probe diameters are small when the beam is focused at short working distances. So high-magnification imaging should be done at short working distances, and low-magnification imaging should be done at long working distances, where depth of focus is high.

Metal Coating for SEM

Metal coating of non-electrically conductive samples for SEM examination is required to prevent charge buildup during imaging, and metal coating increases the SE yield of non-electrically conductive samples. Coatings should be thinner than the size of the smallest surface details to be imaged. It is often written that sample preparation for SEM is "easy." However, great care is required to coat samples with ultra-thin (<5 nm) continuous films needed in order to take advantage of the high resolution now available from LaB_6 and FE-equipped SEMs.

Metal coating is best explained by theories of nucleation and growth [*9*]. During nucleation, metal atoms strike the sample surface and diffuse until they find a nucleation site, often a surface inhomogeneity, where it is energetically favorable for them to stick. Grains grow at each nucleation site as atoms arrive by either surface diffusion or direct impingement. As growth continues, adjacent grains touch and eventually begin to coalesce. When enough of the grains have touched, the film becomes electrically continuous. The area density of nucleation sites determines the size of grains required to form a continuous film. When there are few nucleation sites, grains must grow large in order to form a continuous film. When there are many nucleation sites, tiny grains grow together and form a continuous film. The strategy of ultra-thin (<5 nm) coating for high-resolution SEM is to increase the area density of nucleation sites, so that thinner, continuous films are formed with smaller grains.

Coating techniques for SEM include thermal evaporation, d-c plasma sputtering, and ion beam sputtering. Films are formed by thermal evaporation when metal is heated to its melting point in a high vacuum ($<10^{-3}$ Pa). Films formed by thermal evaporation have large grains compared to other techniques, but grain size decreases with decreasing substrate temperature [*10*]. Thermal evaporation of gold quickly became the standard coating technique when SEMs first became widely available in the late 1960s. But as the resolution of SEMs improved, the grain size of metal coatings became a limit to resolution. Coating techniques that produce thinner,

continuous films with smaller grains were needed. D-c magnetron sputtering is one of them.

In d-c magnetron sputtering, films are formed when ionized, inert gas atoms strike a metal cathode to eject metal atoms, which strike the sample. Ionization efficiencies and, hence, sputtering rates are increased with an annular magnetic field that surrounds the cathode to concentrate electrons in the cathode area [*11*]. Films made with d-c magnetron sputtering have smaller grains than thermally evaporated films. However, grain size is sensitive to contamination [*12*], and artifacts are often present [*13*]. The d-c magnetron coater is now standard equipment in the SEM lab. Many models are available and prices vary widely. Inexpensive models are evacuated with rotary mechanical pumps. Care should be taken not to allow rotary-pumped coaters to reach their ultimate pressure, otherwise pump oil can disrupt nucleation when it contaminates the target and the sample. State-of-the-art magnetron coaters are evacuated with oil-free turbomolecular pumps and equipped with cold stages because low sample temperatures promote nucleation.

A more recent development in metal coating for high-resolution SEM is ion beam sputtering. Films are formed by ion beam sputtering when a collimated ion beam strikes a metal target to eject metal atoms [*14*]. Mean grain sizes of 1 nm have been obtained for both gold and platinum [*15*], too small to be resolved with SEM. Dislodged metal atoms have about 100 eV of kinetic energy. It is speculated that high kinetic energy metal atoms implant themselves into sample surfaces, causing increased nucleation density and small grains. Ion beam sputtering is becoming widely used for ultra-high resolution SEM.

Metal film thickness should be measured to insure that only enough metal is deposited on the sample to form a continuous film. The quartz microbalance is the most widely used instrument to measure film thickness on electron microscopy specimens. Film thickness sensitivity is equivalent to about 0.05 nm of gold. Methods of film-thickness determination were discussed by Flood [*16*].

Cryogenic SEM

Conventional electron microscopes have a vacuum better than 10^{-3} Pa in their specimen chambers. This limits conventional SEM to dry samples. When volatile samples like paints are placed in the SEM specimen chamber, their solvents quickly evaporate, damage the vacuum pumps, and cause the electron beam to scatter. One solution is to lower vapor pressures by freezing and examine samples in an SEM equipped with a stage cooled by liquid nitrogen. The technique is known as cryogenic SEM (cryo-SEM), described by Sheehan [*17-19*] for examining paper-coating formulations. The reader is also referred to Echlin [*20*] for more on techniques of cryo-electron microscopy.

The procedure of cryo-SEM is to fast-freeze each sample and transfer it into a vacuum chamber attached to the SEM specimen chamber. There each sample is fractured, sometimes etched, and then coated with a thin metal film. Then each sample is transferred to the cold stage in the SEM. The challenges of high-resolution cryo-SEM are to freeze fast enough to prevent noticeable growth of ice crystals, transfer without condensing water vapor on the fracture surfaces, coat frozen-hydrated samples with an ultra-thin, continuous metal film, and image in the SEM without too much buildup of contaminants.

Wet microstructures of coating formulations can be examined with cryo-SEM after freezing and fracturing. Complementary fracture faces of a frozen-fractured pigment/latex coating formulation are shown in Fig. 5. Kaolin and calcium carbonate particles can be identified by their morphologies. The dark areas between the particles are ice. Close examination of the complementary faces shows that fracture propagated around the pigment particles.

The stages of drying can be fixed by freezing and examining with cryo-SEM. A cross section of a fractured drop of a 20 wt% aqueous suspension of styrene-butadiene latex is shown in Fig. 6. The drop was placed on a glass slide, air-dried for 3 min, and plunge-frozen into liquid ethane. The lower part of

FIG. 5–Cryo-SEM image of complementary fracture faces of a coating formulation. Bar = 1 μm [*18*].

Fig. 6 is the cross section (CS), and the upper part is the drop's surface (S) that was exposed to air during drying. Latex that was deformed during fracture is seen on the cross section. Hexagonal close packing of latex is seen on the surface.

Environmental Scanning Electron Microscopy

Cryo-techniques are one way to image volatile samples in the SEM. A recent breakthrough in SEM that allows imaging of wet, volatile specimens without freezing is known as environmental SEM (ESEM) [*21*]. In ESEM, samples are imaged in a gaseous environment at pressures up to 2.7 kPa. This is made possible by a combination of a differentially pumped vacuum system, small travel distances for the electron beam in high-pressure gas, and a new biased specimen current detector known as a gaseous detector device (GSD). The gas in the specimen chamber is a medium for SE signal multiplication, and it neutralizes charge buildup on samples. Therefore, metal coating is not required for electrically insulating samples. Ultimate resolution is near that for a conventional SEM, about 5 nm. But one cannot expect this resolution from electrically insulating samples without metal coating because SE contrast is low from electrical insulators in ESEM.

The main advantage of ESEM compared to conventional SEM is that hydrated samples can be examined at saturated vapor pressures of water. This makes accessible dynamic imaging of wetting and drying by controlling sample temperature and water-vapor pressure. An ESEM image of dry paper, taken in 800 Pa of water vapor at 20°C, is shown in Fig. 7*A*. Water was condensed on the same area by raising water-vapor pressure to 1.3 kPa and lowering sample temperature to 12°C. An image is shown in Fig. 7*B*. Most of the fibers are covered with water.

Care must be taken during ESEM of hydrated specimens to avoid specimen damage by radiolysis products of water. Water molecules are radiolyzed by the electron beam into mainly hydrogen and hydroxyl radicals, which diffuse into specimens and sometimes damage them [*22-24*].

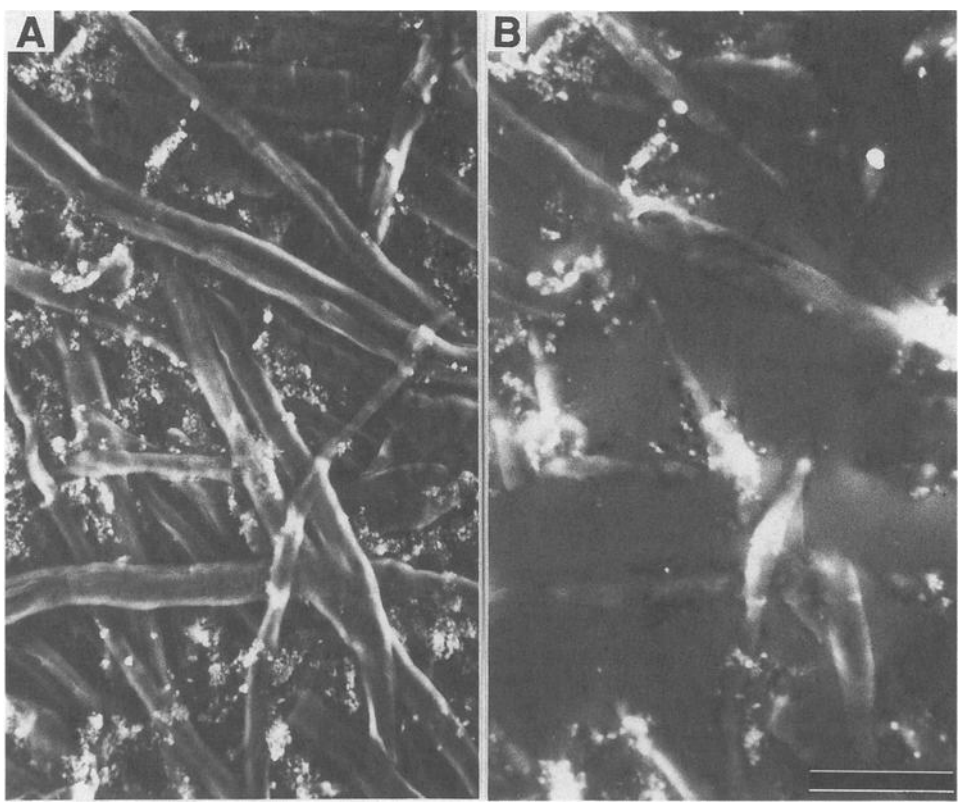

FIG. 7–Two ESEM micrographs of the same area of paper (A) before wetting; (B) wet. Bar = 50 μm.

TRANSMISSION ELECTRON MICROSCOPY

The TEM produces images from electrons that transmit themselves through thin and ultra-thin samples, as shown in Fig. 1. High-resolution TEMs resolve better than 0.2 nm. Types of contrast include scattering, diffraction, and phase contrast. The maximum useful thickness of amorphous samples at 100 kV is 100 to 3000 nm. The maximum useful thickness of metal foils and crystalline materials at 100 kV is 50 to 200 nm [*25*].

Types of Contrast

Electron beam-specimen interactions in thin and ultra-thin samples that lead to contrast in the TEM are shown in Fig. 1. Electrons are elastically scattered by coulombic interactions with positively charged nuclei as they travel through TEM specimens. Scattering contrast is also known as mass-thickness contrast because the amount of scattering depends on specimen thickness and atomic number. Scattering contrast in TEM can be imaged in the bright-field mode and in the dark-field mode. In the bright-field mode, electrons that are scattered at larger angles are intercepted by the objective aperture. Others pass through the objective aperture and form the image. In the dark-field mode, only the electrons that are scattered at large angles are used to form the image. This is accomplished by tilting the electron beam off axis or by moving the objective aperture off axis.

Another type of contrast caused by elastic scattering is known as phase contrast, the result of interference between the scattered and the unscattered electrons. Phase contrast varies as the objective lens focus is varied above or below the specimen.

Diffraction contrast results when Bragg reflections from crystalline planes interfere with the primary beam. The interference image gives information about crystal structures.

Inelastic interactions in TEM are plasmon excitations and inner-shell ionizations. Some TEMs are equipped with electron spectrometers that measure the energy loss spectrum, known as electron energy loss spectroscopy (EELS). Electronic structures are indicated by plasmon losses, whose energies are less than 50 eV. Chemical compositions are indicated by losses from inner shell (K, L, and M) ionizations [*25*].

Optics

A schematic of an electron-optical column of a TEM is shown in Fig. 8. The electron-optical column of the TEM differs from the SEM in several ways. First, the electron beam is not scanned across the sample. Instead, the condenser lens system illuminates the entire area to be imaged and a set of projector lenses beneath the sample focus the transmitted electrons on a phosphor screen, where the image can be viewed. This points to the second major difference: the purpose of the condenser lens system is not to produce a finely focused probe at the sample, as in SEM. Instead, the condenser lens system in TEM illuminates the entire area of interest with the highest electron density that will not damage the sample. Third, the TEM has a projector lens system, making imaging more difficult than in SEM. Fourth, higher accelerating potentials (100 to 1000 kV) in TEM are needed to transmit electrons through thin samples. Accelerating potentials in SEM range from about 800 V up to 40 kV.

In most imaging modes, Condenser Lens 2 is excited and Condenser Lens 1 is shut off. However, both condenser lenses are excited in TEM scanning modes, where a finely focused probe is required.

The purpose of the projector lens system is to project the transmitted electrons into an image on the phosphor viewing screen or photographic emulsion. Magnification is set by the objective lens. The objective aperture blocks scattered electrons in the bright-field mode, discussed above. Contrast is increased if a small objective is selected, but a large objective aperture is needed for high-resolution imaging.

APPLICATIONS TO COATINGS

Film Thickness Measurements

Film thickness measurement requires cross sections. There are several ways to cross-section a dried coating. The simplest is to cut by hand with a razor blade. However, the cross section will be smoother if the cut is with a microtome equipped with a diamond knife. Cross sections of coated paper are made with a microtome after embedding the paper in epoxy [*26*]. A BE image of microtome-sectioned, coated paper is shown in Fig. 9. The coating appears lighter than the fibers because of its greater average atomic number.

ASTM Test Method for Microscopic Measurement of Dry Film Thickness of Coatings on Wood Products (D 2691) states that the specimen may be sliced with a microtome or a razor blade. Whitehead [*27*] pointed out that brittle paint films can be shattered when cut with a microtome. Also, the diamond knife in a microtome is easily damaged by hard paint films. Grinding and polishing of epoxy-embedded specimens is one solution.

Failures and Defects

Pits, cracks, and loss of adhesion can be readily examined with SEM. Some contaminants can be identified by their morphologies and others by their characteristic X-rays. Here are some examples: SEM examination of a paint film that failed rapidly in a salt spray test revealed a textured surface that rusted rapidly in the pitted areas. When the paint was applied with a smooth finish, it passed the salt spray test. Poor scrubbability in a latex paint was due to lack of coalescence, readily apparent after SEM examination revealed many cracks in the film. Loss of adhesion on metal reflectors was due to insect eggs which pulled the paint off as the eggs dried. A glossy varnish which turned out flat was found to be laden with diatomaceous earth from a broken filter [*28*].

Labana and Wheeler [*29*] mapped the distributions of ions in a corroding metal-coating interface of painted phosphated steel. Ion distributions were mapped quantitatively by electron microprobe analysis equipped with wavelength dispersive detectors.

Quach [*30*] used SEM with an EDS to identify contaminants responsible for adhesive failures. Welding splatter was identified as a cause of chipping of paint on a steel building

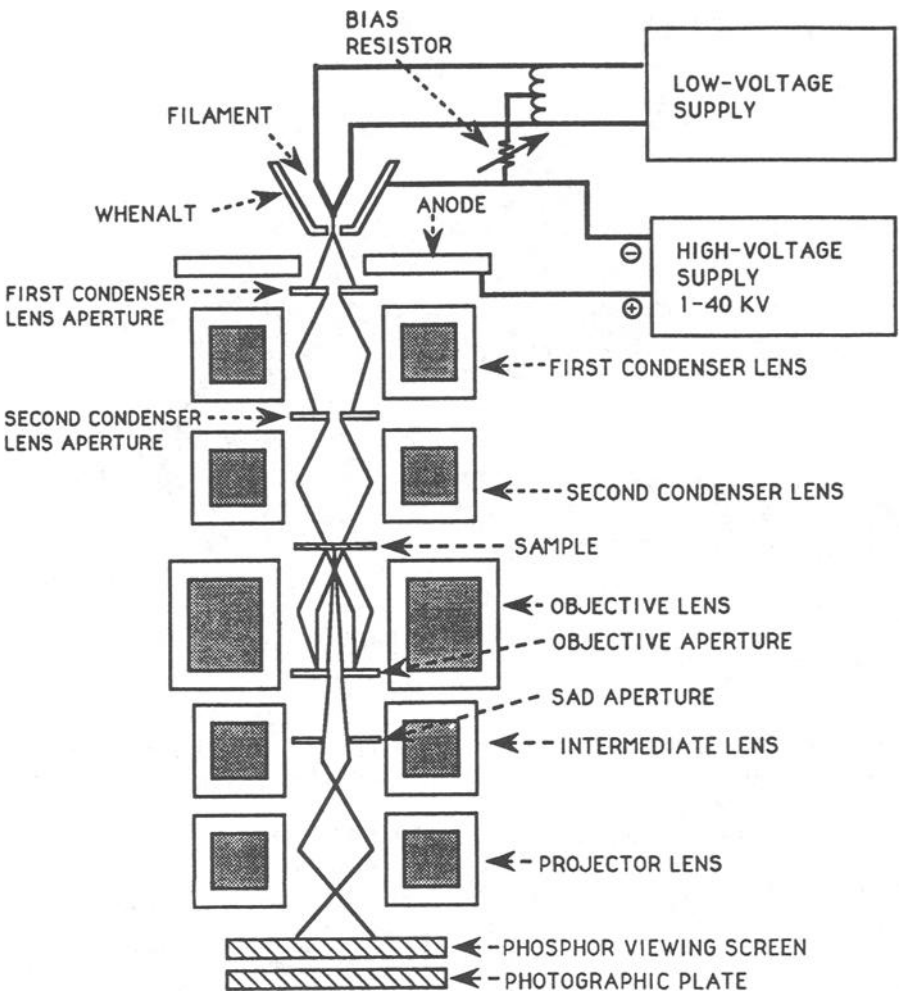

FIG. 8–Electron-optical column of the TEM. Adapted from Thomas [*1*].

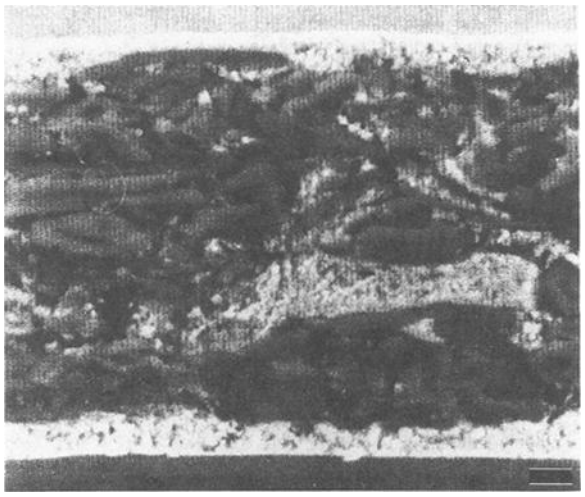

FIG. 9–Microtome-sectioned paper showing thickness of the coating and its penetration into the sheet. Bar = 10 μm. From H. Matsubayashi [*26*].

chord. It was also shown that the EDS identified plaster dust, fly ash, and SO_2 as contaminants that caused adhesive failure in other samples.

Identification of Pigments

Pigments of known morphologies can be identified easily with both SEM and TEM. Some pigment particles are smaller than 0.1 μm and therefore metal coatings must be ultra-thin in order not to blanket morphologies of the particles before SEM imaging. Pigment particles can also be identified in SEM by their EDS spectra if the particles are larger than a few micrometers. Identification of smaller particles in SEM with an EDS is hampered by the large generation volume of X-rays.

Figure 10 shows images of kaolin clay taken with SEM (10A) and TEM (10B). The different contrasts in the SE mode with the SEM and in the bright-field mode with TEM are clear. The SE contrast is topographical, and the TEM contrast depends on mass-thickness. In both, the hexagonal, plate-like habits of particles are indicators of the presence of kaolin.

Pigment Particle Sizing

The microscope is the best and also the most tedious method of determining the particle size of pigments. Other methods do not provide information of the individual shapes of the particles and sometimes give only an average particle

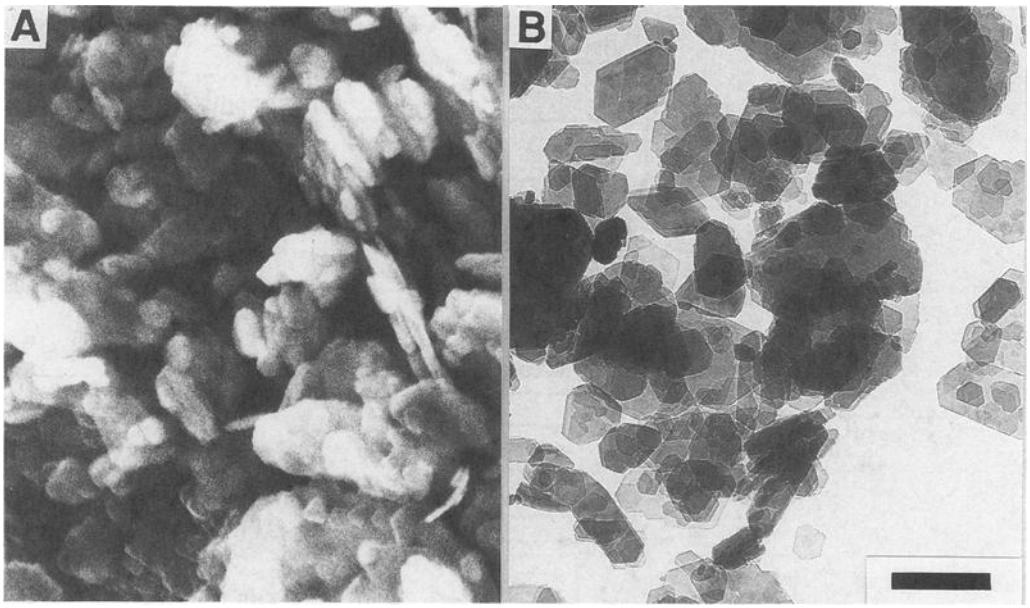

FIG. 10–Kaolin clay imaged in (A) SEM; (B) TEM. Bar = 0.5 μm. Photo by R. P. Gursky.

size without regard to size distribution. The microscope is especially useful for measurement of plate-like and needle-shape particles that do not obey Stoke's law on which the sedimentation methods are based. However, microscopic methods are slow and laborious, a disadvantage [*28*].

In the past, particle-size analysis was made by manually recording particles with the aid of a reticle. The reticle is an aid to manually counting the number of particles in each size class. However, techniques of computer-aided image processing can eliminate tedious, manual counting of hundreds or even thousands of particles.

Structure of Antifouling Paint Films

Bishop and Silva [*31*] examined leaching of pigment in cross sections of anti-fouling paint films. Cross sections were made by fracturing in liquid nitrogen. They found a linear correlation between the leached matrix thickness and the volume fraction of pigment. Examination of complimentary fracture faces was required to see if leached pigment or fracture was responsible for voids. They also showed that the insoluble matrix of microtome-sectioned films was distorted.

Paint Film Weatherability

SEM examination of weathered paint films showed that chalking onsets when binder wears away from between pigment particles [*32,33*]. However, the conclusion was that SEM images point to the cause of chalking, but gloss measurements are a more quantitative and economical method.

Latex Coalescence and Adhesion

Contact diameters of various sizes of latex have been measured with SEM [*34*] and TEM [*35*] and compared to theoretical predictions. Demejo et al. [*36*] imaged with high-resolution SEM extents of latex deformation resulting from particle-substrate adhesion and compared their results to theoretical predictions.

Acknowledgments

Thanks go to H. Matsubayashi (Nippon Zeon Co., Ltd., Kawasaki, Japan) for supplying the SEM micrograph of cross-sectioned, coated paper and R. P. Gursky (Unilever Research, Edgewater, NJ) for supplying the TEM micrograph of kaolin clay.

Infrared Spectroscopy

by Jack H. Hartshorn[1]

INFRARED (IR) SPECTROSCOPY IS AMONG THE OLDEST and most valuable of the instrumental techniques available to the coatings laboratory. It permits investigation of materials in nearly any physical form; liquid, solvent solution, cast film, ground powder, and even dried paint are amenable to this technique. While transmission of the IR beam through a thin film is the preferred mode of analysis, a wide range of accessories permit examination of nearly any kind of sample. IR provides qualitative data not easily generated by other analytical techniques. This is especially useful for probing industrial problems, where one spectrum can frequently produce all information necessary for the solution. Coupling IR instruments to computers has vastly increased their effectiveness. Spectral subtraction can often reveal hidden components and produce separations that are not practical chemically. The identification of unknown materials is now readily performed by spectral searching using digital pattern matching. The evaluation of curing, weathering, and durability chemistry can be conducted on new formulations. IR spectroscopy is currently being used to do quality assurance. Over the past four decades IR instrumentation has grown until it is now an essential part of any coatings laboratory.

INFRARED ABSORPTION

All matter either emits or absorbs radiant energy in response to its atomic and molecular structure. The electromagnetic spectrum, Fig. 1, represents that relationship. The most familiar region of the spectrum is the visible portion because that is the part we see and the paint formulator utilizes to produce his aesthetics. Immediately adjacent is the longer wavelength infrared region. This is of particular interest to the coatings analyst since organic chemicals have unique absorption bands in this range. These products include solvents, resins, polymers, additives, and a host of paint constituents. Many inorganic materials used as pigments absorb here as well. The region from 2.5 to 25 μm (or 4000 to 400 cm^{-1}) is particularly informative since here the structural bonds in organic molecules have fundamental vibrational modes. Thus, molecular compositions can be deduced from IR spectral band assignments. Structural interactions produce spectral signatures or "IR fingerprints" that can be used to identify those materials. Examination of the IR spectrum thus produces important information as to the composition of a paint film and the chemistry of a coating.

An in-depth discussion of IR spectroscopy theory and practice is beyond the scope of this chapter. However, there are a number of excellent texts on vibrational spectroscopy and IR band assignments for those interested in pursuing the subject [*1–3*]. The most useful discussion for the paint chemist is the recently updated and expanded *An Infrared Atlas for the Coatings Industry* published by the Federation of Societies for Coating Technology [*4*].

DISPERSIVE INSTRUMENTATION

Infrared spectroscopy became a practical contributor to the coatings laboratory with the development of double beam instrumentation shortly after World War II [*5*]. This instrumental design directs an IR beam through the sample and compares it with a corresponding reference beam. The spectrum is incrementally scanned to produce a graphic output of the sample's transmission characteristics. Figure 2 shows a simplified double beam IR spectrophotometer depicting the essential elements. An electrically heated wire or ceramic rod source irradiates an IR continuum. Two spherical mirrors, M_1 and M_2, focus that energy to form two equivalent rays, one for the sample and the other a reference beam. Mirrors M_3 and M_4 recombine the two at the "chopper," which alternately views each beam. The chopped beam is then routed through the monochromator, which examines each wavelength sequentially. S_1 is the entrance slit, and S_2 is the exit slit. Their function is to provide spectral resolution and to compensate for variations in source intensity and detector response. Originally, the dispersive element was a rock salt prism, but this was superseded by more energy-efficient gratings. Two or more gratings are usually required to cover the entire IR range. The detector alternately "sees" and compares the sample and reference beams. When an absorption band is detected in the sample, the reference beam is attenuated by interposing an optical wedge to match the sample's transmission. Some recent instruments have employed electronic compensation rather than mechanical blockage. The attenuator is linked to the vertical displacement of the chart pen, while the monochromator is coupled with the horizontal chart drive to produce a transmission versus wavelength or frequency presentation. An in-depth discussion of this instrumentation is available in IR texts [*4,6*] and in manufacturers' literature.

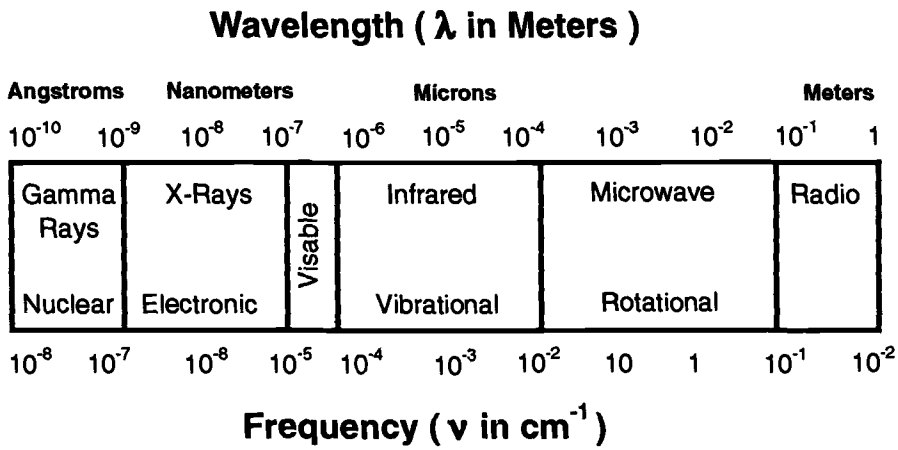

FIG. 1–Electromagnetic spectrum.

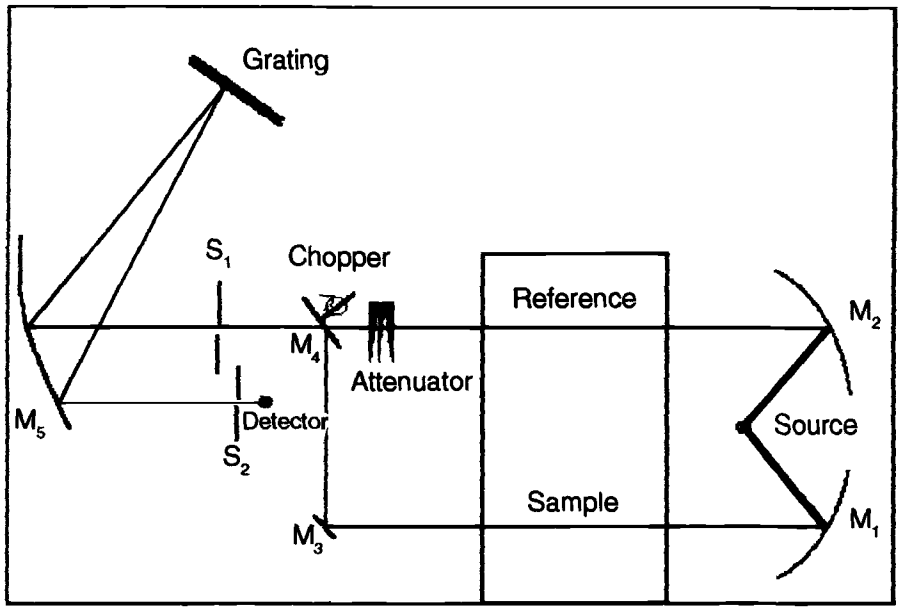

FIG. 2–Simplified double beam spectrophotometer.

Dispersive instruments have contributed substantially to our understanding of coatings and to the solution of many industry problems. However, those instruments have serious limitations that restrict many applications. Throughput energy is often inadequate for unfavorable samples and for many sampling accessories. The paper chart output requires an experienced technician for interpretation so that the value of any spectrum depends upon the skill and competency of the operator.

EMERGENCE OF FTIR

A new approach to producing infrared spectra became commercially available in the 1970s. Interferometry, or Fourier transform infrared (FTIR) spectroscopy as it is more popularly known, acquires data based upon an entirely different principle. Figure 3 shows the essential elements of a FTIR interferometer. Mirror M_1 collimates the energy from an IR source onto a beamsplitter, where the energy is divided between a stationary mirror, M_2, and a moving mirror, M_3. The two reflections are combined at the beamsplitter to produce a harmonically modulated beam. The mirror motion is precisely driven by a linear motor, and its location accurately tracked by a helium-neon laser. Its optical path (M_6 and laser detector, D_L) retraces the beam to produce that information. The interferometer's output goes through the sample compartment and is focused onto the IR detector by M_4 and M_5. Figure 4 shows a typical interferogram. A digital computer mathematically transforms the interferogram via the Fourier relationship into a traditional IR spectrum. The sample spectrum is then ratioed against a reference spectrum, which is usually taken immediately prior to the sample scan and stored in the computer. That results in the familiar transmission versus wavelength or frequency presentation. This equipment is much faster and more sensitive than dispersive instruments, and it also produces spectra with much greater precision and reproducibility. While the optics are fairly sim-

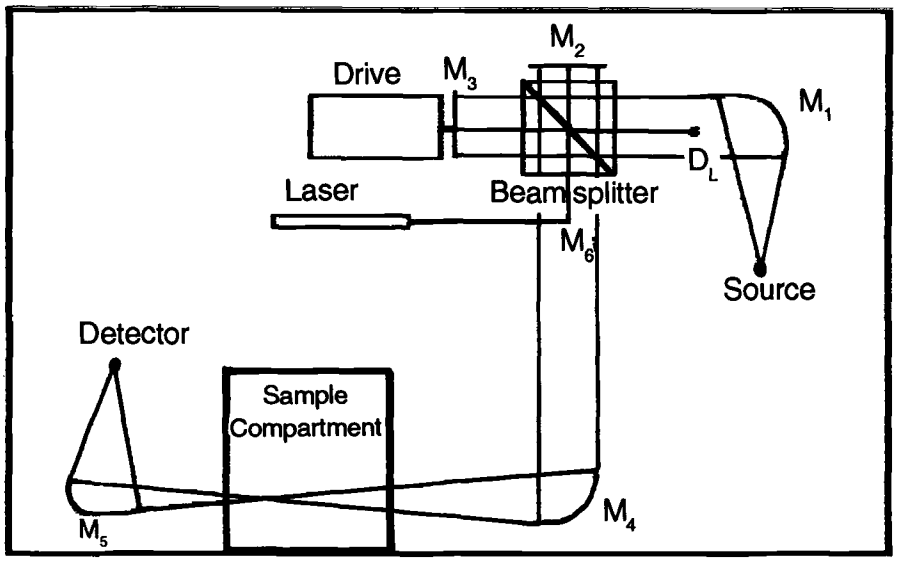

FIG. 3–Fourier transform interferometer.

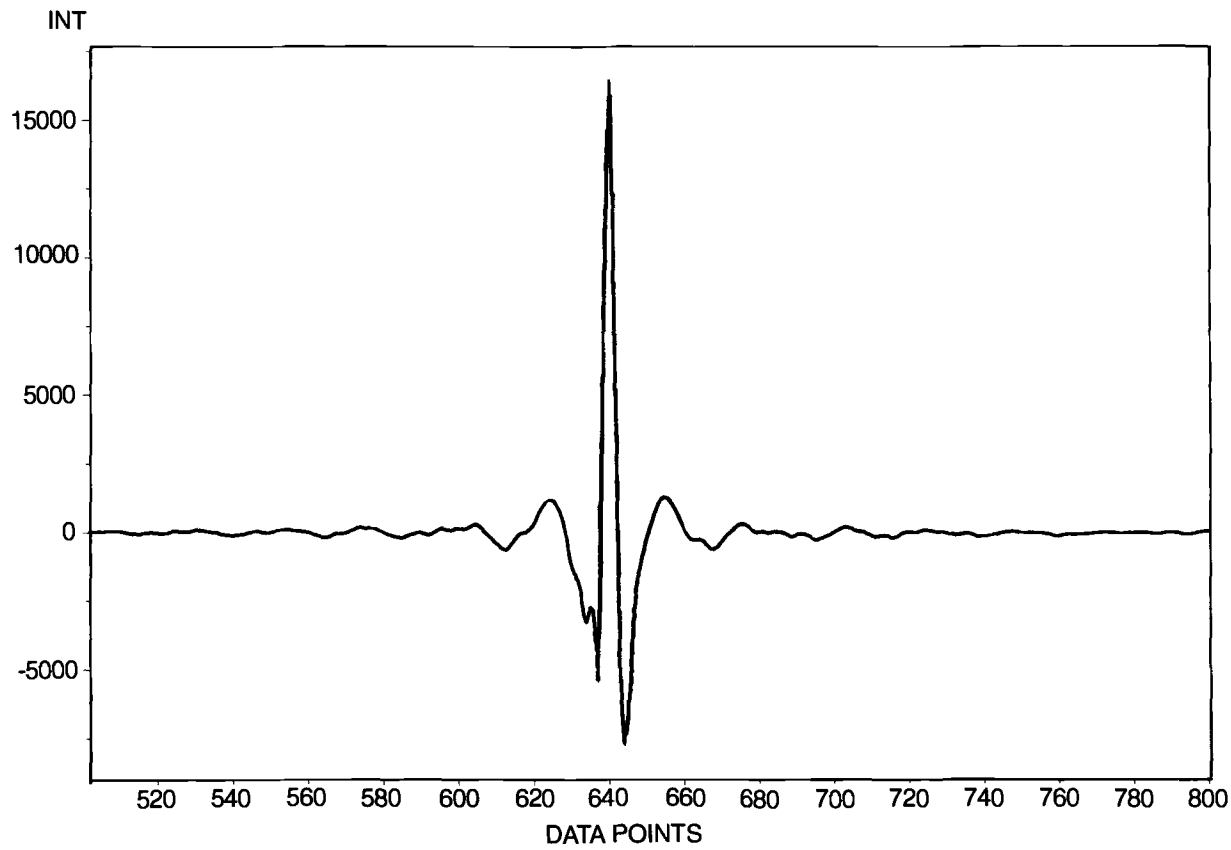

FIG. 4–Typical interferogram.

ple, the theory and calculations are complex. They have been well documented along with the advantages of FTIR [7]. These features make it extremely valuable to the coatings spectroscopist, and the enhanced capabilities permit the use of accessories and techniques that were too inefficient to be used in older instruments. The dedicated computer can also be used to produce uniquely valuable information.

SAMPLE PREPARATION

IR became popular in the paint laboratory because of the useful information that can be obtained by merely spreading the binder on a salt plate, evaporating the solvent, and scanning it [8]. This is still the method of choice whenever possible. However, not all samples can be examined as cast films,

so additional techniques have evolved to fulfill much broader requirements. Gases, which have very sharp, well-resolved spectra, need only be confined in a cell with appropriate windows to be analyzed. Gas cells are available with path lengths from a few centimeters to tens of meters. The volume is matched to the concentration of the gases to be measured. Liquids can be studied merely by squeezing them between two salt plates to produce a capillary film. These films make excellent spectra, and the intensity can be varied by changing the compression. Cells of known path length can be formed by introducing spacers of controlled thickness between the plates. Solids such as pigments are often ground with potassium bromide (KBr) powder and pressed under vacuum to produce clear pellets. Alternatively, solids can be ground in mineral oil or fluorolube and examined as mulls smeared onto salt plates. These techniques continue to be the sample preparations of choice because they are the simplest, most convenient, and have the best reproducibility. The quantity and value of the data generated are unfortunately highly dependent on the skill and experience of the operator. The best applications of this technique rely on the spectroscopist's faculty for pattern recognition and a good spectral library such as the more than 2500 spectra collected by the Infrared Spectroscopy Atlas Working Committee of the Federation of Societies for Coatings Technology [*4*].

SAMPLING ACCESSORIES

The preferred sampling method is to spread a material on a salt plate, flash the solvent, and run a transmission spectrum [*8*]. When this is not feasible, the procedures previously described are the first choices. However, our ability to examine coatings has been enhanced by a host of accessories. Their utility is greatly enhanced by FTIR's speed and sensitivity. The most successful of these techniques is attenuated total reflectance (ATR). Here, the sample is pressed against a special crystal which carries the IR beam. The optical interaction between the two appears similar to a transmission spectrum. There are, however, some major differences in band shape and intensity, which are dependant on the wavelength. ATR units are available in many configurations so that liquids, powders, films, dry panels, and almost any physical form can be accommodated.

With the advent of FTIR, a wide variety of new techniques have been developed for dealing with difficult samples and unique applications. Thin films on reflective surfaces may be investigated via specular reflectance, and rough surfaces or powders are examined by diffuse reflectance. Solids that can be heated may even be studied using their emission spectra. Dry solids and films have been investigated by detecting the sounds they produce when exposed to the FTIR beam (photo acoustic detection). Recently, infrared microscopes have become available which can focus on areas as small as 10 μm. Any of these approaches can be of great benefit to the coatings analyst, but it should be recognized that each has its own unique advantages and limitations.

DATA PROCESSING

The digital computer, which performs the Fourier transform to convert the interferogram into a normal spectrum, can also be utilized for additional tasks important to the coatings analyst. Some of these were previously thought impossible. Since the transformed spectrum is already in digital form, a variety of data processing operations, such as baseline correction, scale expansion, plot modification, smoothing, etc., can be readily performed. The computer can also execute a number of mathematical operations such as conversion to absorbance, band deconvolution, peak height measurement, and area quantitation. However, the most valuable asset is its ability to subtract one spectrum from another. This feature can be used to make separations that would be very difficult to perform chemically. The spectra are stored on magnetic disks for examination at any time and can be retrieved later without any loss in precision or integrity. Thus, samples for comparison need not be run at the same time. The computer can also rapidly compare one spectrum with a whole library of reference spectra and display the most likely choices. This can be a great blessing to the fledgling spectroscopist trying to gain experience. Finally, the computer can be preprogrammed to carry out nearly all the instrumental operations automatically. This allows the operator to concentrate on sample preparation and spectral interpretation. It also permits essentially "black box" operations by technicians.

APPLICATIONS TO ROUTINE PAINT PROBLEMS

Every paint laboratory is confronted at times by crises. The analytical laboratory is usually called upon to contribute to its resolution by answering questions like "What is this stuff?," "Where did it come from?," "What's the matter with this batch?," and "Why is this different from what we expected?." Such questions orginate from all parts of the organization—formulators and polymer chemists, plant support personnel, and customer service representatives. All these requests are important and require immediate attention. Infrared is usually the first step in executing an analysis program since it provides the most qualitative information in the shortest amount of time with the least sample preparation. Fourier transform spectroscopy makes this process considerably easier because it allows the spectroscopist to obtain a useful spectrum from almost any material. A spectrum can be obtained from nearly any amount of material that can be visually detected and isolated. If the amount is too small to see with the unaided eye, one is never certain that it is within the IR beam. With the development of IR microscopes, even this constraint is minimized. Once a spectrum is acquired, much can be learned about the material and an analysis scheme can be formulated to identify it, to isolate it, to determine its properties, and to trace the problem to its source.

For example, a common problem results when a component separates while standing in the shipping container. Figure 5 shows the spectrum of such a "float" found on the surface of a paint can. Using a micropipette, the material was drawn off and spread onto a KBr plate. Even though there

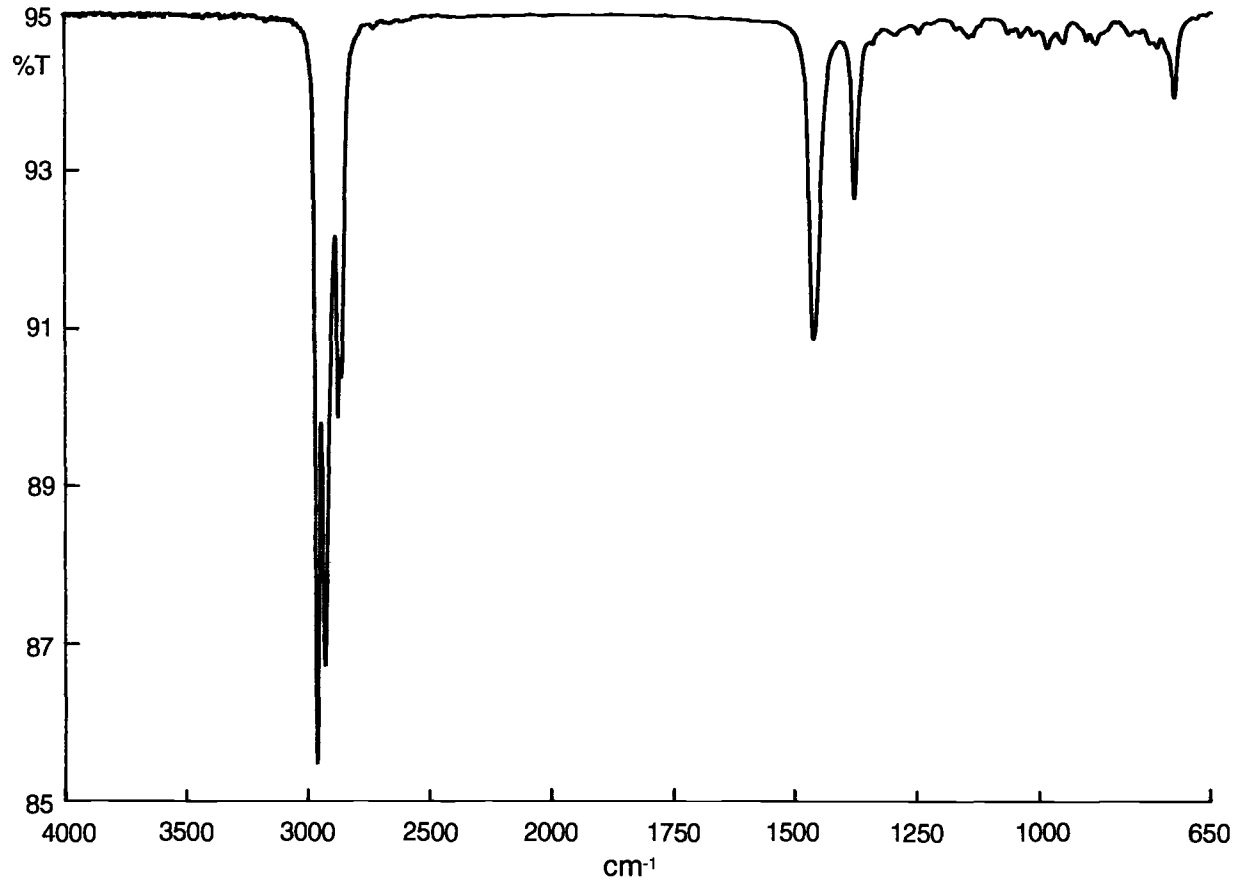

FIG. 5–Material "floating" in paint can.

was only a tiny amount of material, it was sufficient to produce a spectrum with about 10% absorption. Using scale expansion, it was identified as mineral oil. This clue led to the discovery that a shipment of cans had not been adequately degreased.

Another common problem is the "scum" that develops on the surface of panels during exposure testing. It may be caused by an exudate from within the film or it might be deposited from the environment. The amount of material is very small and is easily lost. The material can be transferred, examined, and identified by simply rinsing the exudate from the panel with a solvent and evaporating the rinse solution onto a salt plate. Figure 6 shows the spectrum of such an exudate. The infrared spectrum is that of a polyester that was not supposed to be in that formula and represented a contaminant.

DIFFERENCE SPECTROSCOPY

Probably the most useful contribution of Fourier transform spectroscopy, as far as the coatings analyst is concerned, is its ability to remove known or unwanted components so that hidden or masked materials are exposed [9]. Spectral subtraction allows the analyst to perform separations that would be difficult and time consuming or even impossible by chemical means. Interactive subtraction programs now permit the spectroscopist to manipulate subtraction factors while observing their effects on a video display. Bands resulting from known constituents can be eliminated before your eyes. One can literally strip away portions of a complex mixture to reveal the components of interest. These could be minor additives, contaminants, or possibly subtle chemical variations, but they are nearly always the components of greatest interest.

A typical resin problem illustrates this subtraction approach. Occasionally, a resin batch will not perform as expected. The assumption is always that it is contaminated and, if so, what is the contaminant? Figure 7 is the spectrum of such a contaminated acrylic resin. When compared with a good lot of the resin, it is apparent that there is a spurious band at 700 cm^{-1} and a doublet near 1600 cm^{-1}. However, the source of these bands is unknown, and it would be very difficult to isolate that component (since there is no clue as to where it originated). If the spectrum of a known "good" resin (7*B*) is subtracted from that of the "bad" one (7*A*), the contaminant's "fingerprint" is revealed (7*C*). The isolated pattern can be recognized as a phthalate plasticizer and matches the butyl benzyl phthalate reference. Total time required for this analysis is only a few minutes, far shorter than that needed for chemical separations.

In the hands of a skilled spectroscopist, subtraction is both a qualitative and quantitative tool. If the sample and reference films are carefully prepared and well matched for spectral intensity, several components can be sequentially stripped from the spectrum to reveal very minor constituents.

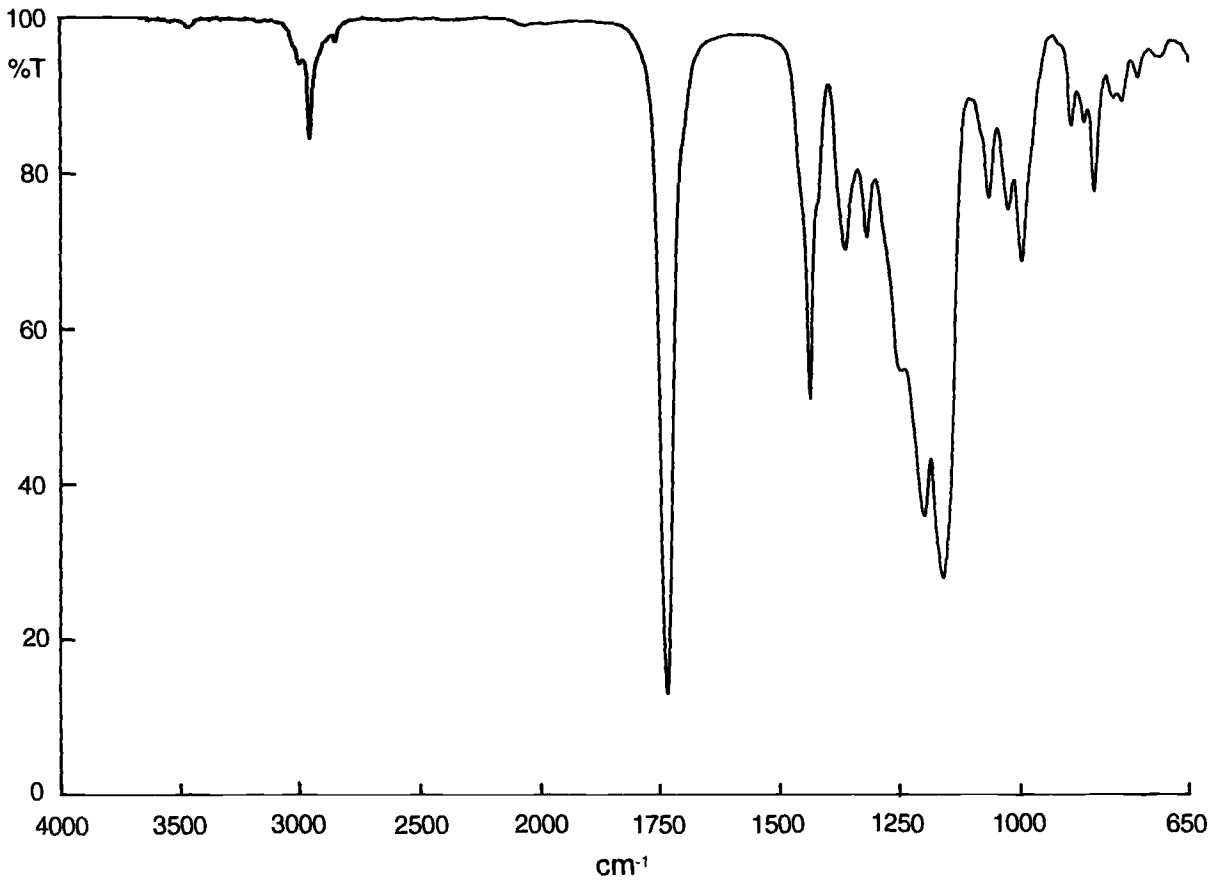

FIG. 6–"Scum" from exposure panel.

This must be done very carefully with considerable knowledge of the system, otherwise a noninterpretable jumble of both positive and negative peaks will result. Alternatively, one may spectrally add the individual components together mathematically and then perform the subtraction. The safest method of difference spectroscopy is a comparison between the unknown and a known composition where the reference is a model synthesized from recognized chemical ingredients. With care, the subtraction factors can be used to estimate the concentration of each component. This may be sufficiently accurate for many applications. With a range of calibration samples, multicomponent analysis can be employed to determine the various constituents. Usually it is prudent at this point to shift to another analytical technique if a more quantitative result is required.

SPECTRAL SEARCHING

Fourier transform instruments are usually offered with spectral searching algorithms as a part of their software package, either included with the equipment or as an additional option. Several third party search packages are also available. These can be very helpful to the coatings spectroscopist, particularly the novice. They provide a quick way to eliminate the majority of possibilities so that one can concentrate on the best fits in their quest to discover what an unknown spectrum is chemically. Several approaches, such as peak matching and vector analysis, have been employed; however, the objective is the same—they all endeavor to pick the best matches to an unknown spectrum from a spectral reference library database [*10*]. These libraries may be generated internally or they can be purchased as a commercial collection, such as those developed by the Federation of Societies for Coatings Technology, Aldrich Chemical Co., and Dieter Hummel. All are available from Nicolet Instrument Corp. One deficiency in this approach is that no search system can find a match for a spectrum not included in the library. However, closely allied matches can suggest possibilities that are helpful in identifying an unknown. One must always compare the actual spectrum with the library reference since even high scoring matches can be wrong and may be misleading. Most laboratories eventually choose to produce their own libraries because it makes searching much faster and the "hits" more accurate.

Another plant-type crisis shows how ingenuity, subtraction, and searching can be used to solve a difficult problem. Sometimes a batch of liquid resin is not as clear as expected. This is often referred to as "cloud" or "haze." The "cloud" can often be concentrated by centrifuging the resin. The contaminant will either be forced to the top or sink to the bottom of the tube. Figure 8 is the spectrum of a hazy resin which was centrifuged. The concentrated material from the bottom of the tube was then spread onto a KBr plate for examination (8*A*). Most of the spectrum is the resin, and only a hint of the "cloud" can be detected. By subtracting the spectrum of the

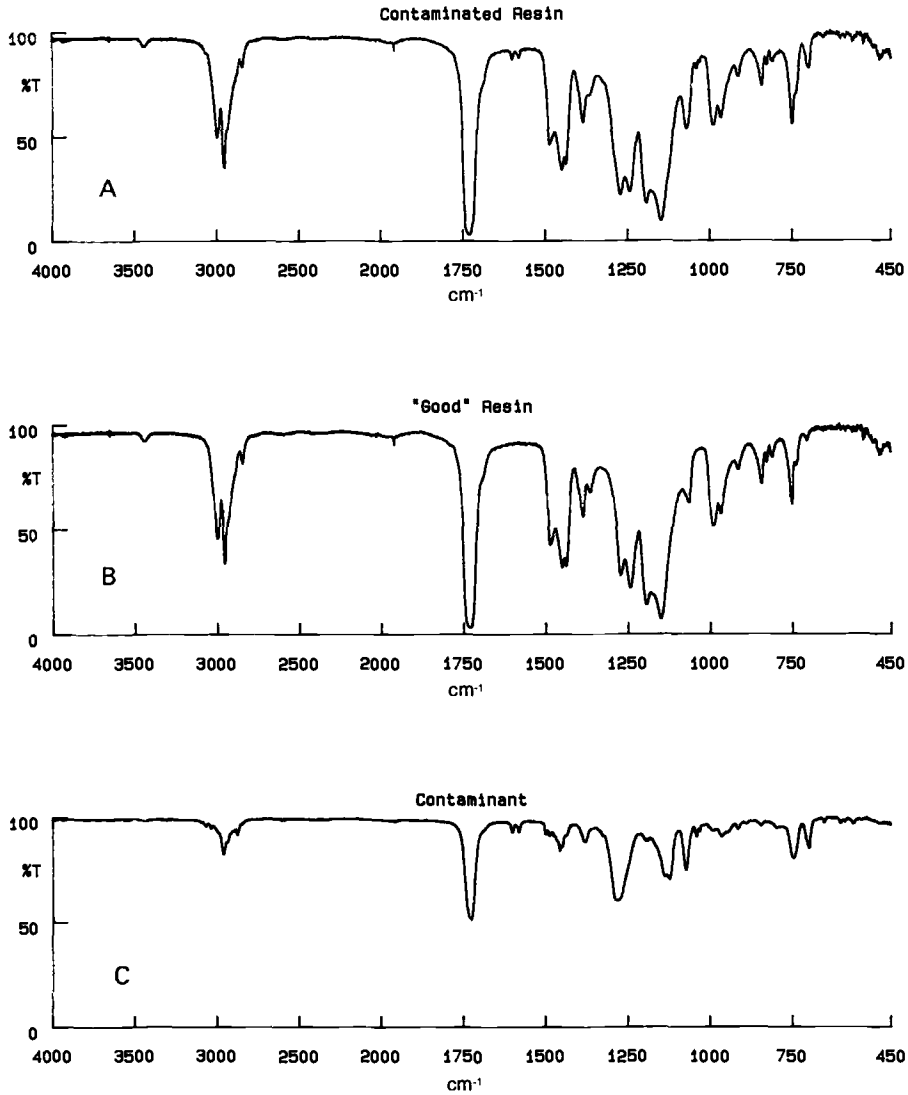

FIG. 7–Resin contaminant isolation.

centrificate (8*B*), the pure spectrum of the haze can be isolated (8*C*). A search of several libraries indicated the best match would be a silica. Silica flock is very often used as a filter aid. Apparently a small hole had developed in one of the process filters, allowing the filter aid to leak through and contaminate the batch.

TIME LAPSE SPECTROSCOPY

Digitized Fourier transform spectra are readily stored on magnetic disks media and can be retrieved at some later time without any lose of accuracy or integrity. This allows spectra to be accumulated over a period of time and compared at leisure. Thus, cure studies may be carried out over hours, days, or weeks, while durability and weathering tests may extend to years. By repeatedly examining the same point within a film, very subtle chemical changes can be detected. This technique is used to determine cross-linking reactions taking place during cure and the degradation resulting from exposure to the elements, i.e., weathering. If spectra are taken and stored at frequent, regular intervals, the course of these reactions can be followed. The spectra may then be likened to the single frames of "time lapse" photography [*11*]. Since the spectral bands are a result of the chemical composition within a film, the chemical changes taking place can be assessed by carefully examining the spectral shifts occurring during that time. In this manner, not only overall conversions, but sequential reactions can be detected. If the intensity of the disappearing bands is measured and correlated with time, reaction rates can be determined [*12*].

QUALITY ASSURANCE

Fourier transform spectroscopy's greatest contributions to the coatings industry have just begun. The recent increased emphasis on product quality makes automated analytical techniques not only practical but necessary to remain competitive. Using computerized spectral subtraction, a fraction of a percent of a foreign material can be detected and identi-

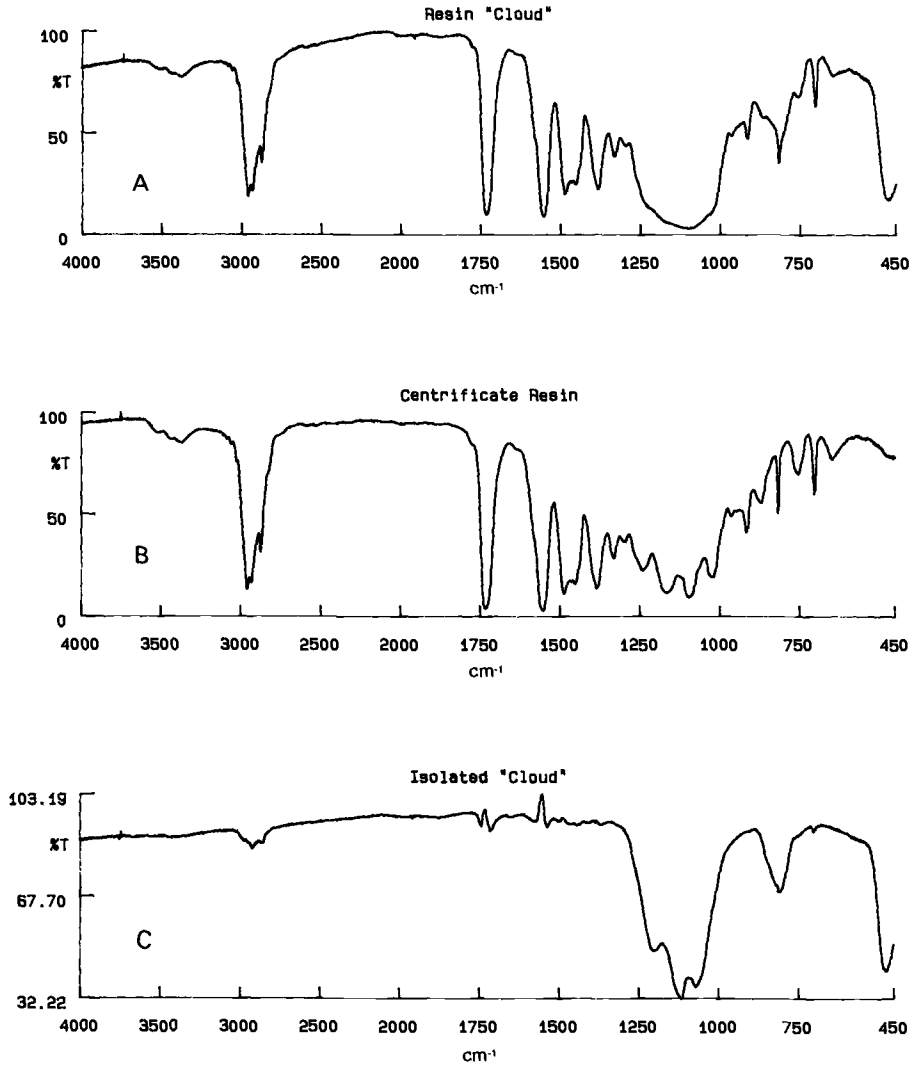

FIG. 8–Resin "cloud" identification.

fied. By preprogramming the spectrometer computer, the spectroscopic functions can be relegated to the background so that it becomes, in effect, a "black box." An operator with minimum training can perform very sophisticated analyses by simply pressing a few buttons. By applying these principles, a system for testing incoming raw materials, manufactured intermediates, and finished products has been developed [*13*]. These programs allow a control laboratory operator to call up a stored standard spectrum, run the current sample, make a comparison, and determine a "goodness of fit" factor—all automatically—in less than 5 min.

CONCLUSIONS

Infrared spectroscopy has proven over the years to be one of the most valuable problem-solving tools available to the coatings analyst. It is usually the first technique applied to difficult analytical problems because it provides unique information about samples in almost any physical state. The extent of the problem can then be assessed and a plan of attack formulated. The advent of FTIR has removed most restrictions imposed by sample size and form. A wide variety of attachments is available that greatly expands the range of samples amenable to examination. Its associated computer allows the analyst to strip away known components to reveal minor additives and contaminants. Spectral subtraction can thus perform separations which would be difficult if not impossible by other means. Data-handling techniques are proving to be the most valuable contributions of this technology for the paint industry. Spectral identification of unknown materials via computer pattern matching has become common place. Digital spectral storage and retrieval permits comparison of films as a function of time so that the chemistry taking place during cure and exposure can be followed. It can also determine when and at what rate those reactions are taking place. The ability to preprogram the spectrometer allows relatively unskilled operators to perform very sophisticated analyses without being burdened by spectroscopic functions. The instrument can then become an automated "black box" quality assurance analyzer.

Methods for Polymer Molecular Weight Measurement

74

by Thomas M. Schmitt[1]

THE BINDERS USED IN COMMERCIAL COATINGS are organic polymers, the molecular weights of which greatly influence the properties of the final coating [*1*]. As a necessary result of the manufacturing processes, synthetic polymers are mixtures of compounds of similar molecular structure but varying molecular weight. For an exact understanding of the system, one must know the molecular weight and weight (or mole) fraction of each species, in other words, the molecular weight distribution. For many practical purposes, an average value of molecular weight suffices. The final cured paint film is generally a cross-linked system resembling a single massive molecule, where the concept of molecular weight has little meaning. Molecular weight determination is thus applied only to coating formulation ingredients.

Many procedures have been used to determine molecular weight. We will limit our discussion to the most practical methods, for which commercial instrumentation is available at reasonable price. Both archaic and research methods will be omitted, as will those methods which are only suitable for determination of low molecular weight compounds.

MOLECULAR WEIGHT DEFINITIONS

While the molecular weight of a single molecule is a simple concept, there are several ways to calculate the molecular weight of a mixture. The most useful values are number average molecular weight, $\overline{M_n}$ and weight average molecular weight, $\overline{M_w}$

$$\overline{M_n} = \frac{\sum_i n_i M_i}{\sum_i n_i} \qquad \overline{M_w} = \frac{\sum_i w_i M_i}{\sum_i w_i}$$

where M_i denotes the molecular weight of component i, n_i is the number of moles of component i, and w_i symbolizes the total weight of component i and is thus equal to $n_i M_i$. Weight average molecular weight is necessarily equal to or higher than number average molecular weight. A mixture of equal numbers of two molecules, one weighing 100 and the other weighing 1000, has a $\overline{M_n}$ of 550 and a $\overline{M_w}$ of 918. The polydispersity of this mixture, $\overline{M_w}/\overline{M_n}$, is 1.7. This indicates that most of the mass of the example mixture consists of higher molecular weight material, but that comparatively small molecules are also present. The higher the value of $\overline{M_w}/\overline{M_n}$, the broader is the distribution of weights of molecules in the sample. Two other measures of molecular weight have found acceptance because they can be directly measured by certain techniques: z-average molecular weight, $\overline{M_z}$, and viscosity average molecular weight, $\overline{M_v}$

$$\overline{M_z} = \frac{\sum_i w_i M_i^2}{\sum_i w_i M_i} \qquad \overline{M_v} = \left[\frac{\sum_i w_i M_i^a}{\sum_i w_i M_i}\right]^{1/a}$$

For the above-mentioned mixture of molecules of weight 100 and 1000, the z-average molecular weight is 991. Clearly, if the actual distribution of M_n, M_w, or M_z is known, the distributions and average values of the other two parameters may be calculated. The exponent a is obtained from the Mark-Houwink equation and is specific to polymer type and branching as well as the temperature and solvent of the measurement system [*2*].

Which molecular weight value is of greatest significance, number average, weight average, z-average, or viscosity average depends upon the particular application of the polymer mixture. Knowledge of M_n and M_w is sufficient for most purposes. M_n is often critical to stoichiometry of curing reactions and controls some properties. For coatings, many of the properties of the final product are controlled by M_w, with M_w/M_n also playing an important part.

METHODS FOR DETERMINATION OF NUMBER AVERAGE MOLECULAR WEIGHT

End Group Analysis

Some polymers used in coatings have reactive end groups which participate in the curing reactions. Assuming that the degree of branching is known and that the end of each polymer chain has such a group, methods for routine quality control may be based on determination of end groups. Since each molecule has the same number of end groups, the result is a number-average molecular weight. Polyurethane raw materials fit this description, and "wet chemical" methods are well-established for rapid and accurate analysis of these compounds. Hydroxy-terminated compounds are analyzed by determination of hydroxyl number [ASTM Method for Testing Polyurethane Polyol Raw Materials: Determination of Hydroxyl Numbers of Polyols (D 4274)]. Isocyanate-terminated prepolymers are analyzed by ASTM Test Method for Polyurethane Raw Materials: Determination of Amine Equivalent of Crude or Modified Isocyanates (D 4666). End group analysis

[1]Manager, Research Services, BASF Corp., 1419 Biddle Avenue, Wyandotte, MI 48192-3736.

Copyright© 1995 by ASTM International

is not limited to polyurethane raw materials. Amine or carboxylic acid functional groups may be determined by acid-base titration, often in non-aqueous solvents, but the parameters of solvent, titrant, and apparent pH at the end point must be worked out for each compound.

End groups may also be determined by spectroscopic methods, usually infrared and nuclear magnetic resonance spectrometry. For example, see ASTM Method for Testing Polyurethane Raw Materials: Determination of Primary Hydroxyl Contents of Polyether Polyols (D 4273).

Even polymers which are not usually thought of as possessing functional end groups may be analyzed. This is because molecules are often terminated by fragments of the catalyst which initiated the reaction. An example is polyacrylonitrile, which may be terminated by a sulfate or sulfonate group. The analyst familiar with the mechanism of polymerization (which should not involve a high percentage of chain terminations which do not leave the desired end group) can often devise a way to measure the molecular weight based on determination of these residues.

Accurate measurement of $\overline{M_n}$, by end group analysis is limited to polymers of molecular weight less than about 20 000, since the end group concentration is too low for precise measurement above this range.

Colligative Properties Analyses

$\overline{M_n}$ may be determined based on colligative properties, i.e., based on measuring changes in solvent properties which are due to the number of molecules dissolved. These properties include vapor pressure, freezing point, boiling point, and osmotic pressure. By derivation from fundamental equations [*2–5*], it can be shown that, at low concentration, the relationship between a colligative property and molecular weight reduces to

$$\overline{M_n} = \frac{KC}{\Delta X}$$

where K is a constant specific for the solvent, C is the weight/volume concentration of the polymer, and ΔX represents the observed change in the colligative property.

K is best determined experimentally, rather than calculated. For the best accuracy, several measurements are made so that the value of $\frac{\Delta T}{C}$ can be extrapolated to find the limit at zero concentration. These techniques are more often used in research laboratories than for quality control purposes. Boiling point elevation and freezing point depression are rarely used for polymers since instrumentation suitable for observation of small temperature differences is not commercially available.

Small molecules have a disproportionate effect on the number average molecular weight. For example, the presence of 0.1 wt% water contaminating a 20 000 $\overline{M_n}$ polymer will result in return of a colligative property value of 9500 for $\overline{M_n}$. This effect is amplified as polymer $\overline{M_n}$ increases. Thus, moisture and solvent must be completely removed prior to analysis. Commercial polymers are first purified by extraction or by dissolution and precipitation to remove additives such as stabilizers and lubricants.

For determination of molecular weight by **membrane osmometry,** a solution of the test substance is separated from pure solvent by a semi-permeable membrane, i.e., a membrane which is permeable to low molecular weight solvent molecules but impermeable to molecules of the test substance. Because of the lowered activity of solvent containing the polymer, solvent molecules will tend to travel across the membrane from the pure solvent. The pressure which must be applied to the solution to equalize this flow is equivalent to the osmotic pressure. Because the change in osmotic pressure is dramatic compared to the small temperature changes observed with the other colligative property methods, membrane osmometry is useful for higher molecular weights, up to about $\overline{M_n} = 10^6$, although accuracy fades at the highest values. The technique cannot be used for low molecular weights because commercial membranes are not sufficiently selective: typically, manufacturers quote cutoff values of 5000 to 20 000 for various membranes, indicating that molecules below that value can permeate the membrane. This property can actually be an advantage in that it is not necessary to purify the polymer to remove low molecular weight additives: their concentration is quickly equalized on each side of the membrane, so that their presence does not affect the molecular weight value. Elevated temperatures may be used with less soluble polymers, but choice of membranes becomes limited as the temperature is increased and as less common solvents are selected.

Vapor pressure osmometry actually is unrelated to osmometry, consisting simply of the measurement of vapor pressure depression in order to determine molecular weight. Commercial instruments measure the vapor pressure indirectly: the vapor pressure difference between a dilute polymer solution and pure solvent is measured by monitoring the temperature difference between drops of each liquid in equilibrium with solvent vapor. Although in principle this is an absolute measurement, in practice these instruments are calibrated with standards of known $\overline{M_n}$. Vapor pressure osmometry complements membrane osmometry in that it is suitable for materials with $\overline{M_n}$ in the range below 20 000, with accuracy dropping off at higher molecular weights because of the very small temperature differences observed.

The experimental procedure is described in ASTM standard D 2503 (Test Method for Molecular Weight of Hydrocarbons by Thermoelectric Measurement of Vapor Pressure), although the manufacturer's literature for the specific apparatus must be considered definitive.

DETERMINATION OF WEIGHT AVERAGE MOLECULAR WEIGHT BY LIGHT SCATTERING

Unlike $\overline{M_n}$, $\overline{M_w}$ is not much affected by the presence of small quantities of low molecular weight impurities. The only common method for direct determination of $\overline{M_w}$ is light scattering. Light is scattered by polymer solutions in a manner which is well understood theoretically and which depends upon the size of the polymer molecules in solution. Classical measurement of $\overline{M_w}$ by light scattering is described in an ASTM standard [Practice for Determination of Weight-Average Molecular Weight of Polymers by Light Scattering (D

4001)]. The technique is usually performed by specialists because of the attention to detail required for accurate values: (1) Traces of dust and other particles must be removed from the solutions; (2) Light scattering measurements formerly needed to be made manually at several angles.

Modern laser light sources make possible measurement of light scattered at angles less than 10° [2]. At such low angles, the equations defining the relation of M_w to scattered light are reduced such that measurement at a single fixed angle is sufficient. Simple measurement of a set of dilute solutions of the polymer to determine scattered light and the concentration dependance of the solution refractive index (RI) suffice to determine $\overline{M_w}$. Instruments are also available which make measurements at multiple angles automatically, so that the radius of gyration as well as the molecular weight of the substance may be determined. With either the low-angle or multiple-angle instruments, operation is no more tedious than if a single measurement were made on each solution. An advantage of the laser light sources is that their intensity makes the sample size requirement lower, so that much less solution need be filtered free of particulates. If the instrument is designed so that the sample solution flows through the cell, interference from particulates is apparent as random sharp spikes, which may be corrected electronically before performing molecular weight calculations.

Light scattering is less suitable for analysis of polymers of $\overline{M_w}$ lower than about 20 000. However, the low-range sensitivity increases as the RI difference between solvent and polymer increases. Methods for molecular weight determination for light scattering are well described in the literature [2–5], but the instructions of the instrument manufacturer are most relevant.

SIZE EXCLUSION CHROMATOGRAPHY

Size exclusion chromatography (SEC) is a type of high performance liquid chromatography (HPLC) in which separation is made on the basis of the size of the molecules in solution [6–7]. It is often called **gel permeation chromatography** (GPC) since the separating medium was historically a swollen polymer gel. The stationary phase is now most often a rigid packing containing pores of the same order as the size of the molecules in the sample. As a sample of a disperse polymer is pumped through the HPLC column, smaller molecules penetrate further into the stationary phase than do larger molecules, with the result that the smaller molecules elute after the larger.

SEC determines size in solution versus standards. Because the interaction of a polymer with a solvent changes as a function of molecular weight, size in solution does not necessarily have the same relationship to molecular weight over a large molecular weight range. Thus, SEC is not an absolute method for determining either $\overline{M_n}$ or $\overline{M_w}$. In spite of this, it is today unquestionably the most widely used procedure for determination of both. SEC has the very great advantage that the polymer need not be purified of additives, oligomers, and residual monomers before analysis. Indeed, SEC can sometimes be used for the determination of these components simultaneously with the characterization of the polymer itself.

SEC Instrumentation

SEC instrumentation consists of a basic HPLC system, including a constant volume pump, injector, column set, detector, and computerized data handling system. HPLC is discussed in another chapter. The *pump* must be capable of delivering solvent with greater precision than is necessary for ordinary HPLC, preferably within 0.1%. This is because of the semilogarithmic SEC calibration curve, where small differences in elution volume result in a large difference in apparent molecular weight. Alternatively, some device may be used to continuously monitor flow rate so that experimental data may be replotted in terms of elution volume rather than elution time. Another approach is use of an "internal standard," usually of very low molecular weight, to permit correction of experimental retention times. Such devices are rarely used nowadays, since the variations they introduce are of the same magnitude as the variations in flow of modern, well-maintained HPLC pumps. Control of the *temperature* of the system is desirable since fluctuations in ambient laboratory temperature add variation to retention times and, more seriously, cause drift in the baseline of the refractive index detector. Ideally, the entire unit is encased in a constant temperature chamber. Unfortunately, these enclosures usually must be constructed by the user because of the limitations of commercial units. Many users make do with temperature control of only the column chamber and the detector, which suffices if the laboratory temperature remains somewhat constant.

SEC *columns* are usually filled with styrene/divinylbenzene copolymer and are always purchased pre-packed. Modern instrument manufacturers supply columns of a uniform high performance. For increased resolution, more than one SEC column is used in series, with as many as four or five 30-cm columns being preferred by many operators. These may consist of diverse columns, each containing packing of a specific pore size, or each may contain packing of broad pore size distribution.

Various *detectors* are used in SEC. The most common is based on detection of changes in refractive index (RI) of the solvent as the solute elutes. This property is closely related to concentration and such a detector is suitable for any material with an RI which differs from that of the solvent. Commercial detectors are designed to minimize temperature fluctuation since RI is strongly dependant upon temperature. Temperature control can be either active (electronic heating devices) or passive (massive metal block surrounding the cell). The mass response of the refractive index detector varies by only a few percent with molecular weight, and it is thus assumed to be a linear concentration detector. It is well to check this assumption if analyses will straddle a broad molecular weight range, particularly at the low end of the range. Caution must be used in the analysis of copolymers since the RI of copolymers changes with composition.

Other detectors are used for special purposes. A UV absorbance detector, usually in series with an RI detector, is suitable for analysis of polymers with strong chromophores, such as those containing styrene, terephthalate, or bisphenol A groups. Infrared absorbance detectors are used to track particular components of the polymer, but limitations in useful wavelengths and solvents prevent their general use. Another

detector is based on "evaporative light scattering." In this instrument the solvent is evaporated as the SEC effluent passes through a gas stream. Any non-volatile solute is converted to a fine aerosol, which is detected by its ability to scatter a light beam. Another detector, based on differences in dielectric constant between solvent and solution, has many of the advantages of the RI detector, but is not widely available. Caution must be used when applying any detector, since, if the response is not linearly proportional to concentration over a wide molecular weight range, calculation of molecular weight distribution from experimental data will result in serious errors.

Two specialized detectors are worthy of mention: A viscosity detector gives an instantaneous readout of the viscosity of the solution eluting from the chromatograph. It is used in series with an RI detector so that both concentration and viscosity of the eluent are determined, permitting estimation of intrinsic viscosity and hence molecular weight. There are low-angle and multiple-angle laser light scattering instruments designed for use as SEC detectors. Like the viscosity detectors, they are used together with a mass sensitive detector, usually an RI detector. A characteristic shared by both detectors is their intrinsically greater sensitivity as the M_w of the solute increases. Thus a trace of high polymer or undissolved material that might be undetected by refractive index appears as a major component to a light scattering detector. Whether or not this sensitivity is advantageous depends on the application. Viscosity and light-scattering detectors are commercially available, reasonably priced, and reliable. Still, they remain very much the province of the specialist. This is because the additional information which they provide is not essential for most practical applications. They are not used for routine analysis of paint components nor are they typically used by synthetic chemists.

An *autosampler* is a valuable accessory for GPC, more so than for other forms of HPLC. This is because the long analysis times typical of SEC and the rigorous calibration procedures make it difficult to attain high sample throughput unless the usual 8-h day can be extended. If the column and mobile phase are rarely changed so that calibration is required infrequently, manual injection is practical.

Calibration and Calculations

SEC is a relative technique which requires calibration with standards of known molecular weight. The calibration curve is semilogarithmic, with the SEC columns usually chosen such that retention volume is linearly proportional to the logarithm of molecular weight over a broad range. Calibration is greatly simplified if specially prepared standard materials of low polydispersity can be used.

The choice of standards is critical since the relationship of retention time to molecular weight varies with different polymers, even those in the same chemical family. Since it is the size of the solvated polymer rather than its molecular weight which determines elution volume, significantly different calibration curves are obtained from branched and linear molecules. The most easily obtainable standards are of polystyrene. Polystyrene has a higher molecular weight for the same chain length than do aliphatic polymers, so a polystyrene calibration curve will give high results for the molecular weight of many common polymers. The method of calibration should always be reported when SEC molecular weight values are given.

A **universal calibration** system has been devised based on the relationship between viscosity and SEC retention time, since each is a function of the size of the solvated polymer. When using universal calibration, standards and samples may be quite different polymers; it is only necessary that the Mark-Houwink coefficients for standards and samples be known. Of course, the Mark-Houwink coefficients must be known for the polymer in the particular SEC solvent at the temperature used. Obtaining these coefficients is not as demanding a task as preparing narrowly distributed standards of a new polymer, and universal calibration has found widespread use. The approach is sufficiently popular that it is described in an ASTM standard: ASTM Test Method for Molecular Weight Averages and Molecular Weight Distribution of Certain Polymers by Liquid Size-Exclusion Chromatography (Gel Permeation Chromatography-GPC) using Universal Calibration (D 3593).

Most analysts use computerized data systems for evaluation of SEC data. These systems are reasonably priced and aid the operator in all phases of data treatment, from preparation of the calibration to determination of molecular weight averages to preparation of attractive graphs of molecular weight distribution. Caution must be used in their application; not all systems will give the same results as an intelligent operator performing manual calculations. The greatest difficulty is in mathematical representation of the calibration curve of retention time versus molecular weight. Use of higher order equations to represent the calibration can introduce large errors compared to simply connecting the experimental data points.

SEC data for narrow molecular weight distributions must be corrected for dispersion contributed by the instrumentation. This correction is not significant for the broad molecular weight distributions typically found in coatings. Band broadening corrections become more important if a molecular weight-sensitive detector is used, such as a viscometer or light-scattering instrument.

SEC procedures and calculations are thoroughly described in ASTM Test Method for Molecular Weight Averages and Molecular Weight Distribution of Polystyrene by Liquid Exclusion Chromatography (Gel Permeation Chromatography—GPC) (D 3536).

Application of SEC

SEC may be performed with either aqueous or organic solvents. Non-aqueous systems are more reliable, but, of course, water-soluble compounds such as polyacrylates are more readily analyzed in aqueous solvents. Non-size exclusion interactions between the column and sample are more common with aqueous systems. These undesirable interactions include adsorption and ion exclusion/ion retardation and can often be controlled by adding salts or a low percentage of organic solvent.

Elevated temperature is necessary for the analysis of some polymers because of their low solubility or because of the high viscosity of the solvents which they require. In general,

this is not a consideration for the relatively low molecular weight polymers used in coatings raw materials.

SEC has long since spread from the specialized central laboratory to the laboratory of the synthetic and formulating chemist. Central analytical laboratories select the SEC column set and mobile phase for optimum resolution of a particular polymer and molecular weight range. Central laboratories also typically perform extensive calibration. Practice in synthesis laboratories is usually different, with a single system used in a comparative fashion for all analyses. Indeed, when SEC is used routinely by resin chemists to follow polymerization reactions, the fine details of calibration are typically ignored and molecular weight is estimated by simple comparison to polystyrene standards, either by visual estimation of "peak" molecular weight or by uncritical acceptance of the default computer-generated report. For most troubleshooting applications, it is enough to overlay the chromatograms of a "good" and a "bad" polymer in order to determine whether differences in molecular weight distribution contribute to a problem. In the case of a product which does not have a single smooth molecular weight distribution but rather consists of two or more discrete distributions, visual comparison of peaks is often more valuable than comparison of numerical values. To monitor a polymerization reaction, it may be enough to watch the gradual disappearance of the peaks due to monomers.

VISCOMETRY

Rheology of paint components is discussed in Chapter 33. We will discuss here only viscosity measurement to determine molecular weight.

Solution viscometry is the method of determining molecular weight most suitable for routine quality control. The viscosity/concentration relationship of a polymer solution is a function of the chain length of the polymer, so viscosity can be used as a measure of molecular weight.

As with other methods, determination of true molecular weight by solution viscosity requires purification of the polymer and extrapolation to zero concentration of a series of ratios representing measured values. The zero intercept, representing the limit of the viscosity/concentration relation as zero concentration is approached, is the intrinsic viscosity, $[\eta]$. It is related to $\overline{M_v}$ by the relationship expressed in the Mark-Houwink equation

$$[\eta] = K\overline{M_v^a}$$

The constants for the Mark-Houwink equation must be determined experimentally using well-characterized polymer standards of narrow $\overline{M_w}/\overline{M_n}$. ($\overline{M_w}/\overline{M_n}$ must be small for valid calibration since $\overline{M_v}$ is numerically different than $\overline{M_n}$ or $\overline{M_w}$.)

Since viscosity is determined by the hydrodynamic volume of the polymer, the relationship with molecular weight is specific for the polymer, the solvent, the temperature, and, of course, the concentration. A relationship determined for a linear polymer will not be accurate if branched molecules are also present. This means that the constants in the Mark-Houwink equation change with various solvents and with polymers having various degrees of branching. Measurements are made at high dilution to minimize the effect of variables other than molecular size. Capillary viscometers, used to measure the solution flow rate at a specific pressure differential, are most generally suitable. Procedures for determination of solution viscosity are contained in Test Method for Diluted Solution Viscosity of Polymers (D 2857), as well as in the other ASTM standards referenced in D 2857.

It is unfortunately not possible to discuss this subject without defining a number of viscosity relationships:

Relative viscosity is the parameter which is actually measured when viscosity is determined. It is the ratio of efflux times for the polymer solution versus pure solvent:

$$\eta_{rel} = t/t_0$$

where t and t_0 are the efflux times for polymer solution and pure solvent, respectively. **Reduced viscosity** takes concentration into account:

$$\eta_{red} = \frac{t - t_0}{t_0 C}$$

where C represents the polymer concentration, usually in grams per 100 mL. **Intrinsic viscosity** is determined by plotting against concentration several values of reduced viscosity, extrapolating to obtain the intercept at zero concentration:

$$[\eta] = \lim_{C \to 0} \eta_{red}$$

where $[\eta]$ represents intrinsic viscosity.

Some workers determine Mark-Houwink constants with unfractionated polymers of measured $\overline{M_w}$, thus relating viscosity to $\overline{M_w}$ rather than $\overline{M_v}$. This non-rigorous approach is viable because $\overline{M_v}$ is usually rather close to $\overline{M_w}$.

Solution viscosity is an excellent method for routine QC of relatively uniform polymers. A single analysis at a fixed concentration and temperature will indicate that the product falls into the stated molecular weight range. For example, ASTM Test Method for Determining Inherent Viscosity of Poly(Ethylene Terephthalate) (PET) (D 4603), describes a method for determining **inherent viscosity** (natural log of relative viscosity, divided by concentration). ASTM Test Method for Intrinsic Viscosity of Cellulose (D 1795) describes a one-point procedure for estimating intrinsic viscosity. The results of such measurements can be related to molecular weight and are useful for predicting properties of different batches of well-understood commercial resins. Many polymer chemists routinely make one-point viscosity measurements to monitor synthesis experiments, reserving more sophisticated molecular weight measurements for products chosen for commercialization.

Melt viscosity, the viscosity of the pure polymer, is correlated with $\overline{M_w}$. Equations developed to relate degree of polymerization with melt viscosity use a temperature-dependant function which differs for each polymer system. As a practical matter, polymer melts are non-ideal fluids, and their true viscosity cannot usually be measured with simple equipment. Thus, melt viscosity is usually determined because of its significance to polymer processability, rather than as an estimate of $\overline{M_w}$. **Pour point,** the temperature at which the polymer begins to flow, is similarly related to molecular weight, and may be used to estimate it.

Coatings Characterization by Thermal Analysis

by C. Michael Neag[1]

THERMAL ANALYSIS (TA) ENCOMPASSES A VARIETY of techniques used to measure changes in material properties with changes in temperature. These techniques apply broadly in materials science and find use in characterizing liquids, polymers, and inorganic materials. The many results obtained using TA fit neatly into Van Krevlan's [*1*] classification of material properties. He divides material properties into three distinct but interrelated categories: (1) intrinsic properties, (2) processing properties, and (3) product or article properties. Intrinsic properties such as the glass transition temperature (Tg) or elastic modulus arise from the chemical and physical structure of a material, can be measured with precision, and may form the basis for predictive empirical relationships. A material's process properties depend on the interplay of intrinsic properties and process conditions (e.g., synthesis temperature or mixing time). In essence, they reflect a material's intrinsic properties in a dynamic environment. In practice, the interaction of a material's intrinsic properties and process properties yield a unique product embodying still different properties. Unfortunately, the relationship between intrinsic properties and process properties is poorly understood, difficult to measure, and more difficult to predict. Because product properties depend on this ill-defined relationship, their meaning becomes quite subjective. Simply put, a paint made and applied one day may behave quite differently than a paint made and applied another day, and the reasons for the observed differences often remain obscure.

Thermal analytical techniques provide tools to help clarify these hard-to-understand relationships, helping to reduce product development time and manufacturing costs, while shaping the best possible product. The instrumentation supporting thermal analysis has grown remarkably in both versatility and sophistication: automated systems, absolute control of applied stresses, and tenth-of-a-degree temperature resolution have replaced strip chart recorders, spring-loaded stresses, and "give or take a degree" temperature resolution.

The advent of the inexpensive microprocessor chip probably represents the most significant step in the development of improved commercial thermal analyzers. The development of powerful PC and microcomputer-based controllers have dramatically simplified experimental procedures, data collection, and data analysis in thermal analysis. In general, automating these instruments has dramatically improved the experimenter's control over the sample environment. These improvements allow technologists to complete complex experiments involving multistep heating programs and several purge gases. At the same time, calibration routines were also simplified and the accuracy and precision of the results improved. All of these advances came with the additional benefit of unattended operation. In fact, several commercial suppliers offer instruments with robotic control that permit the analysis of scores of samples at the touch of a button.

The simple yet highly sophisticated character of these instruments has a major drawback: their simplicity significantly increases the potential for misinterpreting experimental results. With advances in automation, thermal analytical techniques have moved closer to simple "turn-key" operations and have reduced considerably the technical demands on the user. TA has become a marvelously simple process that unfortunately requires little understanding of the instrumentation or the results. A few minutes in sample preparation yields a raft of data from sophisticated data analysis software, considerably increasing the potential for error in data interpretation or analysis. The improvements in instrumentation and software demand greater caution from the scientist in experimental design and results interpretation. Wendlandt [*2*] and Earnest [*3*] discuss the advent of automation in thermal analysis, and two volumes edited by T. Provder [*4,5*] describe laboratory automation and computer applications in polymer science more generally.

Coatings and TA

In the coatings industry—limited here to commercial paints and industrial coatings—TA has proven to be a cost effective means for understanding the interrelationship between a coating's synthesis, formulation, and end-use performance [*6*]. Techniques historically important in coatings characterization can be broadly grouped under the headings of differential scanning calorimetry (DSC), differential thermal analysis (DTA), thermomechanical analysis (TMA), dynamic mechanical analysis (DMA) and thermogravimetry (TG). Techniques such as dielectric analysis (DEA) and evolved gas analysis (EGA) have gained popularity as tools for coatings characterization as well. Although results are easily obtained using these techniques, they are grounded in complex thermodynamic and kinetic principles. Excellent overviews of the foundations, instrumentation, and applications of thermal analysis can be found in reviews by Wendlandt [*2*], Wunderlich [*7*], and Turi [*8,9*]. The International Confederation for Thermal Analysis (ICTAC) also provides an overview of TA and a list of reference articles [*56*].

While a single TA technique may adequately characterize a research or production problem for a given system, questions often arise in the coatings industry that require several analytical techniques for adequate characterization. In fact, relying on a single characterization method could lead to serious errors in interpretation and, depending on the problem, serious financial consequences as well. The continuing development of simultaneous methods in TA underscores the value of combining techniques. They offer the advantage of simultaneous analysis of changes in physical and/or chemical properties under identical thermal conditions. There are a variety of these instruments available: examples of these "hyphenated" techniques include TG-MS (mass spectrophotometry), TG-DTA or TG/FT-IR (Fourier transform infrared spectroscopy).

Industrial applications of thermal analysis for coating characterization fall loosely into four areas:

- Product research and development.
- Problem solving.
- Quality control and quality assurance.
- Competitor products analysis.

While the results obtained using thermal analysis often focus on intrinsic properties such as component Tg's or the complex analysis of a material's viscoelastic behavior, thermal analytical methods are more typically focused on process properties and product properties. This paper provides an overview of the use of TA in the coatings industry and includes descriptions of the instrumentation, experimental conditions, and typical results.

EXPERIMENTAL TECHNIQUES

Scans were made using the TA Instruments' (formerly DuPont) 990, 9900, 2000, or 2100 temperature programmer controller. Nonisothermal studies were completed at heating rates varying from 5 to 15°C/min; isothermal temperatures will be noted as required. All scans were made under dry nitrogen or air. Each instrument was calibrated and operated using the manufacturer's recommended procedures. The typical operating conditions for each instrument are described below, with other important key experimental variables noted where necessary. A general overview of running experiments with each instrument is included at the end of each section.

DSC—Nonisothermal scans were made variously using the TA Instruments' 910 and 2910 DSCs, typically with 5.0 ± 0.1-mg samples. Materials were usually scanned twice, initially to establish uniform thermal histories and again to learn about specific physical properties. Runs were generally made at heating rates of 15°C/min between −125° and 250°C under a 50 mL/min nitrogen or air purge. In some instances, latex samples were introduced into liquid drop pans and dried in a controlled humidity chamber for a minimum of 24 h before analysis.

DSC Reaction Kinetics—Similar conditions to those described above were used, although heating rates were generally held to about 5°C per minute. Samples of unreacted material weighing about 10 mg were placed in special pans for liquid samples. In the residual heats of reaction experiments, heats of reaction were determined for samples removed from a batch reactor at 10-min intervals throughout the reaction process. The residual heats were measured under nonisothermal conditions using commercially available software. The ratio of partial heats of reaction to total heat of reaction as the polymerization progressed was given as the percent chemical conversion.

DMA—DMA scans were made variously in vertical and horizontal modes on TA Instruments' 981, 982, and 983 DMAs. All studies were completed at 5°C/min, usually under nitrogen purge. Cure studies employed either fiberglass braid supplied by TA Instruments or stainless steel mesh (Cleveland Wire Cloth & Mfg., Cleveland, OH). In cure studies, 100-μL wet samples were applied to substrates mounted in the DMA using analytical pipettes [50 mL ± 0.5% to deliver (TD)]. Isothermal temperatures were typically attained by mimicking the come-up time in an oven. For example, if a coated panel required 4 min to reach bake temperature in a production scale oven, then a similar time schedule was programmed into the DMA.

TMA—Thermomechanical and dilatometric experiments were made using TA Instruments' 942 and 943 TMAs. Scans were made at 5°C/min under nitrogen or air between about −50 and 250°C. In general, the sample was cooled at least 50°C below the expected transition temperature. TMA scans were typically made directly on coated substrates, while dilatometric experiments were completed on samples varying between 0.1 and 0.6 mm in thickness. In the penetration experiments, loads were typically about 5 g (0.05 N).

DEA—The TA Instruments' 2970 DEA and either the parallel plate or ceramic single surface sensors were used in the dielectric experiments. Parallel plate sensors were used to study thin films removed from various substrates. Ram force varied from a few newtons to 175 N depending on the coating. The ceramic single-surface sensor was used to study resins and powders. 100-μL samples were spread uniformly on the sensor and dielectric measurements recorded from 0.1 Hz through 100 kHz in order-of-magnitude increments. Heating rates were selected to ensure that an entire set of frequencies (0.1 Hz through 100 kHz) could be recorded for each 1°C increase in the sample temperature. Samples were typically scanned at 1 to 2°C/min between −125 and 200°C under nitrogen.

TGA—TA Instruments' 950, 951, and 2950 TGAs were used in the examples described here. Samples used in typical thermogravimetric experiments usually weighed between 3 and 10 mg. Scans were made at 10°C/min under nitrogen beginning at room temperature (RT) and ending at 600°C. The high-resolution thermogravimetric analysis described here was completed at 50°C/min in nitrogen at a resolution factor of 5; sample weights ranged between roughly 10 and 12 mg.

DIFFERENTIAL SCANNING CALORIMETRY

In differential scanning calorimetry (DSC), the difference in heat flow between a sample and a reference is measured under precisely controlled thermal conditions. Coatings generally possess one or more characteristic transitions, includ-

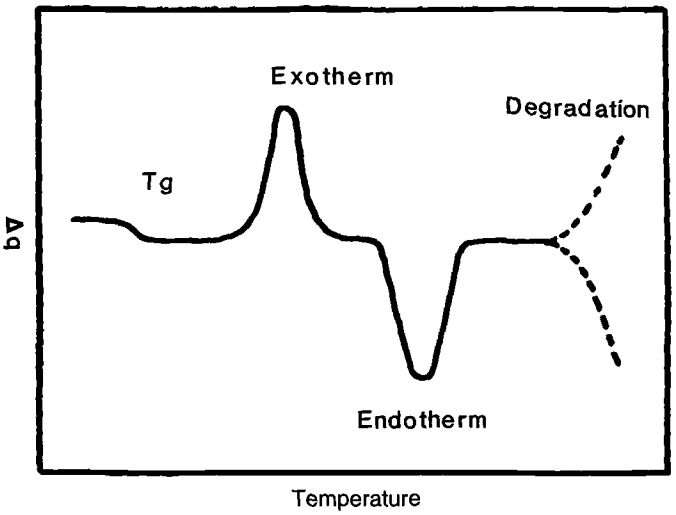

FIG. 1—Schematic DSC curve illustrating common transitions observed by DSC (Δq = heat flow).

ing (1) the glass transition (Tg) or a transition related to changes in specific heat; (2) exothermic peaks brought about by a physical process or a chemical reaction such as crystallization or a chemical process such as a cross-linking reaction; (3) narrow endothermic peaks related to fusion or melting; (4) broader endothermic peaks caused by the volatilization of low-molecular-weight materials, dissociation, or decomposition; and finally, (5) an increase or decrease in heat flow with oxidative or thermal decomposition. The results shown in Fig. 1 illustrate most of the transitions common in coatings. The DSC has a number of important uses in coatings characterization; two of the most important—Tg determination and reaction kinetics analysis—are described in more detail below.

Glass Transition Temperatures—Probably the best understood and most commonly used property of polymers, glass transition temperatures are important in virtually every phase of a coating's development and manufacture. The Tg marks a polymer's transition from an amorphous glass to a rubbery solid and defines the limits of processability for most polymers. In a nonisothermal or rising temperature DSC experiment, the glass transition coincides with a relatively sharp increase in heat flow to the polymer and a corresponding increase in the polymer's specific heat. Several techniques can be used in the assignment of a DSC Tg, including the onset, midpoint, and endpoint of the transition; in practice, the Tg is most commonly assigned to the extrapolated onset of the transition.

Sample Preparation and Tg Measurement—Measuring the glass transition temperature usually means nothing more than removing a sample from a substrate, placing it in a sample pan, and heating through the glass transition temperature in the DSC. Either of two techniques can be used to determine the Tg. When the "product" Tg (including all processing and thermal history effects) is of interest, Tg's are obtained with a single temperature sweep. Where thermal history effects are unwanted complicating factors, two temperature sweeps are used. The first sweep removes thermal history effects (for example, sample preparation or aging effects) while the second sweep gives the Tg. The latter technique works very well provided that there are no chemical changes, solvent losses, or morphological alterations during the first sweep.

Sometimes, inconsistencies in sample preparation or a seemingly unimportant detail can significantly influence the interpretation of the results—particularly when first run transitions are required. In the example below, two latexes—one scraped from a glass slide and placed in a vented pan and the other dried directly in a liquid drop pan—produced considerably different results. The samples were dried side by side in a dessicator before analysis.

The sample scraped from the glass slide shown in Fig. 2 exhibits a large endothermic peak centered around 75°C. Normally, this endotherm would suggest the loss of a volatile component or an important morphological feature. However, the results for the latex dried directly in the liquid drop pan suggest that something else is influencing the results. The heat flow curve for the latter sample exhibits no endotherm and has a Tg some 15°C higher than the sample removed from the glass slide. High-resolution videography resolved the issue, showing that the difference in Tg and the endothermic "event" was probably brought about by the softening and subsequent relaxation of the latex pieces scraped from the glass slide. What appeared as a significant morphological feature was nothing more than an artifact of the sample preparation process. In a typical two-sweep Tg measurement, this endotherm most likely would have been ignored and only the second run Tg reported, but, in studies that require the first-run data (as was the case here), the wrong conclusions could have been drawn.

Tg and Composition—Tg's obtained by DSC are also used to confirm the accuracy of Tg's calculated from additive relationships like the Fox equation [*10*]. The Fox equation and others like it are employed by coatings chemists in synthesizing copolymers to a specific Tg. Tg's obtained with these equations are based on the interrelationship of the molar or weight fraction of each monomer and their corresponding Tg's. While experimental results usually confirm the accuracy of Tg's calculated with these relationships, experimental and calculated results can deviate significantly from one another, a fact that underscores the need to verify expected results with an objective measure.

The discrepancy between calculated and experimentally obtained Tg's for four acrylic copolymers, shown in Fig. 3 and Table 1, aptly demonstrate the importance of corroborating calculated Tg's by DSC. In this example, the Tg's determined by DSC are much lower than the Tg's obtained using the Fox equation. Close examination of the DSC heat flow curves gives outstanding clues about the character of the polymers being analyzed. Compared to a typical Tg, the transitions in Fig. 3 are very broad—covering some 40 to 50°C—and quite shallow, falling less than 0.1 cal/s/g from beginning to end. The character of the glass transition region in a typical DSC is quite different. The temperature range of this region is usually no more than about 25°C wide and usually drops more than 0.5 cal/s/g over the Tg range. The differences between assigned and calculated Tg's probably stem from the combined effects of monomer sequence distribution [*11*] and end group effects related to the relatively low molecular weight

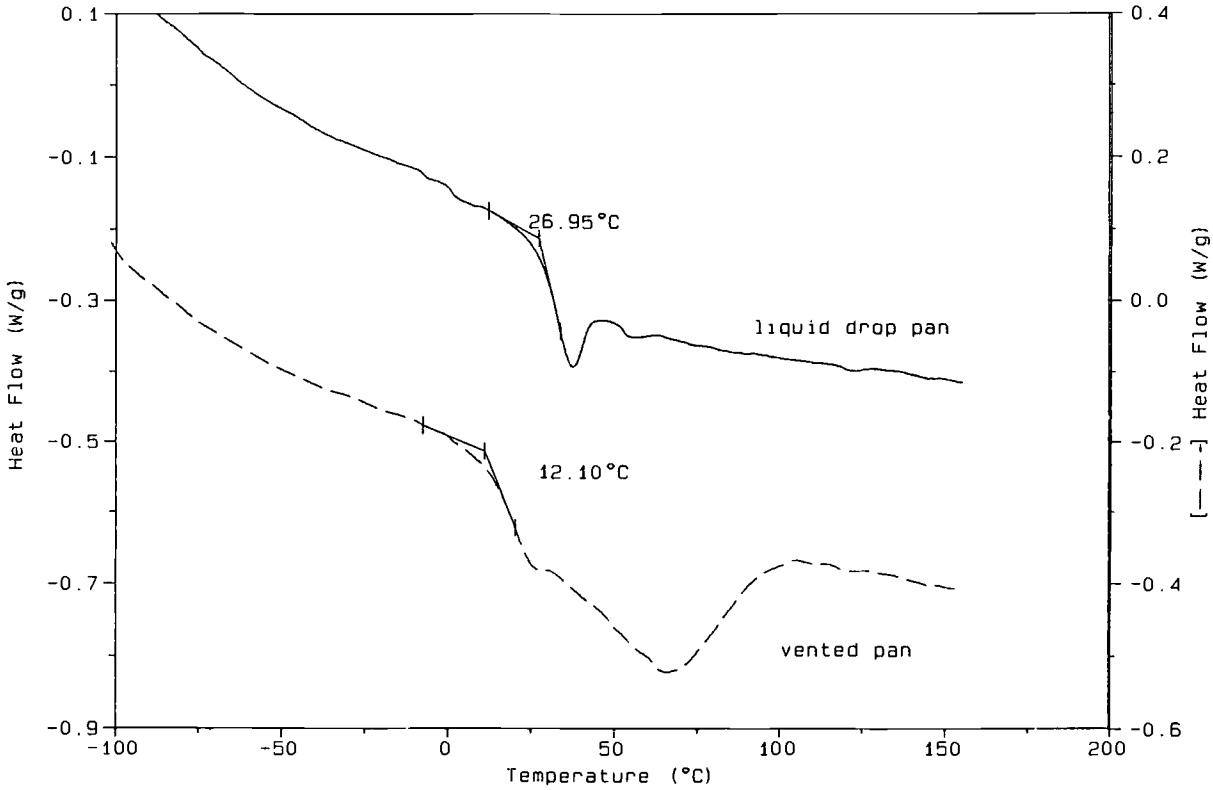

FIG. 2–Characteristics of the glass transition in identical latexes prepared by different methods.

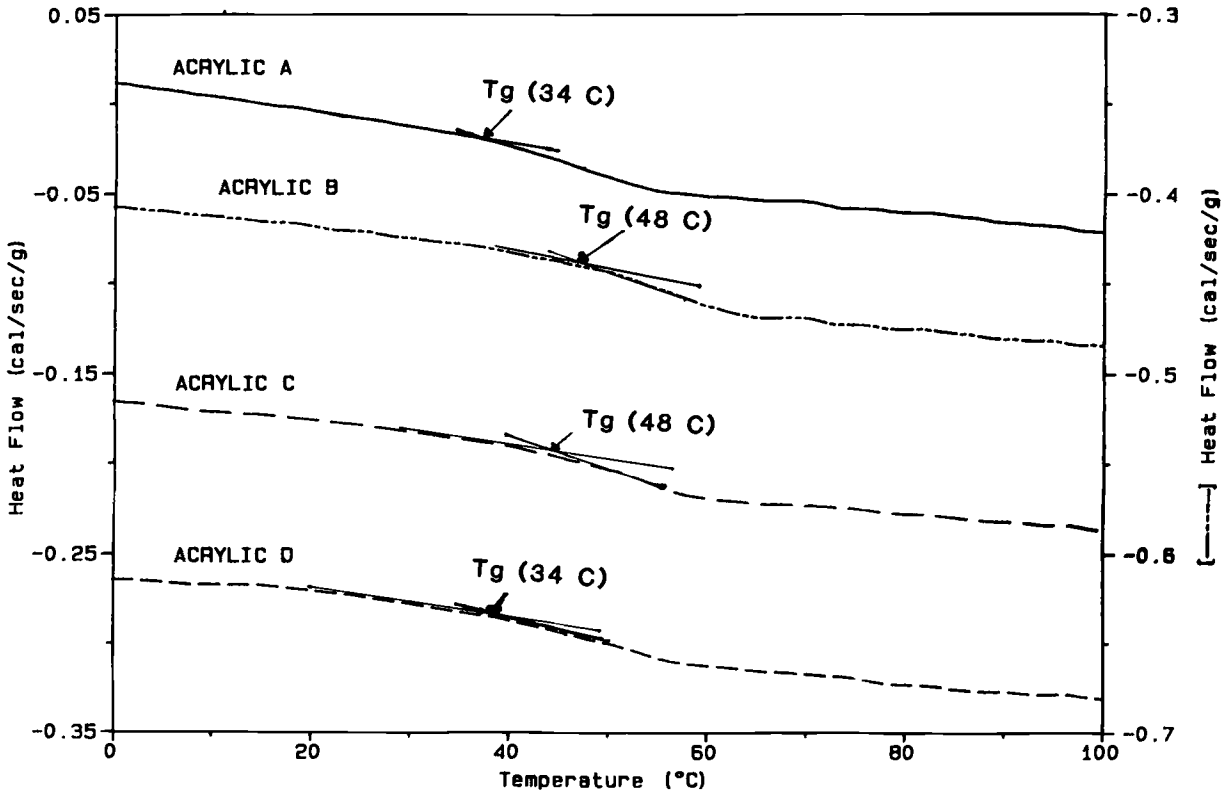

FIG. 3–Glass transition temperatures for four acrylic copolymers.

[a]Tg's were calculated using the Fox equation.

[*12*] of these copolymers. The polymers used in this experiment were all low-molecular-weight tetramers (number average molecular weight < 5000) composed of various combinations of methylated and butylated acrylics. Van Krevlan [*1*] provides a more comprehensive overview of polymer properties which could have an influence on the assignment of the glass transition temperature.

REACTION KINETICS

A number of techniques have been developed for measuring the kinetic parameters of chemical reactions from DSC data. The primary advantage of these techniques over traditional wet chemical techniques is their speed and simplicity. Research in reaction kinetics analysis by DSC includes studies focused on isothermal techniques [*13–15*], nonisothermal (also known as temperature variant, rising temperature) or dynamic methods [*16–17*] and multiple scan methods [*18–19*]. Each method uses the rate of heat evolution as the computational parameter, implicitly assuming that the reaction is not autocatalytic, has one rate-limiting step, and is unaffected by changes in reactant concentration or volume. The validity of kinetic data obtained using nonisothermal procedures has been the source of considerable technical effort and discussion in the literature (see, for example, Refs *20* and *21*).

Nonisothermal reaction kinetics analysis plays an important role in the characterization of coatings. Differential methods based on the work of Borchardt and Daniels [*16*] are the most commonly used in obtaining reaction kinetics parameters by DSC. These methods assume that the heat evolved during a reaction is proportional to the extent of reaction. The order of reaction, n, the activation energy, E (kJ/mol), and the Arrhenius constant, A (s^{-1}), are determined using an equation based on a general nth order rate expression

$$\frac{dF(t,T)}{dt} = k[1 - F(t,T)]^n \quad (1)$$

where $F(t,T)$ is the fractional extent of conversion [partial heat of reaction ΔH (t,T) divided by the total heat of reaction H_0], k is the rate constant, t is time, and T (K) is the absolute temperature. The temperature dependence of the rate constant is given by the Arrhenius expression

$$k = A \exp(-E/RT) \quad (2)$$

where R is the ideal gas constant (J/mol K). The methods used here have been described in detail elsewhere [*22–23*].

In nonisothermal kinetics experiments, autocatalytic reactions and first-order reactions are virtually indistinguishable because both reactions produce a uniform, monomodal, exothermic peak as the experimental temperature increases. The only way to determine the nature of the reaction mechanism is by running an isothermal experiment. An isothermal experiment will clearly differentiate between the two reaction types because the exothermic peak marking the maximum rate of reaction will occur at very different points, depending on the nature of the reaction. In a reaction that obeys first-order kinetics, this peak will occur immediately after reaching the isothermal temperature. In an autocatalytic reaction, the maximum rate of reaction—and therefore the peak maximum—occurs well after reaching the isothermal temperature.

Epoxy-Amine Reaction Kinetics

Maximizing the efficiency of a reactor and minimizing raw material waste in a chemical reaction depends inherently on knowing how a reaction proceeds and, more specifically, how long the reaction takes to reach completion. Unfortunately, measuring the rate and degree of conversion in reactors holding hundreds or even thousands of gallons is a prohibitively expensive process during product scale-up. Small-scale laboratory DSC experiments representative of a production reaction can significantly reduce reactor time and process costs. Modeling the extent of reaction using DSC kinetics analysis can further shorten the development process and can be used to predict the extent of reaction under widely varying temperatures and reaction times. In the example that follows, these techniques were used to optimize reactor time and improve productivity in manufacturing. The reaction involved a typical diglycidyl ether of bisphenol A (DGEBPA) epoxy and an amine.

In this example, chemists arbitrarily placed the time to form an epoxy adduct at 8 h, a substantial manufacturing cost when considering reactor time and labor. However, predictions based on nonisothermal DSC reaction kinetics showed that the reaction should actually reach completion much faster than 8 h. In fact, DSC reaction kinetics parameters (n = 1.1, E = 72.0 J/mol, and ln A = 19.2) indicated that the process should take about 2 h under the specified polymerization conditions. These results were then corroborated by measuring the residual heats of reaction (see experimental for details) observed in small samples taken from a 100-gal reactor. Figure 4 compares predicted conversion with the residual heats of reaction measurements. While neither method was extended to show the actual time required to reach 100% conversion, extrapolation to 100% conversion indicates the reaction should reach completion after about 2 h. Table 2 compares selected data from Fig. 4 at specific reactor times. These results show that the reaction reached a higher level of conversion (based on DSC residual heats) in the manufacturing process (88%) than predicted by DSC (67%). Nonetheless, the extrapolated end-point from the DSC kinetics analysis—although a bit high at 2.5 h—is much better than the 8-h reactor time set arbitrarily by the chemists.

The discrepancies between the measured and calculated degrees of conversion are probably related to competing side reactions that could occur in DSC experiments (i.e., at elevated temperatures) but not during manufacturing and also to the vast difference in the reaction conditions: DSC kinetics

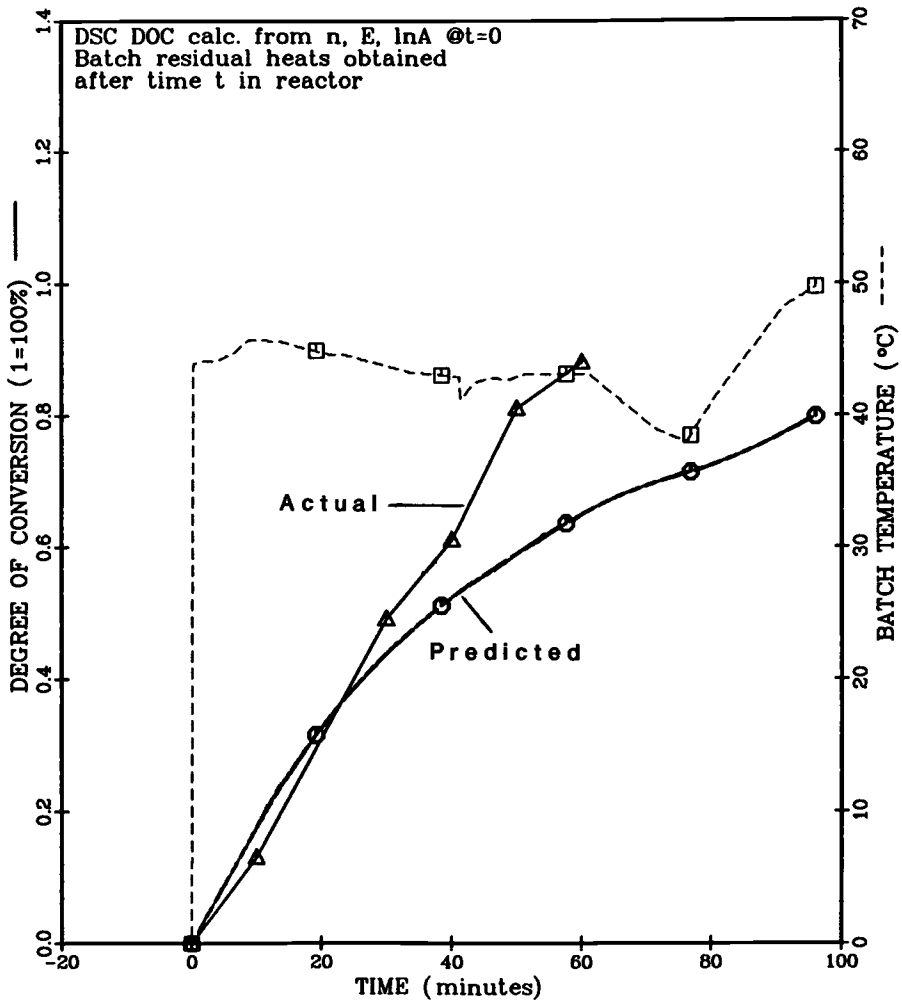

FIG. 4—A comparison of actual and predicted degree of conversion in an epoxy-amine reaction. The predicted degree of conversion at each point was based on DSC kinetics analysis, while the actual degree of conversion at each point was based on the residual heat of reaction on samples removed from the reactor.

analyses were made using fresh 5-mg samples, while the residual heat studies were made with samples taken from a 100-gal reactor.

Coatings Characterization by DSC

Sample Preparation: The materials typically analyzed in the coatings industry can come as either solids or liquids. Solids require little special preparation; they just need to fit in the pan and, most importantly, remain very flat on the bottom of the pan. Liquids are another matter and usually require a special container for analysis. No matter what the form, limit your sample size to somewhere between 5 and 10 mg. Large samples (>10 mg) may not heat uniformly, with the outer layers heating more rapidly than the center of the sample. You can also get results with samples in the 1-mg range, but using smaller masses can reduce resolution. For a more accurate assignment of the Tg, use high sample weights (ca. 20 mg) and slow heating rates (1°C/min).

Either open or closed pans can be used. We prefer closed pans with perforated (use a fine needle) lids. Lids help keep the DSC oven or cell clean; the perforations prevent pressure buildup caused by solvents or low-molecular-weight reaction products. Many others use only open pans.

Liquid paint and latex samples are treated somewhat differently in that they are placed in open pans (especially designed for liquids) and allowed to dry (24 h minimum) before analysis. This approach prevents the development of artifacts that sometimes occur when a dried sample is scraped from a substrate and placed in the pan.

TABLE 2—Chemical conversion obtained from residual heats of reaction and simulations using DSC kinetics parameters.

Reaction Time, min	Actual % Conversion	Predicted % Conversion
0	0	...
10	14	19
20	31	33
30	49	43
40	61	53
50	81	61
60	88	67

Purge gas: The selection of purge gas depends on your objectives. High-purity dry nitrogen (99.99%) is typically used. It offers low cost and reasonably good heat transfer. Argon, another frequently used gas, improves heat transfer and the resolution of the analysis but at increased cost. Purge rates vary with the instrument.

Temperature Range and Heating Rate (β): Start each temperature sweep at about −125°C and end at least 50°C above the Tg. This temperature range will include any transitions in typical coating systems that could affect performance. If you know the Tg of your sample and you are unconcerned about ancillary transitions, use the 50/50 rule: start runs 50°C below the Tg and end them at least 50°C above the Tg, making sure that the sample has time to equilibrate at the starting temperature.

The important consideration in selecting a heating rate is heat transfer and the steady state conditions in the sample. For routine analysis, a 15°C/min heating rate offers a good compromise between run time and resolution. Keep in mind that high heating rates can produce thermal lag in the sample and tend to broaden transitions. And, when there are two or more transitions, they tend to run together. Slower heating rates are usually used where there is a need for high resolution. But, when time is not a concern, slower rates are always preferable. There are also instances, for example film formation experiments, where isothermal temperatures are necessary. Choose an experimental temperature slightly higher than ambient, say 30°C, for controlled room temperature experiments.

Thermal History: In most analyses, the sample should be analyzed twice. In unreactive systems, the first sweep erases any effects of the sample's previous thermal history and establishes a uniform baseline for each sample—this is especially important in comparing a series of samples.

In reactive materials, analyze through the cure temperature and allow for the reaction to reach completion. Determining the proper temperature range may require some "scouting" experiments. In isothermal cure studies at elevated temperatures, try to simulate bake conditions. Select an initial heating rate that approximates come-up time for a substrate in an oven and add enough time at the bake temperature to match the typical oven "dwell" time.

Data Collection: In non-isothermal or rising temperature experiments, try to average between two and eight data points per degree Celsius increase, depending on the experimental objectives. Higher heating rates require higher data-collection rates to obtain the same resolution. Note that high data-collection rates at slow heating rates can produce large data files. Data collection for isothermal studies must be tuned to the time required for an event to occur. Fast events would require high data collection rates; slower events would require correspondingly lower rates.

DYNAMIC MECHANICAL ANALYSIS

DMA measures the viscoelastic response of a material under a periodic load. Dynamic mechanical analysis represents one of several methods for mechanical properties analysis [*24–26*] providing a valuable link between chemistry, morphology, and performance properties [*27–29*]. The DMA's applications range from the measurement of bulk viscoelastic properties to the sophisticated analysis of the kinetics of the cross-linking reaction. Depending on the geometry of the clamps and the instrument's design, the oscillatory load applied may be in flexure, tension, compression, or torsion; sample oscillation may be either at resonant frequency or at fixed frequency. These tests simultaneously produce elastic modulus and mechanical loss or damping values. Modulus values (flex, Young's, shear, bulk) provide an indication of material stiffness, while mechanical damping correlates with the amount of energy dissipated as heat during the deformation of the material. In tensile mode, these instruments can provide creep and stress relaxation data and can even be used in WLF [*30*] transformations (see Ref *30*).

In the coatings industry, DMA is broadly applicable to the study of film properties [*31*] and particularly important for cure process studies [*32–34*]. Another important application of the instrument involves characterizing paints after application and the film-formation process. A detailed overview of the use of DMA in thermoset cure studies is provided later in the chapter. Figure 5 illustrates the typical viscoelastic response for a generalized polymer coating. In this example, the glass transition temperature corresponds to a large decrease in modulus beginning near 25°C and a peak centered at about 70°C on the loss modulus curve. In noncrystalline polymers, transitions found below the Tg or in the glassy state are usually associated with the molecular motion of the backbone or small groups pendant to the main chain. At the same time, modulus values in the region above the Tg—the rubbery state modulus—impart information about a material's molecular weight or degree of cure, depending on the material. In thermoplastic materials, increasing rubbery state modulus values usually indicates increasing molecular weight. In thermoset materials, increasing rubbery state modulus values indicates higher cross-link density. A more complete description of the dynamic mechanical properties can be found in monographs by Nielsen [*24,25*] and Ward [*26*].

Synthetic Variables and Morphological Character

One of the strengths of dynamic mechanical analysis lies in its utility for resolving the effects of relatively minor changes in formulation or processing. Differences in these variables (usually) induce easily discernable changes in the viscoelastic properties of a polymer. For example, the materials shown in Figs. 6*A* and 6*B* are both epoxy acrylic coatings used in food packaging. While the coatings are made of virtually the same materials, their chemistries and processing conditions are different.

The presence of two glass transitions in the relative modulus curves in these graphs indicates that both coatings are heterogeneous systems. However, these curves give little indication as to whether the epoxy or the acrylic is the continuous phase. A comparison of the damping peaks reveals a difference in the peak intensity (or peak height) of the two transition regions. In filled systems, polyblends, and grafted systems, the intensity of the damping peak gives a rough estimate of the concentration of the components and an indication of which phase is continuous. The greater the concentration, the larger the damping peak and the more likely that phase is continuous [*24*]. In Fig. 6*A*, the epoxy phase peak at roughly 130°C has considerably greater magnitude than the

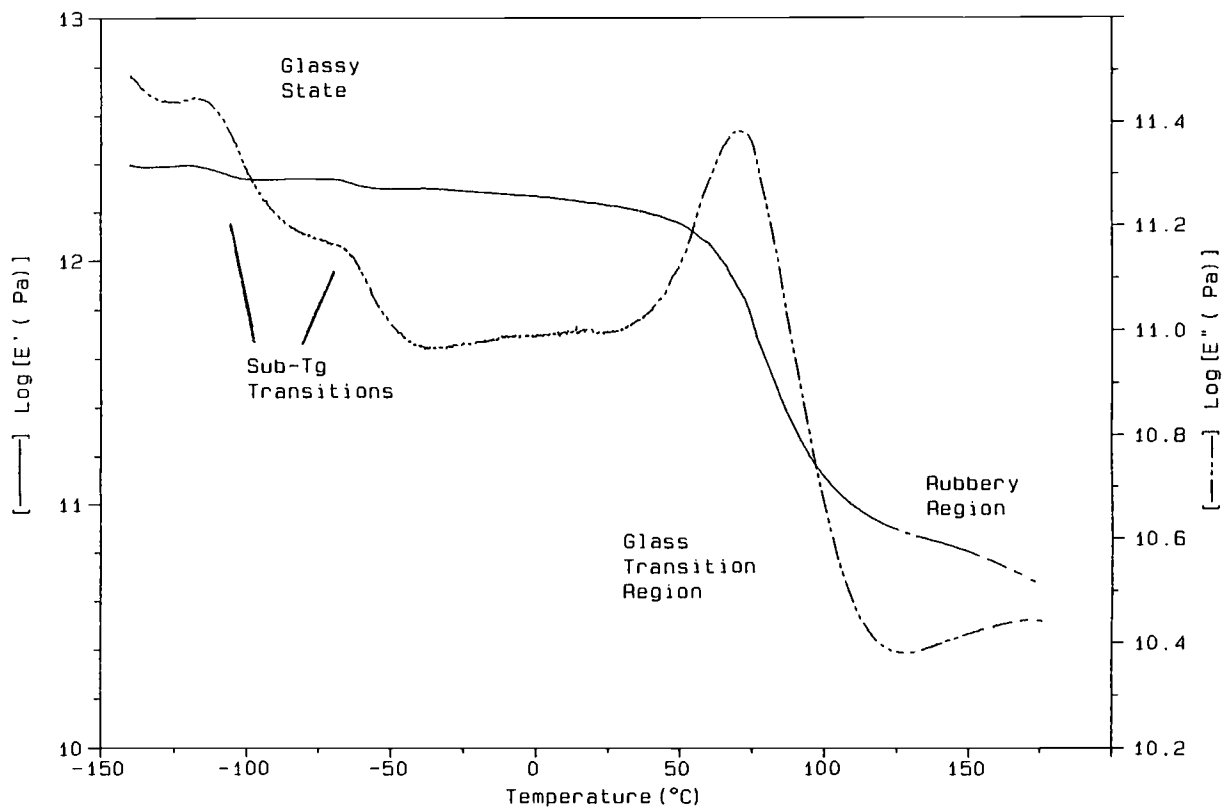

FIG. 5–Typical viscoelastic response in polymeric systems, log relative modulus (*E'*) and log relative loss (damping, *E"*).

one assigned to the acrylic and so would be the continuous phase. In Fig. 6*B*, the opposite is true. In this case, the acrylic phase centered near 90°C is continuous while the epoxy is the dispersed phase.

Aside from the information on morphology, these curves also give us information on the relative miscibility of these systems. If these two polymers were totally miscible, both the modulus and damping curves would have only one transition. Since there are two, it is clearly a two-phase system. Careful scrutiny of the two systems reveals that the peaks in Fig. 6*B* fall much closer together than those in Fig. 6*A*. This strongly suggests that the conditions used to produce the material in Fig. 6*B* produce a more miscible polymer.

Coatings Characterization by DMA

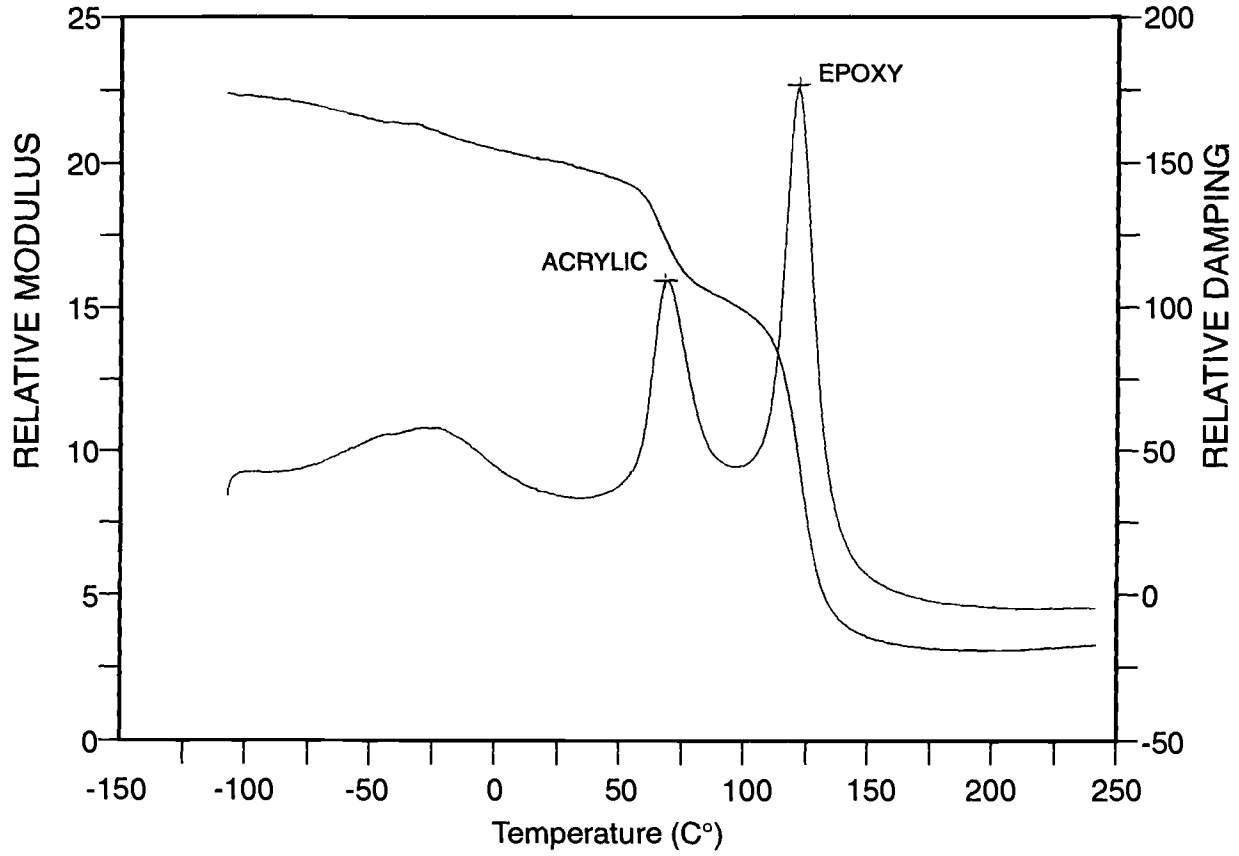
Dynamic mechanical analysis can be one of the most demanding and least forgiving of all the TA techniques. It's vitally important to spend time learning the instrument's idiosyncrasies before putting complete faith in the viscoelastic measurements the instrument produces. Each commercial instrument offers unique sample mounting geometries and usually offers a variety of experimental approaches. Regardless of the experimental approach, take the time to run a half-dozen experiments using identical experimental conditions so that you can better understand the range of results to expect under a given set of experimental conditions.

Sample Preparation: There are several approaches to forming free films for DMA investigations. These include coating low-energy surfaces like PTFE (Teflon) or polypropylene or coating thin aluminum sheet stock, allowing sufficient time for film formation, and dissolving the aluminum away with an alkali. Sample dimensions must always conform to the limits prescribed by the instrument manufacturer; wherever possible, however, sample thickness should closely approximate the thickness of the coating film in the field. In this way, test results will more closely represent those found in realistic end-use conditions.

Unfortunately, free films are not always a viable experimental choice. In those instances, coated substrates, e.g. very thin stainless steel shim or fiberglass braid, are often used. Although constitutive equations are available for obtaining absolute mechanical properties values from coated substrates, usually only relative measurements are made using this approach.

To insure uniform thermal histories, prepare specimens in a controlled environment. Small differences in film-forming temperature or humidity in replicate runs on the same coating can make it appear as if two different coatings had been tested. Well-controlled and consistent sample preparation allows the additional advantage of comparing results from tests made over many months or years without concern about differences in film-forming conditions.

Heating Rate: Undoubtedly, one of the most, if not the most, important consideration is choosing proper heating rates. While most instruments make rapid heating rates available (some manufacturers claim 200°C/min), it is wisest to choose very slow heating rates—at most, heating rates of about 1 or 2°C/min. Slow heating rates allow the entire sample to equilibrate to temperature change and thereby improve the reliability of transition temperature assignments. When



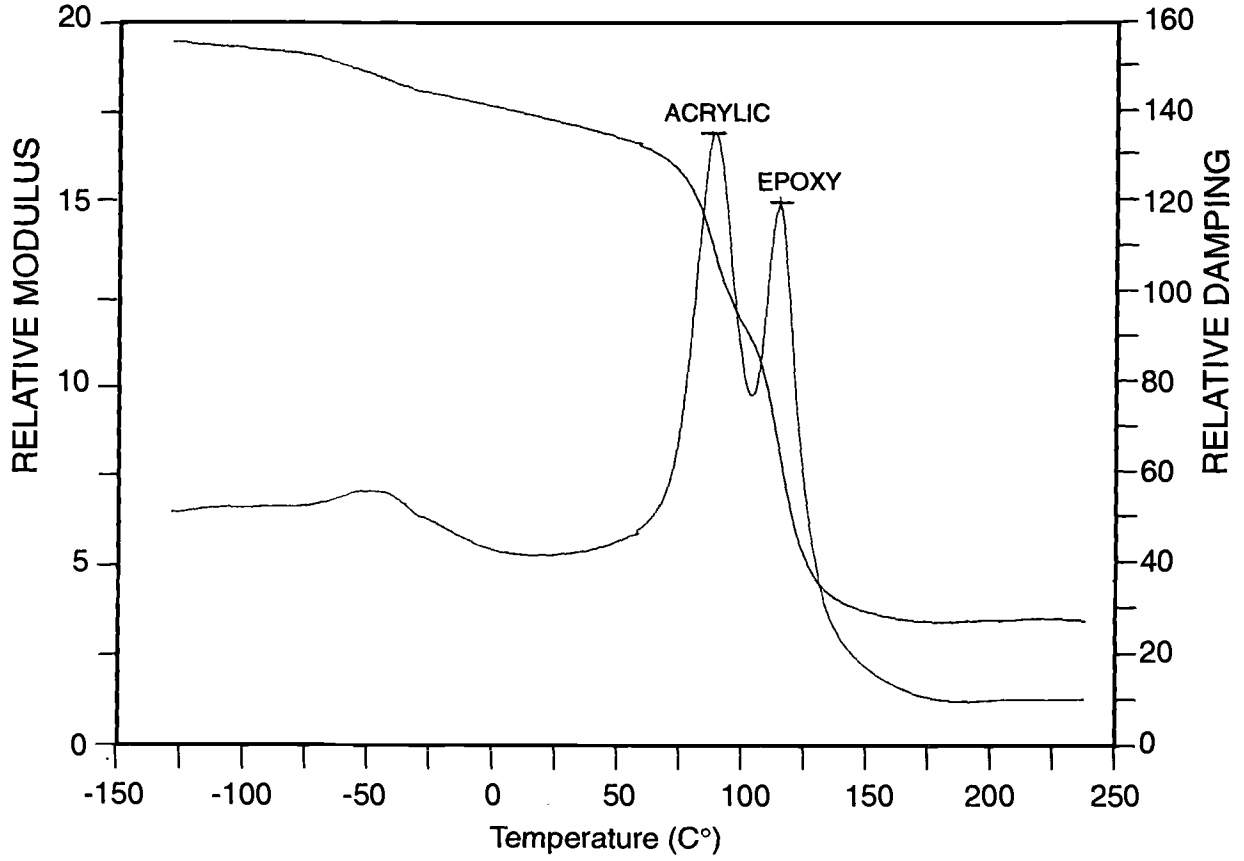


FIG. 6–Dynamic mechanical properties of epoxy/acrylic copolymers.

time allows, the best way to control thermal lag in the sample is by using step-change experiments. This kind of experiment combines slow heating rates (1 to 2°C/min) and isothermal "steps" (1 to 5 min), which allow the sample to equilibrate before heating to the next isothermal step. For thin coatings, shorter isothermal periods (1 to 2 min) are satisfactory, while thicker samples require longer (e.g., 5 min) isothermal steps.

Strain or Oscillation Amplitude and Frequency: In general, the greater the applied stress, the longer the relaxation time. Ideally, the sample should come close to full recovery from one applied stress before the next one begins. This means the experimenter should choose well-matched amplitudes and frequencies. For example, choosing a large mechanical deflection means that the time between the applied stresses should be longer. Conversely, higher-frequency experiments should have correspondingly smaller applied stresses. The proper relationship between the test frequency and oscillation amplitude will ensure that the sample has come close to mechanical equilibration between "events." In most instruments, the amplitude of the deflection is based on controlled strain. In these instruments, the maximum applied strain should be at 0.1% or less. This is particularly important in filled systems (like coatings), which will exhibit nonlinear responses more readily than unfilled systems.

Because mechanical relaxation times vary widely in polymers, there are no specific rules governing the selection of oscillation amplitudes and test frequency. As a general rule, oscillation amplitudes of a few tenths of a millimeter at 1 Hz are commonly accepted practical "standards." In very hard (brittle) or very soft materials, however, it's generally best to perform a controlled stress (stress relaxation or creep) experiment rather than an oscillating stress experiment.

Gas Flows: Where possible, apply a uniform gas flow. We arbitrarily set our gas flow rates so that gas content in the oven chamber "turns over" about once every 1 to 2 min. Since the size of these chambers varies considerably, flow rates will, too. If in doubt, use the manufacturer's recommended purge rates.

THERMOGRAVIMETRY (TGA)

Thermogravimetry describes an analytical technique used to monitor a change in sample mass as a function of time or temperature. Depending on need, either isothermal or nonisothermal experiments are possible; nonisothermal experiments—where the sample temperature changes at a linear rate—represent the most frequently used mode. In coatings technology, the instrument is most frequently applied in compositional analysis, e.g. nonvolatile content, and for studies of thermal stability. The technique can also be applied in studies of accelerated aging, decomposition kinetics, and oxidative stability.

In recent years, improvements in commercial instrumentation have enhanced resolution to about 0.05 mg. The primary differences between the types of commercial instrumentation center on the furnace type, the quality of the software, the control of gas flow, and the sensitivity of the microbalance. In addition, high resolution TGA and a robotic system are also available. Coupled with a mass spectrometer, gas chromatograph, or FT-IR, TGA becomes a powerful analytical tool combining both physical and molecular probes in a single technique.

Compositional Analysis—From time to time, performance properties will change because a material supplier makes changes in the formulation or manufacture of a product. Although the supplier may not recognize it, relatively minor changes in a material can engender major changes in a coating's performance, sometimes with a monetary consequence. Thermogravimetry provides one means for learning more about the composition of a material and when problems arise helps maintain acceptable performance. In this example, an unusual "settling" problem was traced to a subtle difference in the composition of a wax used in the paint formulation.

Other than a difference in the melt enthalpies, studies by DSC and conventional TGA (ramped at 10°C in N_2) analysis revealed that these waxes were virtually identical. However, when characterized using high-resolution thermogravimetry, small but significant compositional differences between the good (A) and suspect (B) samples became apparent.

Figure 7*A* shows the relative weight change in these materials as they decompose to carbon-char. Weight loss follows roughly the same path, regardless of the lot tested: beginning with a small step near 175°C, weight loss proceeds through a major step at around 300°C and ends with another small step between 450 and 500°C. The derivative (%/°C) curves shown in Fig. 7*B* offer the best illustration of the differences between lots. Each of the peaks in this figure represents a different decomposition step or combination of steps. If these materials were truly the same, the shape of the peaks and the peak temperatures would be virtually identical, but these materials possess several differences. Most notable are those associated with the peak between 250 and 300°C: the shape and position of this peak varies significantly. Working closely with the wax manufacturer, these results helped to identify a processing error and led to narrower manufacturing specifications. Earnest [*3*] provides a more detailed overview of thermogravimetry and its application to compositional analysis. Table 3 describes the differences in the thermal behavior in these lots of wax.

Volatile Organic or Moisture Content—With ever-tightening regulatory requirements, measuring the moisture or volatile organic content (VOC) has become increasingly important in the coatings industry. Figure 8 shows the relative nonvolatile content of two polystyrene latexes. Beyond simple measurements of volatile content, the technique is an excellent way to determine the amount and rate of evolution of decomposition products.

Thermal Stability—TG is also used widely to monitor the stability of polymeric coatings. Figure 9 shows that the long-term degradative stability of a coating based on a vinyl-ester resin was superior to a similarly formulated coating based on an epoxy resin. The information shown here was useful in establishing the cost-effectiveness of the vinyl-ester system.

Coatings Characterization by TGA

Sample Preparation: The materials typically analyzed in the coatings industry can come as either solids or liquids. Neither solids nor liquids require special preparation; they just need to fit in the pan. Like DSC, limit your sample size to

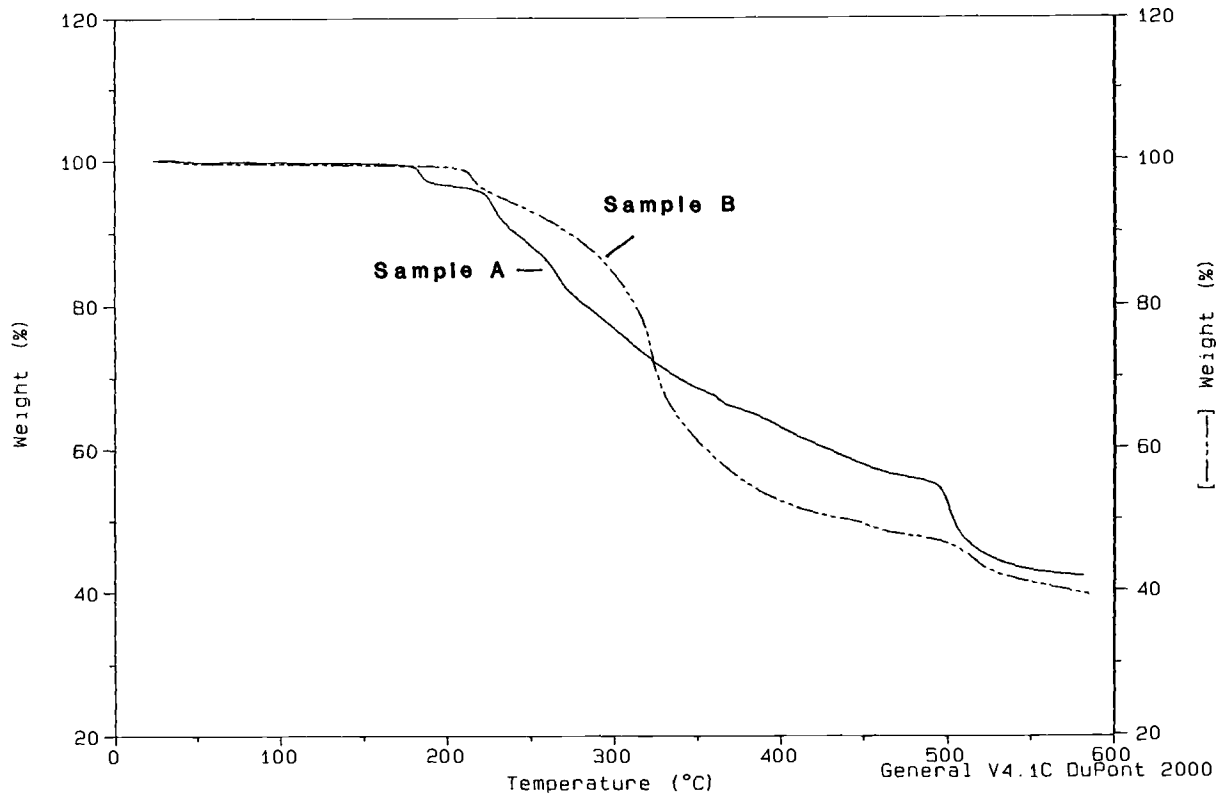

FIG. 7*A*–Weight loss curves for waxes with ostensibly identical compositions.

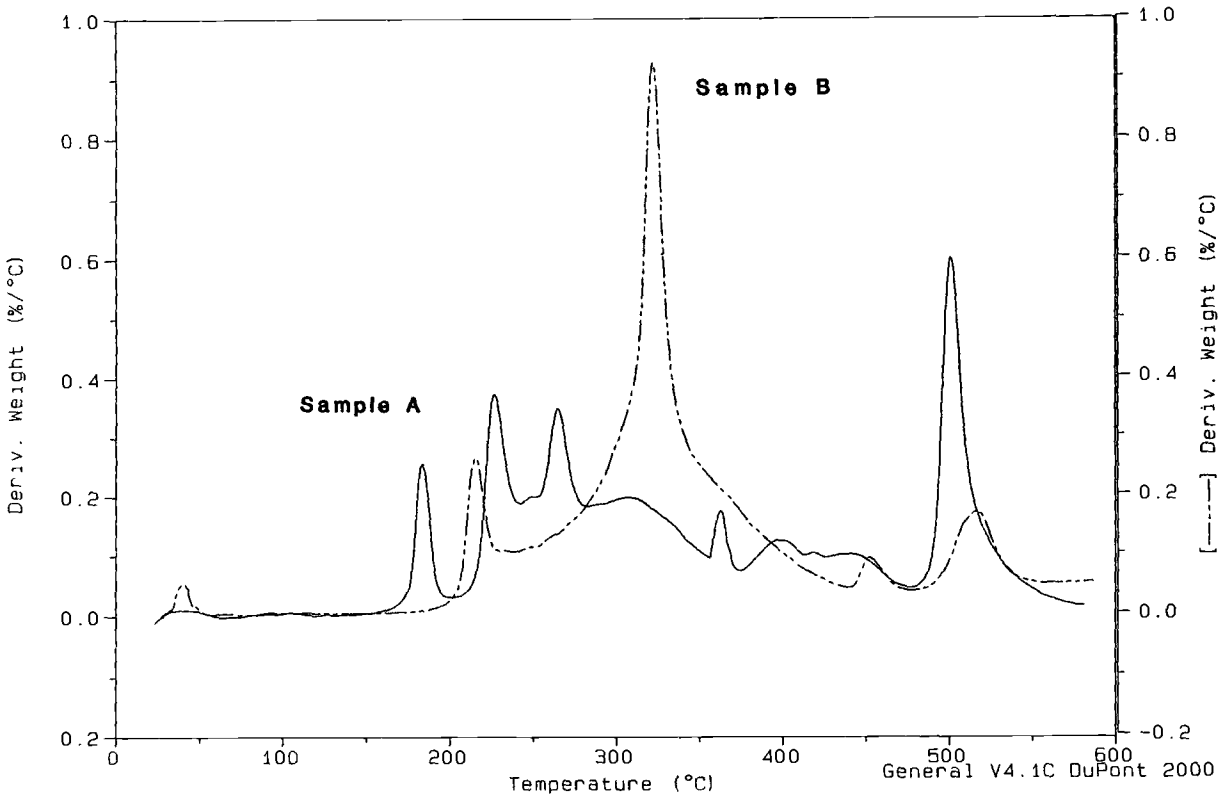

FIG. 7*B*–A comparison of the weight loss derivatives for the weight loss curves shown in 7*A*.

TABLE 3—Wax melt characteristics and decomposition characteristics.

Sample	Condition	T_m − 1(°C)	Total ΔH_m	Decomposition Onset-1, °C	% Char
A	Control, dry	87.7	75.7	172	38
B	Suspect, dry	87.4	46.1	150	43

NOTE: T_m = melt temperature.

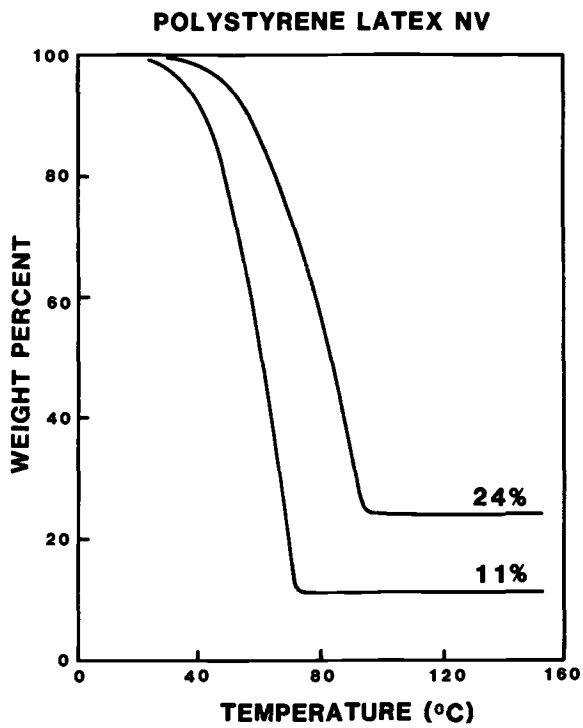

FIG. 8–Polystyrene nonvolatile (NV) content measurement obtained through TG.

somewhere between 5 and 10 mg. Large samples (>10 mg) may not heat uniformly, with the outer layers heating more rapidly than the center of the sample. For solids, the physical form of the sample is very important to the resolution of the test results. If the surface area is large, for example a powder or highly divided solid, then higher masses—as much as 40 mg—may be used without significantly reducing the sensitivity measurement. Choose the mass of a liquid sample based on the amount of solid material present, for example, use at least 10 mg of a liquid containing 50% solids. Beyond sample considerations, be aware that both aluminum and platinum—metals which are used in a typical TGA pan—can occasionally catalyze a portion of the decomposition process in some materials.

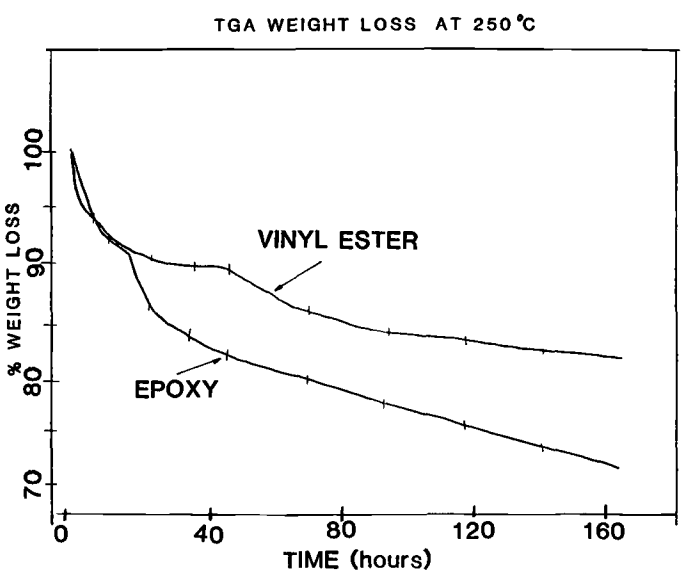

FIG. 9–Thermal stability of vinyl-ester resin.

Purge gas: Like DSC, the selection of purge gas depends on your objectives. High-purity dry nitrogen (99.99%) is typically used. It offers the benefit of low cost and reasonably good heat transfer. Argon, another frequently used gas, improves heat transfer and may improve the resolution of the analysis but only at increased cost. In some instances, you may want to control the humidity of your purge gas. A simple, low-cost method involves bubbling the purge gas through DI water in a bubble tube and running the effluent into the instrument. Relative humidity values can reach 80% using this approach. Purge rate requirements vary with the instrument.

Temperature Range and Heating Rate (β): In most compositional analyses, our experiments are run between room temperature and 600°C. This temperature range suits most coating systems because, as a rule, polymers (coating binders) usually begin to decompose somewhere between 250 or 350°C and are gone by 450°C. When running liquids, pay very close attention to the instrument's set-up time before it begins to collect data. In highly volatile materials, as much as 10% of the volatile material can be lost before the first data point is collected in the experiment. The difficulties with interpretation in this situation should be obvious.

The most important consideration in selecting a heating rate for your experiments is heat transfer and the steady-state condition of the sample. For routine analysis, a 10°C/min nonisothermal temperature ramp offers a good compromise between run time and resolution. Keep in mind that high heating rates can produce thermal lag within the sample, which in turn will broaden transition regions. In instances where a sample exhibits two or more weight loss transitions, they will tend to run together at higher heating rates. Slower heating rates are usually used where there is a need for improved resolution and run time is not a concern. Where isothermal temperatures are necessary, choose an experimental temperature most representative of the end use requirements.

A few instrument vendors offer "high or enhanced resolution" capabilities, a technique which, in essence, combines the virtues of a rising temperature experiment with the benefits of an isothermal experiment. Whatever the manufacturer's recommendation, make certain that the gas flow rates are *identical* for each part of your experiment. Analyzing the same sample with even small variations in gas flow (less than 5 mL/min) can produce dramatic changes in the weight loss curves or the weight loss derivative curves. In fact, one mate-

rial can appear to be two simply because of differences in the purge gas flow rate. These differences occur because the degradation mechanism is sensitive to temperature and holding the sample under near isothermal conditions can amplify a mechanistic step that would normally play a minor role in a standard rising temperature experiment. All of these precautions serve to emphasize one important fact: the experimenter must have a good grasp of the chemistry of decomposition when performing these experiments. Otherwise, he runs the risk of misinterpreting the results obtained for the decomposition process.

Data Collection: Try to average between two and eight data points per degree Celsius increase, depending on the experimental objectives. Higher heating rates require higher data collection rates in order to obtain the resolution obtained at lower heating rates. In some commercial instrumentation, the data collection rate can be varied from low to high at various steps in the experimental procedure. Note that high data collection rates at slow heating rates can produce large data files (using valuable disk space!) while yielding little or no improvement in the resolution of the data.

THERMOMECHANICAL ANALYSIS (TMA)

Thermomechanical experiments measure changes related to sample dimension as a function of time or temperature. These changes depend on both viscous (energy dissipative) processes and elastic (energy storing) processes within the material. Daniels [*35*] linked thermally dependent changes in dimension with various kinds of molecular motion: changes in dimension correlate with chemical reactions, lattice vibrations, changes of state, the glass-rubber transitions, changes in crystalline structure, or some combination of these phenomena. Riga and Neag [*36*] and Earnest [*37*] provide a thorough review of thermomechanical techniques and application in materials science.

The techniques associated with TMA are broadly applicable in materials science and are used in characterizing liquids, polymers, and inorganic materials. In practice, TMA is most commonly used in assigning transition temperatures or determining the coefficient of linear thermal expansion (α) by linear dilatometry. Descriptions of thermomechanical analysis (TMA) generally include linear dilatometric techniques because the same instrument can be used for thermomechanical and thermodilatometric experiments. When changes in sample dimensions are measured with a negligible load, the technique is more properly referred to as linear thermodilatometry (TDA). Depending on the experimental objective, any one of several probe types may be used.

TDA is typically applied in studies of ceramics, glasses, and metals—materials that exhibit a primarily elastic response (particularly for α)—or for determining glass transition temperatures (Tg) in polymeric materials. Dilatometric experiments are usually applied over a range of temperatures representative of the product's end use, but may begin near absolute zero and reach as high as 2500°C [*35*]. Thermomechanical analysis is most often applied in characterizing polymers or composites (e.g., most coatings), where the viscoelastic properties of a substance often dominate the material response. Thermomechanical studies usually employ a narrow range of experimental temperatures, typically falling between −175 and 850°C.

Instrumentation—The kind and quality of information obtained from a thermomechanical analyzer depends primarily on the arrangement of the sample and probe type. The penetration mode is probably the most commonly used arrangement in TMA and is usually used in assigning transition temperatures, such as the glass transition temperature or softening point temperature, in polymeric materials. In this mode of operation, substrate effects become increasingly important as the sample thickness decreases. This is particularly true in the analysis of thin films and coatings [*38*]. Tension tests are often used in characterizing the properties of thin films. In fact, improvements in instrumentation, particularly in controlling the applied force and fully automated operation, make possible the characterization of more fundamental viscoelastic properties such as creep and stress relaxation. These improvements have also increased the resolution of these instruments considerably. The resolution of these instruments ranges from about 500 nm in first-generation commercial instruments (ca. 1975–80 and earlier) to claims of less than 5 nm in second-generation instruments.

Dilatometry—This method has broad applicability in coatings technology, such as in determining the coefficient of thermal expansion (CTE). It is particularly valuable in failure analysis. For example, mismatches in CTE appear to play a role in the failure of two-coat systems such as gel coats.

Gel coats are polyester/styrene systems that are sprayed directly onto a mold surface and allowed to advance to a tack-free state. A fiberglass mat is then placed onto the partially cured gel coat and a reinforcing laminating polyester resin applied to the fiberglass mat. The laminate is removed from the mold after reaching optimum cure under ambient conditions. If the gel coat or laminating resin is improperly formulated or undercured, differences between the CTE values may be large enough to cause delamination at the interface.

Ideally, the CTE values for the members of the part should be the same or only slightly different. In this instance, however, the differences in CTE values shown in Table 4 led to delamination and the eventual failure of the part. Subsequent analysis of residual heat of reaction by DSC showed that the gel coat was improperly cured. Inadequate cure led to appreciable differences between the CTE values of the gel coat and laminate, and ultimately, to the failure of the system. Figure 10 provides a comparison of the CTE curves for the gel coat and polyester laminating resin.

TABLE 4—Gel coat and laminating resin CTE values (PPM/°C).

Material	No. of Runs	Avg CTE	Standard Deviation	Range
Gel Coat	4	5.0	0.2	5.0–5.3
Laminating Resin	5	5.9	0.1	5.8–6.1

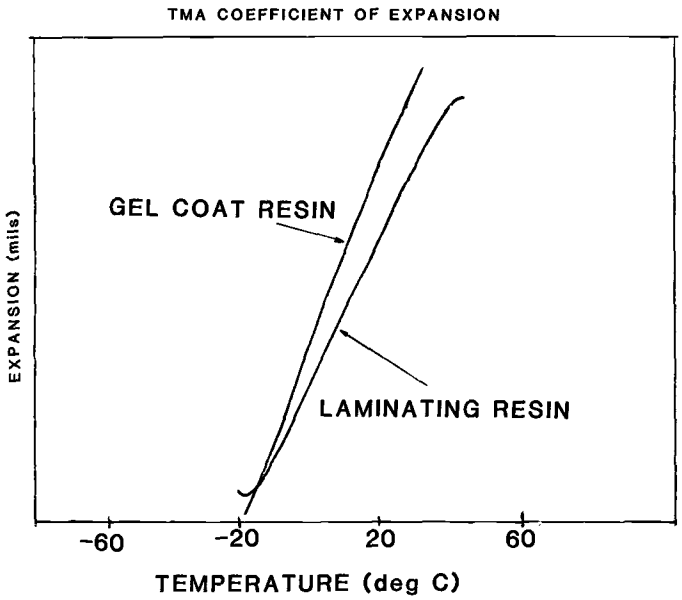

FIG. 10—A comparison of the CTE curves for the gel coat and polyester laminating resin.

Thermomechanical Analysis

Softening point temperatures (SPT) and total probe displacement obtained using thermal mechanical analysis provide valuable insight into a coating's performance, particularly in comparing the relative degrees of cure in production materials. For example, when cure levels in two container coatings were compared—one of which failed QC tests after manufacture—TMA results strongly suggested that the failed coating was undercured. The TMA results in Table 5 show that the failed coating had a lower softening point temperature and greater total displacement than the coating that passed. Rebaking the failed coating led to an increase in SPT and a decrease in probe penetration. While the changes in SPT and probe displacement indicate an improvement in performance, they still failed to match those of the coating that passes the QC test. Intentionally undercured coatings yielded similar results, strongly suggesting that the coatings that passed reached a higher degree of cure than the coating that failed. Perhaps more importantly, these materials were characterized directly on the container substrate, indicating the TMA's value in situations not amenable to characterization using more routine analytical methods.

Coatings Characterization by TMA

Sample Preparation: Sample preparation requirements vary depending on the test mode, usually either force/deflection (penetration) or dilatometric experiments. Either free films or coated substrates can give excellent results. While free films are probably best—provided that they lay flat and retain their shape during the experiment—it's usually more practical to run TMA experiments with coated substrates. If you use a coated substrate, pay close attention to sample thickness, the dimensional stability of the substrate during the experiment, and the size of the sample in relation to the probe tip. The larger the sample in relation to the probe tip, the better.

Substrates, like the coating, can change with experimental conditions and consequently influence experimental results that an experimenter might attribute to coating properties alone. The best way to avoid substrate effects is to increase the thickness of the sample. Ideally, samples should be about 500 μm (20 mils) thick, but films this thick are rarely found in any application. Moreover, increasing the thickness of the sample may improve resolution at the expense of validity. In practice, films measuring 20 μm (about 1 mil) will yield excellent quantitative results. In general, if you can make the sample thicker without compromising the validity of the results, you should. The need for thick samples doesn't mean that thin samples may not be tested. In fact, significant *qualitative* results can be obtained at film thicknesses as small as 5 μm provided that the sample preparation conditions are extremely well controlled.

If you have doubts about potential substrate effects, analyze the uncoated substrate and try to determine if the substrate will contribute to changes in the TMA's response. Some software packages will allow you to subtract baseline effects from the total response of the coated substrate. As with the DMA, ensure uniform thermal histories by preparing specimens in a controlled environment.

Heating Rate: For most applications, use heating rates around 5°C. The primary consideration in selecting a heating rate are potential problems with thermal lag in the sample. Temperature gradients within the sample can broaden transition regions and force them to occur at artificially high temperatures. In contrast, slow heating rates allow the entire sample to equilibrate to temperature change, which, in turn, improves the accuracy of transition temperature assignments.

Applied Force: This only applies to penetration experiments because dilatometric experiments require that the probe be brought into very light contact with the sample. In penetration experiments, applying very low forces may not provide adequate change in the sample to accurately monitor subtle transitions during an experiment; conversely, large forces may actually damage the sample during an experiment. In instruments that use weights, the applied force should be between 5 and 20 g. In servomotor-controlled TMAs, use 0.05 to 0.2 N forces for probe tips with a 0.4-mm radius.

Gas Flows: As with all of the instruments, purge gases provide a stable test environment and ensure uniform heat transfer to the sample. Use the manufacturer's recommended purge rates for all experiments.

TABLE 5—TMA softening point temperatures (°C) and probe displacement values (μm).

Material	Production SPT	Probe Displacement	Rebake SPT	Probe Displacement
Passed	100	1.1	104	0.3
Failed	91	4.8	99	0.9

Special Applications: Many of the newest commercial TMA's are quite versatile instruments and come with special attachments for performing unique experiments. For example, most TMAs come with clamps for tensile testing—good for measuring everything from tensile modulus to shrinkage with age or cure. These techniques almost always require special preparation and operating conditions. Work closely with the supplier when designing these experiments, or, better still, ask the manufacturer for a contact familiar with the technique.

DIELECTRIC ANALYSIS

Dielectric thermal analysis (DEA) is a convenient nondestructive test that relates fundamental molecular motions to a variety of polymeric properties. Applications in coatings science include the characterization of new materials and processes, cure studies, film formation studies, formulations optimization, applications development, performance prediction, competitive product evaluation, and QC/QA applications. General descriptions of dielectric properties can be found in a variety of papers [*27,39–41*].

Because engineering limitations prohibit the characterization of the complete continuum of dielectric properties, there are a number of commercial dielectric analyzers available, each offering advantages in their potential range of applications. The operating principle of all of these instruments, however, is the same: a polymeric system is polarized in an electrical field and the time, temperature, and frequency-dependent dielectric relaxations monitored. Commercially available instruments may be divided into two broad categories: those polarizing samples with an alternating current (ac) and those using a direct current (dc). Each instrument may also have one or more sensors or analytical configurations; these include remote single-surface, ceramic-single-surface or parallel plate geometries.

All dielectric analyzers measure two fundamental electrical characteristics of a material—capacitance and conductance. Capacitance measures a material's ability to store electrical charge, and conductivity measures its ability to transfer electric charge. These components are used to determine geometry-independent values for the material's permittivity (e') and loss factor (e''), serving as molecular probes that correlate with the changing chemical and physical states of the material. Permittivity corresponds to the alignment of dipoles in the electrical field; permittivity values are relatively low at temperatures below Tg or in highly cross-linked polymers and relatively high above the Tg. The loss factor corresponds to the amount of energy required to align dipoles and move ions in the electrical field. The latter term is frequently used in monitoring rheological changes during processing or for monitoring the progress of a cure reaction. More complete descriptions of the use of dielectric analysis in thermal analysis [*9*], film formation [*42*], and thermoset cross-linking [*43–45*] can be found elsewhere.

Thermally stimulated current (TSC) represents a relatively new approach where dipole moments are polarized in a d-c field at temperatures above the sample's main transition temperatures [*46*]. Following polarization, the sample is quench cooled to a low temperature, and then scanned at a constant heating rate through the polarization temperature. As the sample depolarizes, the charge stored in the polarization process is then measured as a function of time. Current peaks obtained this way correlate well with transition temperatures obtained by mechanical relaxation, DSC, or by a-c dielectric spectroscopy.

Another d-c technique—relaxation map analysis (RMA)—is closely allied to TSC and represents a sophisticated extension of TSC experiments. According to theory, this procedure isolates the individual relaxation modes that constitute a typical TSC by varying the polarization temperature and monitoring the depolarization current over small (less than 5°C) temperature "windows." In this way, individual relaxation modes can be isolated from the entire spectrum of modes that make up a typical TSC curve. An Arrhenius plot of the individual relaxation times forms a relaxation map for a material. Coatings characterization using TSC and RMA is described in more detail elsewhere [*47,48*].

Although the dielectric techniques date back to the early 1900s, the lack of high-quality equipment and the attendant experimental difficulties limited the value of DEA for coatings characterization and in materials science generally. Advances in engineering design have dramatically improved the utility of commercial DEAs and rekindled interest in the technique. DEA now promises to play an important role in coatings characterization. The two examples described here—powder coating cure and resin characterization—underscore the value of DEA for coatings characterization. Ceramic single-surface sensors were used in both of the studies.

Powder Coatings—Changes in the complex permittivity e^* of unpigmented powder coatings were correlated with the melt transition (about 60°C) and the onset of cross-linking (about 100°C) in these powders. Dielectric measurements, particularly transition temperatures and relative intensities, correlated very well with DSC results. Five powders, each formulated at different cross-linker levels, were scanned during and after cure. Figure 11 illustrates a typical DEA plot combined with results from the DSC. As the results show, major transitional features in these two sets of data correspond closely. One significant deviation occurs in the region between roughly 65 and 80°C where e^* exhibits a dramatic increase at all frequencies; there is virtually no DSC response over the same temperature range. The increase in e^* probably coincides with increasing molecular mobility as the polymer's volume increases above the melt. Dielectric properties should change rapidly over this temperature range while changes in enthalpy (and therefore DSC heat flow measurements) should be minimal.

Resin Properties—A comparison of the dielectric properties of an appliance powder coating formulated with polyester from two different manufacturers reveals distinct differences. Figure 12 reveals differences in the breadth of the melt transition and the cure onset temperature. Although the performance properties of the resins were indistinguishable, the DEA results clearly indicate the technique's sensitivity to relatively small differences in materials that were virtually identical by all other measures.

Film Formation—The complexity of the film formation process in coatings, particularly latex coalescence, makes this

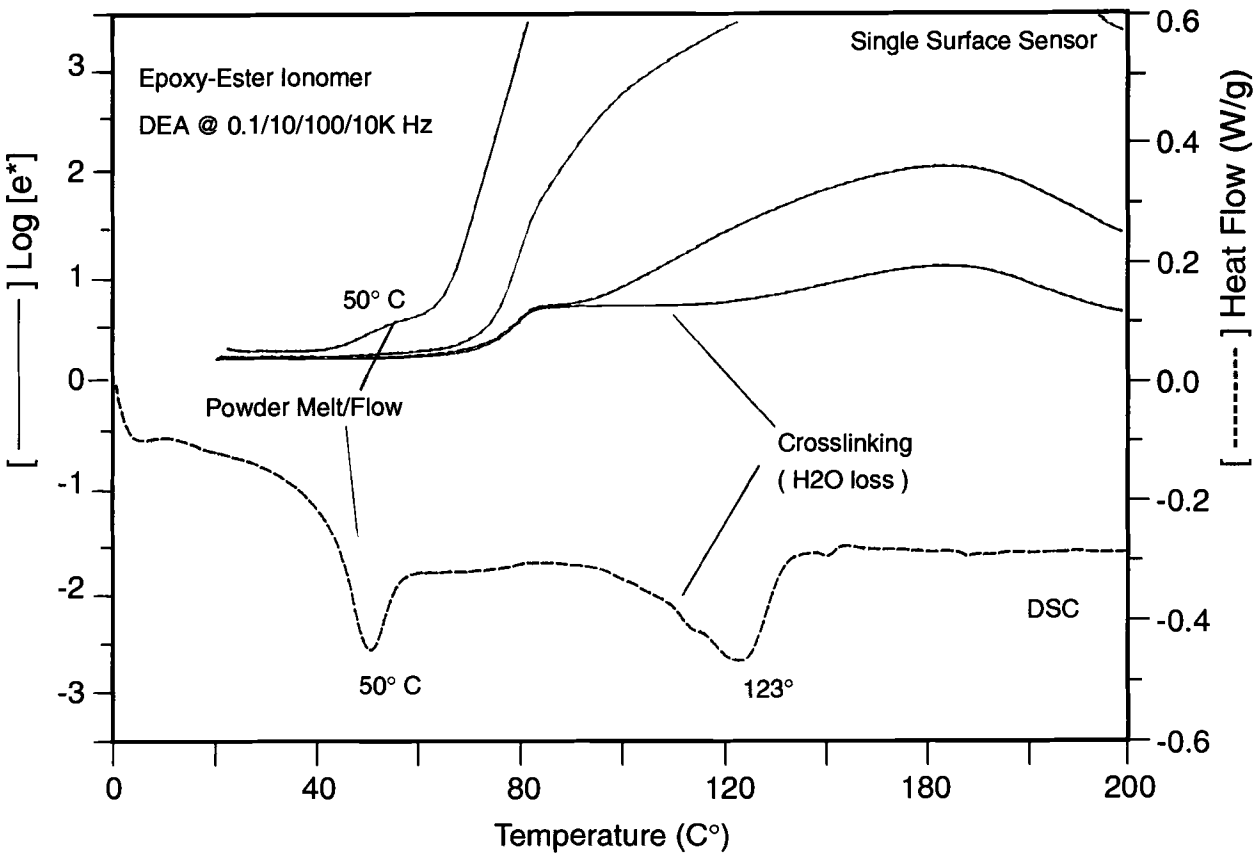

FIG. 11–DEA and DSC results for powder coating cure.

a difficult subject to characterize and understand. Improvements found in newly available dielectric analyzers indicate that DEA will offer, at the very least, a significant step forward in our ability to follow film formation. Figure 13 follows the change in the dielectric constant (complex permittivity) in two latexes, one catalyzed and the other uncatalyzed, after they were applied to a DEA sensor. By comparing the changes in log e^* with the observations from optical microscopy, DSC and TGA (results not included here), some inferences about the nature of the film formation process were made. In the catalyzed sample, the drop in e^* over the first 20 min of the experiment correlates to the loss of free water. Between roughly 20 and 30 min, the latex particles begin to deform and pack tightly together. Finally, over the next hour or so, there is a loss of ionic mobility that probably coincides with polymer interdiffusion at the particle-particle interface. The catalyzed latex had formed a clear, uniform film by the end of the experiment.

The dielectric behavior of the uncatalyzed film was far different. While changes in permittivity associated with water loss and particle packing were evident, the lengthy period thought to correlate with interdiffusion was missing. In fact, this latex was a poor film former, leaving an opaque, severely cracked film on the surface of the sensor.

Coatings Characterization by DEA

Sample Preparation: This depends very much on the type of sensor used. Parallel plate sensors are typically used for free films, while film formation studies would typically employ single-surface sensors. As with other approaches, free films should be made in well-controlled environments and *must* meet the minimum film thickness specifications of the manufacturer. Whenever possible, though, the sample thickness should closely approximate the thickness of the coating after application. As noted earlier, free films can be made by coating low-energy surfaces like PTFE or polypropylene or coating thin aluminum sheet stock and dissolving the aluminum (after the film has formed, of course) with an alkali.

Single surface sensors can be used for any material, but they are especially useful for studying liquids or materials that require a gas/polymer interface for proper analysis. Applying liquids, for example in film formation studies, often requires special preparation to ensure that the electrode surface is completely and evenly covered. For example, when studying low-viscosity liquids, we first calibrate the sensor, then build a low silicone polymer border at the edge of the electrode to keep the sample in place. The volume of liquid applied should leave a final film roughly twice as thick as the distance between electrodes when the sensor uses interdigitated comb electrodes. Always use analytical pipettes to ensure that the applied volume is uniform from experiment to experiment. While absolute measurements of dielectric properties may be in doubt using this approach, it is a valid way to make relative comparisons provided that each material is prepared and handled in *exactly* the same way.

Frequency Selection: In general, there are two components of the dielectric response to an applied electrical field: dipole polarization and free charge migration. The former is most frequently associated with high frequencies (100 kHz or

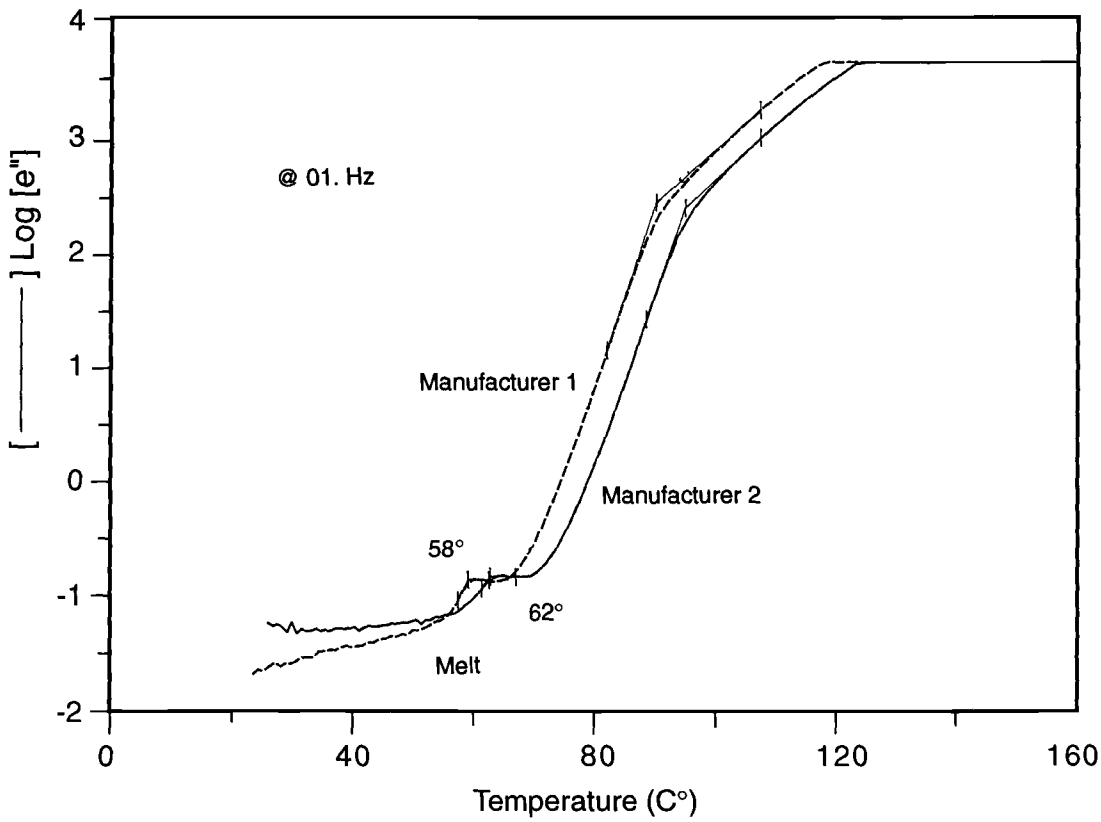

FIG. 12–A comparison of the dielectric properties in identically formulated resins from two manufacturers.

more) while the latter is associated with lower frequencies. Because the dielectric response of polymers varies widely in polymers (and sometimes within classes of polymers), there are no specific rules governing the selection of a test frequency. As a general rule, apply as broad a range of frequencies as your equipment will allow early in the experimental process. After the kinds of responses for given material are better understood, use more limited frequency ranges in subsequent experiments.

Heating Rate: This is an extremely important factor that depends inherently on the frequencies selected for an experiment. Our heating rates are chosen to ensure that we have approximately one data point for each °C increment at each frequency. Low frequencies (<0.1 Hz) require slow heating rates so that the sample has reequilibrated after imposing the a-c electrical field. For example, if we choose to test at frequencies ranging from 0.1 Hz to 100 kHz in order of magnitude increments in our equipment, then a complete cycle (six frequencies) takes about 1.1 min. Based on this cycle time, we would choose a 1°C/min heating rate. Cycle times are much faster at higher frequencies, usually less than 0.2 min, so correspondingly higher heating rates may be used. In isothermal studies we usually collect about 6 to 12 data points per applied frequency for each minute of the experiment depending on the length of the experiment.

Gas Flows: Where possible, apply a uniform gas flow. As with the DMA, we set our gas flow rates so that the oven chamber "turns over" about once every 1 to 2 min. Since the size of the oven chambers in various instruments varies considerably, flow rate requirements will as well. If in doubt, use the manufacturer's recommended purge rates.

Most DEAs are also excellent instruments for running controlled atmosphere experiments. For example, controlled humidity experiments (to 80% RH) require bubbling the purge gas through water (or a salt solution of known humidity) before entering the instrument chamber.

THERMOSET CURE STUDIES

The interrelationship between the network formation process and performance properties make cure process studies critically important in product development. A thermoset coating's performance properties depend inherently on cure conditions. Important characteristics of the cross-linking reaction include the gel point, Tg, and the kinetics of the cross-linking reaction. These properties establish a quantifiable link between the cure reaction and the development of thermoset properties. In essence, they provide a way to "picture" the cure process and a tool for optimizing materials handling, processing, and cure.

Characterizing cure behavior also helps to distinguish between complete cure and optimum cure, an important distinction in thermoset applications. Completely cured thermosets are "ideal systems" where the cross-linking reaction has reached 100% conversion and properties are constant for practical purposes. Optimally cured thermosets are "non-ideal" systems where the cross-linking reaction is incomplete and satisfactory performance properties rather than 100%

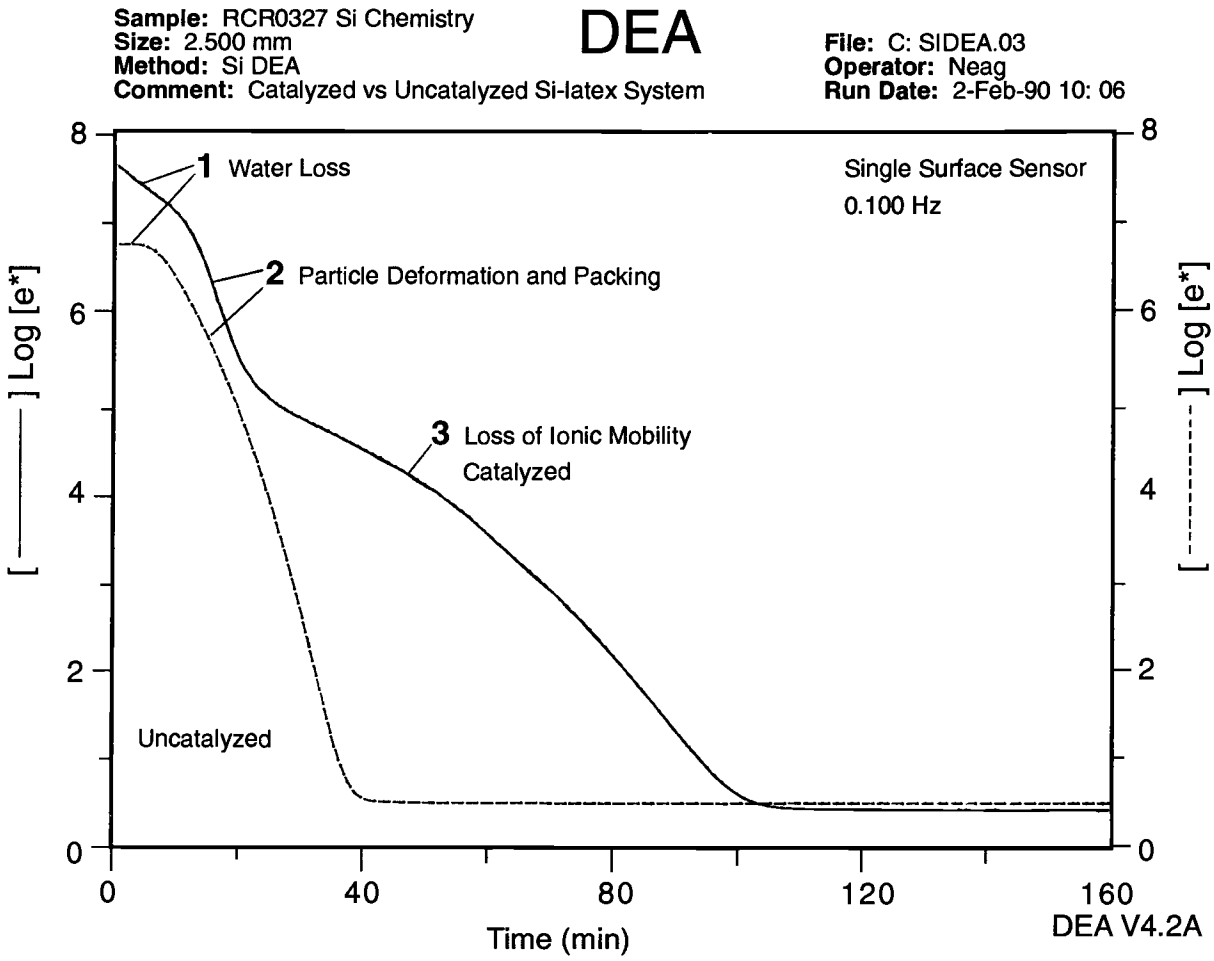

FIG. 13–Changes in complex permittivity during latex film formation.

chemical conversion mark the end of the cure process. In practice, coatings can usually be categorized as nonideal thermosets.

DSC Cure Studies—DSC cure studies have been particularly beneficial in optimizing cure schedules for gel coats—polyester/styrene thermoset coatings used in marine and sanitary applications. The initiation of the cure reaction in gel coats begins with the decomposition of a peroxide and the subsequent copolymerization of styrene with unsaturated groups in the polyester resin backbone [*49*]. When fully cured, these systems are highly cross-linked. Elementary kinetics analysis [*50*] indicates that the reaction order should be 1.5, first order in monomer and half order in initiator.

Evaluation of the kinetics of the gel coat cross-linking reaction using DSC and FT-IR agreed remarkably well. The data in Table 6 also show that the order of reaction obtained by both DSC and FT-IR almost match the value of 1.5 obtained using a theoretical kinetics approach.

TABLE 6—Kinetics parameters for the cure of gel coat resins.

	n	E, kJ/mole	ln A, s^{-1}
DSC	1.56	105.0	28.4
FT-IR	1.54	107.6	29.2

DSC studies revealed that the onset of the gel coat cure process corresponds to the decomposition of the peroxide initiator; according to these results, the reaction began at about 75°C and ended just prior to 150°C. The temperature range (72 to 148°C) selected for the kinetics evaluation using DSC was based on FT-IR spectra. These results showed that the reaction of styrene, and presumably its reaction with the polyester, began and ended at similar temperatures in the DSC and FT-IR. FT-IR reaction kinetics were based on the disappearance of the styrene vinyl group (779 cm^{-1}). While both methods produced excellent results, the DSC results were obtained in a single temperature sweep, while the FT-IR results required significantly more experimental effort to produce and analyze. Results for gel coat cure by DSC, FT-IR, and also DMA are covered in detail elsewhere [*51,52*].

DMA Cure Studies—As a thermoset cures and the number of cross-links increases, a coating's modulus, or resistance to deformation, also increases. In dynamic mechanical analysis, a rise in resonant frequency or relative modulus parallels the development of properties during network formation. The characteristic rise in relative modulus—particularly its rate and intensity—reveals much about the cross-linking process. The curves in Fig. 14 illustrate how a coating's relative modulus (or stiffness) and damping (energy dissipation) change during cross-linking or film coalescence. Throughout the

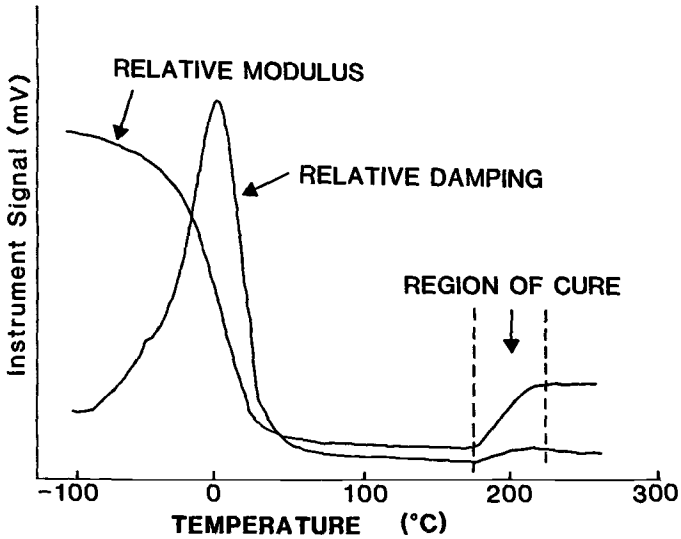

FIG. 14–Generalized dynamic mechanical cure response.

glass transition region—between roughly −80 and 20°C—the relative modulus of the sample decreases until it reaches a minimum. Between 50 and 180°C, the coating is really a low-viscosity liquid that has little measureable dynamic mechanical response. The only measurable mechanical response in this region is due to the substrate used in the experiment. As the temperature increases, cross-linking (or film coalescence) begins and the relative modulus begins to rise. When the reaction is complete, about 220°C in this example, the development of mechanical properties reaches a plateau.

Cure studies by DMA can also help explain the interrelationship between cross-linker characteristics and the cure process. Figure 15 shows the change in the rate and degree of cure in relation to the reactive groups on melamine cross-linkers. As the imino (—NH) concentration increases, the rate and degree of cure both increase. At low imino levels, the rate and degree of cure are low; beyond about 15% —NH, the rate of cure changes significantly, while the DOC appears to reach an asymptotic limit.

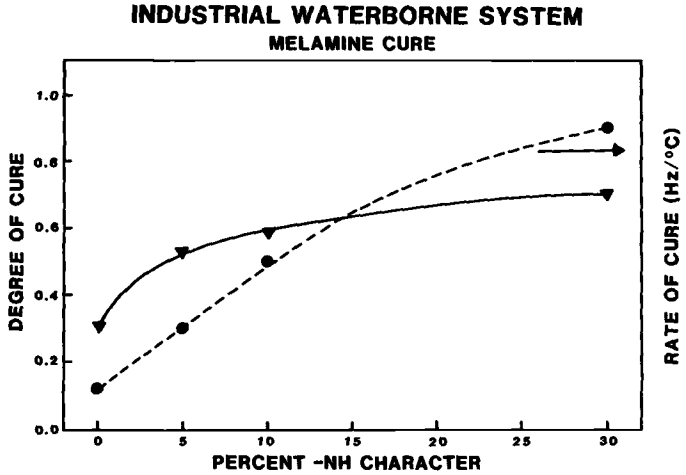

FIG. 15–The relationship effects of cross-linker characteristics on the rate and degree of cure of a waterborne coating.

When the experimental objective is to make a quick comparison of the effects of formulation variables like cross-linker levels or catalyst levels, simple cure curves like these offer an excellent way to make qualitative judgments about the cure process. Sometimes, however, customers may demand more than simple "faster/slower" or "more/less" comparisons. For example, a customer may want to know how long the film formation process will take under a variety of cure conditions different, often substantially different, from those used in past experiments. In cases like these, models of the film formation process are a valuable tool for predicting the time required to complete the film formation process. The virtue of modeling lies in its ability to provide a well of information from a relatively small database or, in this case, a few film formation experiments.

The time-temperature superposition (TTS) approach, while somewhat more demanding experimentally, is a far more versatile method for characterizing the cure process than individual cure scans. This approach uses a series of isothermal cure curves (usually four) to determine the activation energy for the cross-linking process. Once the activation energy is known, an Arrhenius model is used to predict relative rates of cure at different isothermal cure temperatures. The curves shown in Fig. 16 illustrate portions of the storage modulus curves typically used in TTS cure studies. These curves were obtained for an epoxy-polyester powder cured at four isothermal temperatures. The characteristic form of these "cure" curves discloses several important aspects of the cross-linking process, such as the time to gelation, the rapid increase in relative modulus during cure, and a plateau region that marks the end of the cross-linking process.

From a processing perspective, the onset of the rise in modulus about 3 min into the "bake" scan represents the most important feature of the curve. The onset of the rise in frequency in these curves approximates the time to gelation, or the point where the polymer transforms from a viscous liquid to an elastic gel; this point marks the processing limit of the thermoset. Beyond this point, cross-link density increases, approaching a plateau which marks the end of the cross-linking process. In Fig. 16, these powder coatings fail to reach this plateau, even at the highest cure temperatures and/or longest cure times. The continued rise in relative modulus indicates incomplete network formation, even after 100 min at temperatures as high as 210°C. Longer cure times or higher cure temperatures would eventually establish the end-point of the cure process. The modest increase in relative modulus at later cure times may be related to annealing effects or some combination of cure and annealing. Generally, thermosets cured to the plateau will possess less damping, have higher Tg's, and are more brittle than thermosets cured to a point below the plateau.

Degree of cure curves for powder coatings were obtained from DMA data by measuring the increase in relative modulus (measured as a frequency increase here) occurring as cross-linking proceeds. The DMA degree of cure was calculated from Eq 1 below. This equation allows the estimation of the relative degree of cure between the gel point (0% DMA DOC) and the fully cured thermoset (100% DMA DOC). In these experiments, the gel point is defined by the initial rise in the modulus curves. This point in the modulus curve marks the formation of an intractable gel. Full cure is defined by the

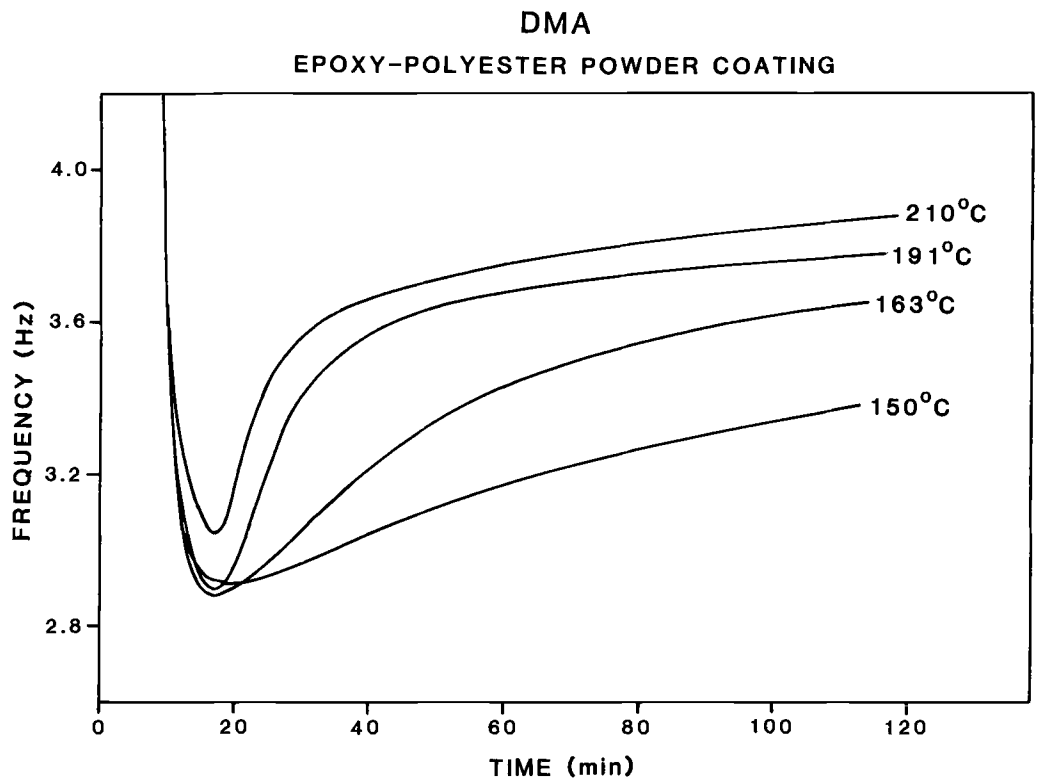

FIG. 16–Dynamic mechanical cure response of an epoxy polyester powder coating at four isothermal temperatures.

plateau region of the modulus curve occurring just after the sharp rise in modulus.

DMA DOC is defined as:

$$\text{DMA DOC} = \frac{\text{Hz}(t,T) - \text{Hz}_{\min}}{\text{Hz}(\infty,T) - \text{Hz}_{\min}} \quad (1)$$

where $\text{Hz}(t,T)$ is the frequency measured during cure at time t and isothermal temperature T; $\text{Hz}_{\min}$ is the minimum pregelation frequency (roughly equivalent to the resonant frequency of uncoated stainless steel mesh) and $\text{Hz}(\infty,T)$ is the frequency of a fully cured coating at temperature T after reaching complete cure.

The DMA degree of cure curves shown in Fig. 17*A* reveals that the rate and degree of "mechanical cure" vary dramatically with the cure temperature. These differences carry important kinetic information about the cure process, information that forms the basis for generating mathematical models of the cure process. By applying a time-temperature superposition method developed by Prime [*53*], the data from the isothermal cure curves at several different isothermal temperatures can be shifted to form DMA degree of cure mastercurves.

Based on the shift factor required to superimpose the data of Fig. 17*A*, the activation energy for the epoxy-polyester cure reaction in this example was estimated at 77.4 kJ/mol. As the DMA mastercurve in Fig. 17*B* shows, the superposition of data to times at 191°C is very good. The key advantage in applying reaction kinetics analysis in dynamic mechanical analysis (and other applicable techniques) is efficiency: a few experiments can provide as much information about the cure behavior as far more extensive laboratory work under many different baking conditions. For example, in Fig. 18, simulated DMA degree of cure curves were generated at three bake temperatures and compared with the DOC at minimum impact resistance. The time required to reach a minimum performance level varies considerably; at 150°C, the coating fails to reach the minimum DOC even after 90 min. At 177 and 204°C, minimum DOC is reached after roughly 15 and 30 min, respectively. Obtaining the same information by a conventional experimental approach would require a considerable amount of time and effort in the laboratory. Moreover, techniques like the DMA TTS methods described here can predict the time required to reach a specified level of performance for any isothermal cure schedule.

COMBINED TECHNIQUES IN PROBLEM SOLVING

Thermal techniques usually reserved for routine analysis and characterization or research support are also useful for solving problems that arise in process or production. Because problems in manufacturing present unusual experimental difficulties, solving them usually requires several methods for adequate characterization. A solitary piece of evidence, whatever the quality, usually needs corroborating information from other sources. Multiple techniques are particularly valuable in settling financial or legal claims where the need for undisputable evidence becomes preeminent. In the example described below [*54*], quality control tests in manufacturing indicated that container coatings sprayed on the interior of aluminum beverage cans were improperly cured, the cus-

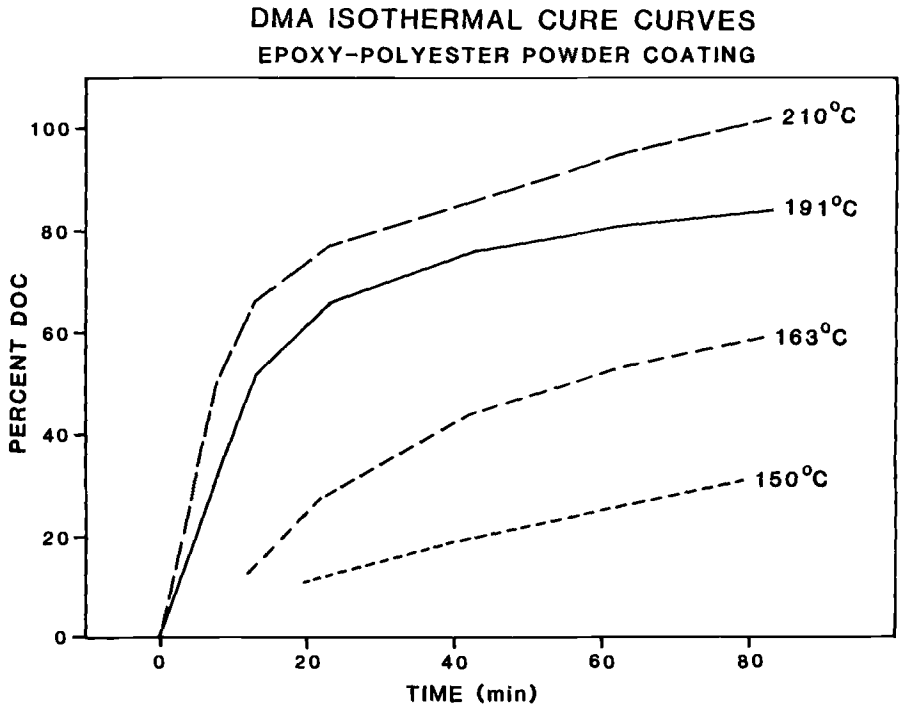

FIG. 17*A*–Epoxy polyester powder coating degree of cure curves.

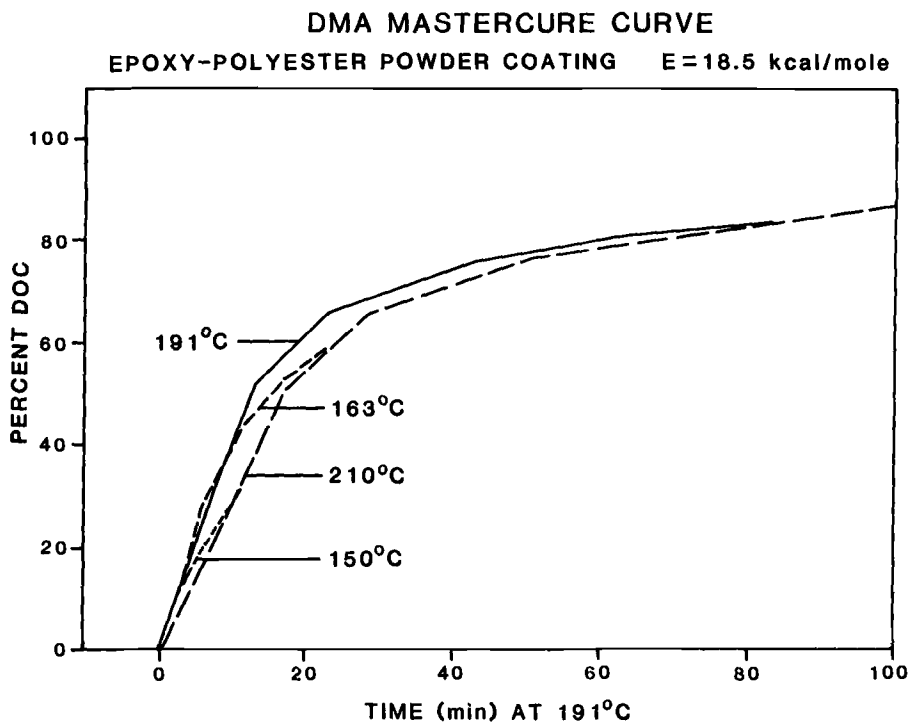

FIG. 17*B*–Epoxy polyester powder coating DMA mastercurves for cure at 191°C and an activation energy of 18.5 kcal/mol.

tomer attributing the cure problem to errors in the synthesis or formulation of the coating.

Four analytical techniques were required to adequately characterize various coating materials and pinpoint the cause of the problem. Compositional differences were assessed by FT-IR; morphological characteristics were observed with scanning electron microscopy (SEM); DSC was used to assess differences in thermal behavior; and relative cure kinetics were measured using DMA. Each of the analyses revealed that differences between the problem coatings and other materials—either laboratory standard or production line standards—were not due to differences inherent in the

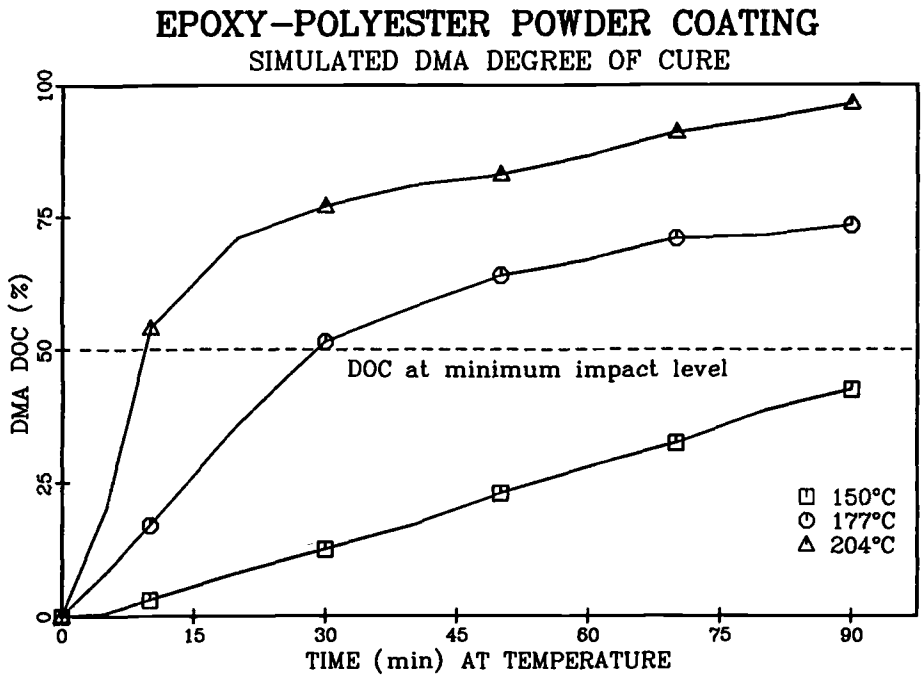

FIG. 18–Predicted time to minimum acceptable impact resistance at three isothermal bake temperatures.

chemistry of the coatings or formulation. Instead, these tests revealed that oven temperatures were probably too low to properly cure the coatings. After raising the oven temperature a few degrees, all of the coatings passed the QC test. Figure 19 compares the DSC heat flow characteristics of a properly cured standard with curves of the problem coating before and after rebake. The key feature shown in this figure is a weak endotherm, apparently related to the level of cure in the problem coating. After rebake, this endotherm disappears and the thermal behavior of the problem coating is virtually

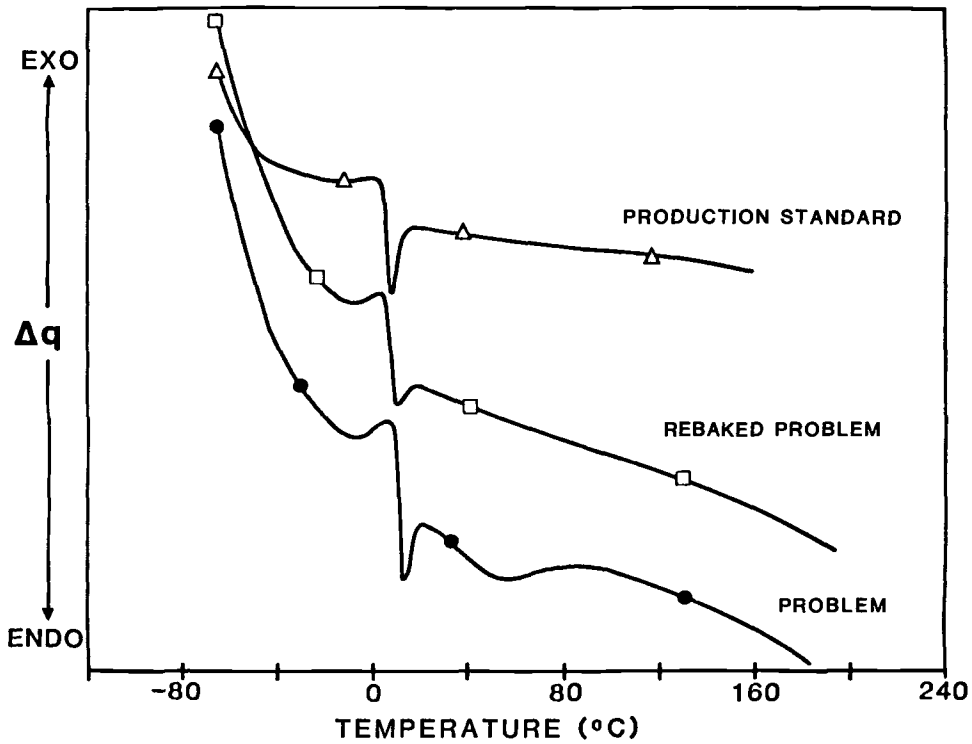

FIG. 19–Comparison of the DSC heat flow characteristics of a production standard, a problem coating, and the rebaked problem coating (Δq = heat flow).

identical with that of the properly cured coating. Similar comparisons using FT-IR to follow changes in reactive sites during cure showed that the "good" and "bad" coatings were virtually indistinguishable (provided that their thermal histories were the same). In fact, the results obtained from each of the instruments led to the same conclusion: when the problem coating was rebaked, it was virtually identical to the properly cured material. Taken together then, these results showed that the manufacturing problem was unrelated to the coating's chemistry. Instead, QC failures were caused by oven temperatures set too low to properly cure the coating.

SUMMARY

Thermal analysis occupies a unique place in research and development. In most instances, the utility of an analytical technique is strictly limited by its output. For example, spectroscopic tools like NMR or IR tend to be viewed as standalone operations that provide a specified result. TA differs from other analytical operations because the instruments offer greater versatility. In fact, thermal analysis is generally recognized as a broad technology encompassing many instruments and many more applications. Depending on the need, the results delivered by TA can range from the straightforward, like Tg's, to the complex, like reaction kinetics parameters.

TA realizes its greatest value, however, when more than one instrument is focused on a research or production problem. In combination, these instruments can provide tremendous insight into the relationship between formulation, processing, and the ultimate performance of material, often clarifying hard-to-understand relationships [*55*]. When applied throughout the product development cycle, these instruments can reduce product development time, manufacturing costs, and, in the end, help shape the best possible product.

Acknowledgment

Thanks are due to the many coworkers at Glidden for their contributions to the work described in this paper. The author is particularly indebted to Leo Tischer, Tony Parker, Mary Logue, Tammy Chalmers, Sharon Chang, and Patti Wilson for their diligence in obtaining much of the experimental data described here and also to Richard Holsworth for his thoughtful contributions to experimental design and the analysis of the results over many years. In addition, Mark Koehler, Ted Provder, Ted Niemann, and Ann Kah deserve recognition for their pioneering efforts in the automation of the DSC and DMA. Without the time savings acquired in data acquisition and analysis made possible through their efforts, much of this work would have been a practical impossibility. Thanks also to Ann for redrawing many of the figures used in support of the text. Finally, I'm indebted to Dr. Stephen Cheng (University of Akron), Dr. Richard Chartoff (University of Dayton), Dr. David Kranbuehl (William & Mary), Dr. Don Burlett (Goodyear), Dr. Charles Earnest (Berry College), and Dr. Peter Kamarchik (PPG Industries) for their valuable comments and insights on instrument operation and experimental detail.

Ultraviolet/Visible Spectroscopy

by George D. Mills[1]

THE USE OF ELECTROMAGNETIC RADIATION (EMR) for the analysis of paints and coatings is best addressed by looking at the way this energy source is absorbed by the system under investigation. Most EMR analytical techniques attempt to measure the energy difference between the incident beam and the emerging beam and to relate this energy difference at a particular wavelength (energy) to the absorbing species' concentration or chemical makeup. The emerging beam may pass through the system or be reflected from a surface. There are many sophisticated instruments that use EMR, and they operate from the lowest energy bands in microwaves to the highest energy γ-rays. The region of the spectrum most commonly used in the paint laboratory lies between the infrared and ultraviolet bands. The instrumentation operative in this region can be relatively low in price, and the information that can be obtained about concentration and molecular structure is very useful.

Absorption in the infrared region of the spectrum occurs because the atoms within a molecule or ion can react to these specific energies by increasing the amplitude of some vibrational mode. This mode of energy absorption occurs because of the ability of connected atoms to stretch, bend, or move about relative to one another. The energy that can be absorbed in a particular situation is dependent on such factors as strength of the bond, mass of the atoms, interaction of adjacent species such as the remainder of the molecule or solvents, as well as other factors. The energy of EMR in the ultraviolet and visible (UV/VIS) regions of the spectrum is somewhat higher. Because this higher energy affects the electrons within the molecular and atomic orbitals rather than the mass of the atoms, this mode of energy absorption reveals information about the bonding within the molecule or is specific to a given specie. This allows both qualitative and quantitative determinations of species that have the ability to absorb at these specific energy levels.

An important quality of paints and coatings is their visual appearance. Although the visual region of the spectrum is rather small, it is very important when analyzing coating systems. Color and color stability is a very important aspect of paints. UV/VIS spectroscopy can also provide information on concentration of active species, wavelengths of highest absorption, filtering efficiency of UV protection additives and their optimal concentration, as well as other needs. Transmission spectroscopy is useful in performing analysis on solutions containing binders, stabilizing additives, and coloring agents such as dyes. UV/VIS reflectance and fluorescence spectroscopy provides information about color and general appearance.

Polymerization of some very fast curing systems use UV as the initiating energy source. These curing mechanisms employ free radical and cationic initiation and propagation for film formation, and they are often the preferred coating materials for very fast moving, highly productive coating lines.

Binders, additives, and pigments that absorb at frequencies in the ultraviolet and visible region may suffer degradation from these energetic absorptions. While the techniques used for UV/VIS spectroscopy may be helpful in determining the frequencies at maximum degradation and may assist in engineering the optimum stability package for the coating system [*1*], degradation testing per se is addressed elsewhere. UV exposure testing and weathering analysis employ test procedures such as ASTM Practice for Conducting Tests on Paint and Related Coatings and Materials Using Filtered Open-Flame Carbon-Arc Light and Water Exposure Apparatus (D 822), ASTM Practice for Testing Paints, Varnishes, Laquers, and Related Products Using Enclosed Carbon-Arc Light and Water Exposure Apparatus (D 5031), ASTM Practice for Conducting Tests on Paint and Related Coatings and Materials Using a Fluorescent UV-Condensation Light and Water-Exposure Apparatus (D 4587), and other standards currently under revision.

The objective of this chapter is to discuss the use of UV/VIS spectroscopy in the analysis of coating systems and components. It is important to be mindful of the actual mechanism of absorption. This is closely tied to molecular structure and will allow a better understanding of the total task of engineering the coating formulation with maximum life expectancy for the end use environment as well as allowing the design of quality control techniques useful at the manufacturing level. At the values of energy levels represented by the frequencies of UV radiation, certain chemical bond energies can be surpassed. A knowledge of the mechanism of UV absorption can be helpful in allowing better choices for binders that may be susceptible to degradation, development of UV-initiated polymerization catalysts [*2*], as well as allowing judicial choices of UV stabilizers for those coating systems.

It is important that the paint analyst be aware of the principles of operation of the instrumentation used to probe paint systems and components. This will allow for a clear understanding of what the information received really means. It is also very important for the analyst to know the limitations of his instrumentation. Action taken on poor data can be far worse than taking no action taken at all!

ELECTROMAGNETIC RADIATION

Electromagnetic radiation is a form of energy that possesses both wave-like characteristics and particle-like characteristics. The wave-like nature allows the radiation to travel at extremely fast velocities and to be refracted. Unlike sound, this energy form may be transmitted through the vacuum of space without a supporting medium. As a particle, when radiation interacts with matter, it is absorbed in discrete packets of energy called photons. The radiation is composed of an electrical field of oscillating field strength superimposed on an oscillating magnetic field at right angles to one another.

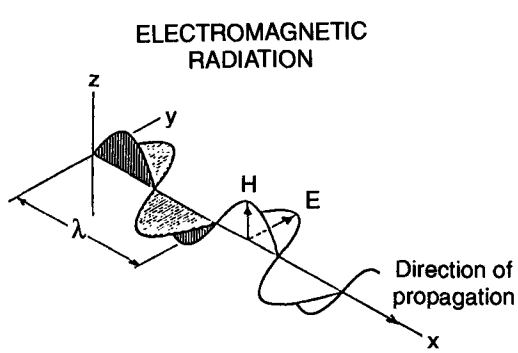
If the vectorial values for the electrical and magnetic field strength are plotted as a function of distance from the moving point charge that is generating the EMR, the graphical presentation in Fig. 1 is obtained. In this plot, the magnetic field strength, $\vec{\mathbf{H}}$, is represented as a vector in the *xz* plane, and the overlapping plot of the electric field strength, $\vec{\mathbf{E}}$, is presented as a vector in the *xy* plane. The direction of propagation is down the *x* axis. This represents the plot of a plane polarized wave. If all waves coming from a collection of similar radiators are in the same spacial orientation, we call the radiation *plane polarized light*. In nature, radiation coming from a collection of point sources will usually be randomly oriented and therefore will not be polarized. It is useful to note that when a beam of polarized light passes through a collection of absorbing species that has at least one area of asymmetry, polarized light will be rotated to some degree. This principle is used to obtain information about the shapes of particular molecules and quickly gather information on their concentration.

The wavelength, λ, is usually expressed in units of centimeters, microns, millimicrons, or angstroms. The frequency of the oscillations, ν, is the number of cycles that occur in 1 s and is therefore equal to the speed of the radiation divided by the wavelength.

$$\nu = c/\lambda \tag{1}$$

The reciprocal of the wavelength is called the wave number, $\bar{\nu}$, and is frequently used in spectroscopy. Its units are in reciprocal centimeters. The wave number of the radiation, like its frequency, is proportional to the energy of the radiation, i.e., the higher the wave number the higher the energy of the radiation.

$$\bar{\nu} = 1/\lambda \tag{2}$$



Electric and magnetic field strengths in electromagnetic radiation.

FIG. 1–Plot of the magnetic and electric field strength as a function of distance of propagation away from the generating point charge.

Figure 2 presents the EMR spectrum and the common name usually used for that portion of the spectrum.

It is interesting and useful to understand how this form of energy interacts with the components of coatings. Note that the value of the energy in the UV/VIS band of the spectrum is relatively high, sufficiently so to cause electron excitation in atoms and molecules. When the energy is great enough to cause the homolytic split of the two electrons that form a chemical bond in a molecule, two free radicals are formed. This is quite probable when one (or both) fragments have a degree of stability in the degraded condition. This is the reason for the chalking so common in epoxies. Some crystals are susceptible to degradation as well. The anatase form of titanium dioxide is a good example of UV degradation of crystalline pigments.

Should the system be prone to damage from UV radiation, it is certain that the system will absorb in this region. The testing of coatings for degradation caused by these wavelengths is treated elsewhere, but UV/VIS analysis may assist in determining failure mechanisms, optimum UV screening agent concentrations, measurement of residual stabilizers after testing, and others. Current technology provides UV/VIS instrumentation for use in various modes, similar to that used in the infrared region. This includes transmission mode, fluorescence mode, and specular and diffuse reflectance modes.

BASIC INSTRUMENTATION

The basic optical path or layout of modern scanning instruments has not changed appreciably over the past decade or two. The optical diagram of a modern instrument is presented in Fig. 3. Low-cost computers for doing sophisticated calculations and better diffraction gratings have allowed important enhancements. Increased electronic noise suppression has allowed lower cost-to-benefit ratios in the newer instruments. Software now provides full instrument control, enhanced data analysis including rapid graphics, and considerable options in report generation. Three-dimensional plotting enables easy representation of reaction mixtures, allowing kinetics studies of active systems. While following the

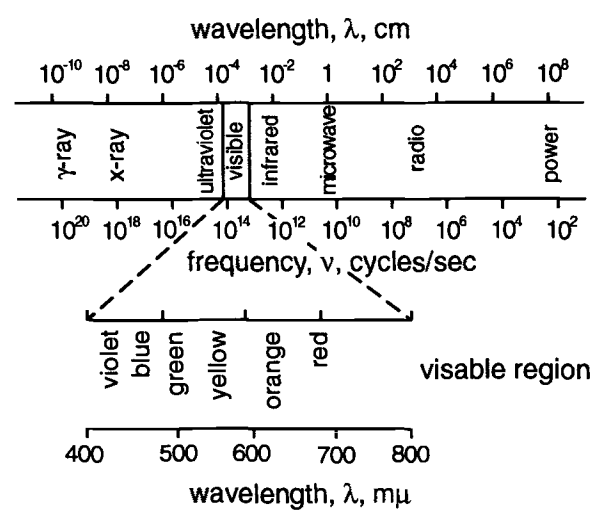


FIG. 2–The complete electromagnetic spectrum.

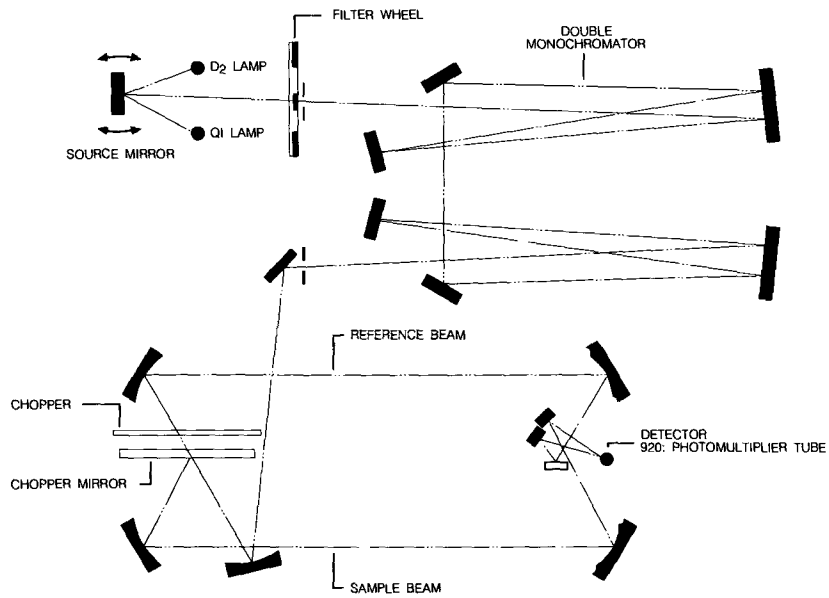

FIG. 3–The optical path of a modern UV/VIS spectrophotometer (Model 920, GBC Scientific Equipment, Arlington Heights, IL 60004).

curing kinetics, it is possible to see the influences of catalysis as a function of temperature.

Principle of Operation

Basically, the classical instrument will have a source of radiation, a method for isolating a very small band of that radiation that is passed through the sample (the "monochromator" section), a sample holder arranged in such a manner as to allow passage of radiation having a low band width, a detector to monitor the quantity of radiation passing through the sample, and a read-out or data collection system. This is represented schematically in Fig. 4.

With the advent of the diode array detector, multifrequencies may now be detected at one time. The schematic for this type of instrument is presented in Fig. 5. Here the sample is irradiated with a broad band of radiation. The light that emerges is then sent to a "monochromatic" device that spreads the radiation out across an array of CCD detectors banked in such a way as to "see" all of the emerging broad-band radiation. The separation of the signal occurs because each area on the detector is read independently and the position where the radiation falls on the detector is a function of its wavelength (energy) for that region of the spectrum. Those parameters that are most important for UV/VIS/NIR spectroscopy include reproducibility, sensitivity, and wavelength range.

Calibration of Instruments

The calibration of instruments having absorptions in the UV/VIS/NIR wavelengths may follow ASTM Practice for Describing and Measuring Performance of Ultraviolet, Visible, and Near Infrared Spectrophotometers (E 275) [3]. Here, a mercury arc provides twelve very unique peaks having extremely precise wavelengths for comparison with the values reported by the instrument. Figure 6 presents the mercury arc emission spectrum in the UV/VIS region showing the reference wavelengths.

Another useful standard that provides established specific reference peaks is holmium glass (Corning No. 3130). This standard has the advantage over the mercury arc in that it may be conveniently placed within the instrument with minimum problems. That spectrum is presented as Fig. 7.

SPECTRAL INTERPRETATION: QUALITATIVE AND QUANTITATIVE INTERPRETATION OF SPECTRA

The output of the UV/VIS spectroscopy instrument will usually be a plot of absorbance versus wavelength and is called the absorption spectrum. Absorption of the UV/VIS radiation usually occurs when an electron within the active specie absorbs the energy of a photon. The molecular conse-

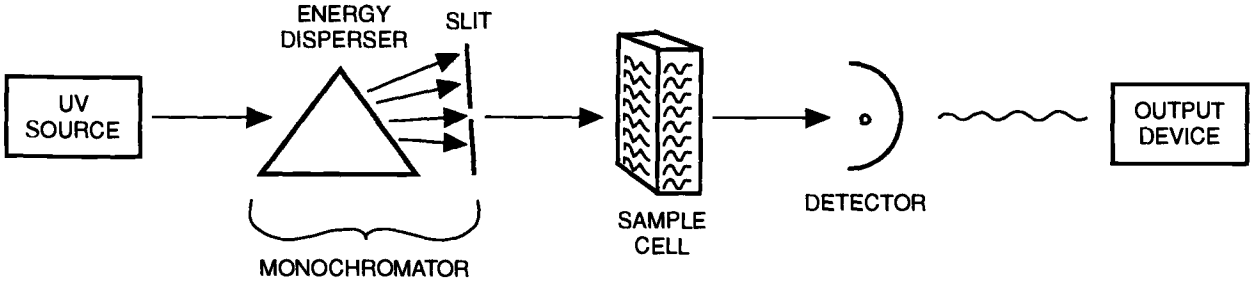

FIG. 4–Component arrangement of the classical UV/VIS instrument.

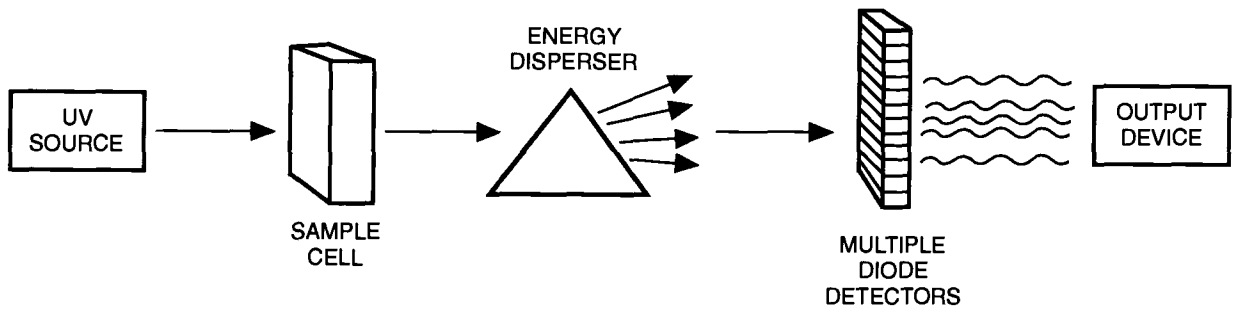

FIG. 5–Component arrangement of the modern UV/VIS instrument using a diode array detector.

quence of the energy absorption process is for an electron to jump to a higher energy level within the specie. This loss of energy in the incident beam is taken as the absorption, and the plot records these losses as a function of wavelength. In most instances, the energetic electron will return to its former stable state by liberating heat. In some instances, the very energetic electron may step down by way of other orbitals. The energy released may then be in the form of radiation, but at a different wavelength. This is the basis of fluorescence spectroscopy and adds another dimension to analysis of some coating components.

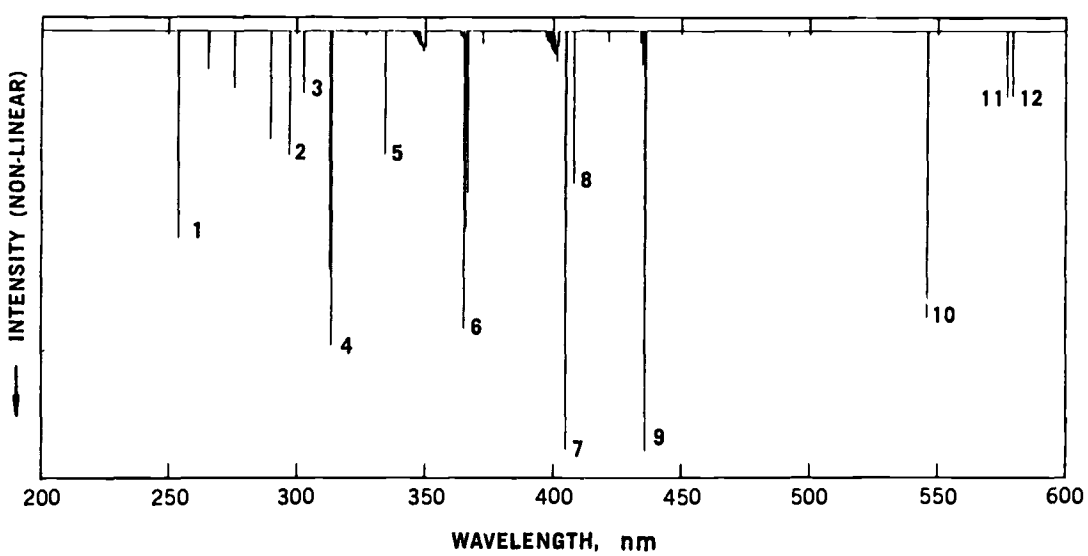
The use of UV/VIS spectroscopy techniques to identify an unknown is possible because the intensity of the absorption at a given frequency is characteristic of the species. By comparing the wavelength at maximum absorption, the intensity tables will provide probable candidates. One such set of tables, about 80 pages, is given in Ref *4*.

The derivation of the quantitative relationship using absorption of radiation requires consideration of the term *radiant power*. Radiant power, P, is the amount of radiant energy striking a unit area per unit time. If we use a constant cell length, two factors affect the amount of power observed at each successive location along the path of a monochromatic incident beam as it passes through the solution. One is the amount of power, P, at the start of each successive arbitrary step along the way, and the other is the number of absorbing species in the path of the radiation. This can be stated as a proportionality. The incremental change in power, ΔP, is proportional to the power of the radiation and the number of absorbing species, ΔN. This may be expressed mathematically as

$$\Delta P = -kP\Delta N \tag{3}$$

The negative is the result of power being lost. By making the intervals between measurements infinitely small, the mathematics reduces to the differential equation

$$dP/P = -k\,dN \tag{4}$$



Line Number	Wavelength, nm	Line Number	Wavelength, nm	Line Number	Wavelength, nm	Line Number	Wavelength, nm
1	253.65	4	313.16	7	404.66	10	546.07

Slit Width: 0.025 to 0.105 mm
Spectral Slit Width: 0.10 to 0.40 nm
Sample Thickness: 2.6 mm

FIG. 7–Spectrum of holmium glass (Corning No. 3130) showing reference wavelengths (from ASTM E 275).

If we integrate between the limits of P_0 when $N = 0$ and P at some value of N, we have

$$\int_{P_0}^{P} \frac{dP}{P} = -k \int_{0}^{N} dN \tag{5}$$

$$\ln (P/P_0) = -kN \tag{6}$$

To convert the actual number of absorbing species to a more convenient term of concentration, c, we consider the volume where contained and Avogadro's number. Thus

$$N = (6.023 \times 10^{23} cbs/1000) \tag{7}$$

where c is concentration in moles per liter, b is the path length in centimeters, and s is the cross-sectional area in square centimeters. When the constants are combined, this yields

$$\log (P/P_0) = \epsilon\, bc = A \text{ (the absorbance)} \tag{8}$$

which is Beer's law.

Beer's law is the basis of all quantitative spectral measurements. This law, often referred to as the Bourger-Beer or Lambert-Beer absorption law, may be stated exponentially, with intensity of the radiation rather than power, as $I = I_0\, e^{-abc}$. The logarithmic form is used more often

$$A = \log_{10} (I_0/I) = \log_{10}(I/T) = abc = \epsilon bc \tag{9}$$

where

A = absorbance (often referred to as optical density),
a = ϵ = molar absorptivity or absorbency,
b = cell path length, cm,
c = concentration, moles/litre,
I_0 = intensity of incident radiation of the sample,
I = intensity of radiation transmitted by the sample, and
T = (I/I_0) fraction of radiation transmitted by the sample or transmittance.

ASTM Practices for General Technique of Ultraviolet-Visible Quantitative Analysis (E 169) is given in Ref 3.

The reliability and sensitivity of the quantitative method will depend on the choice of a suitable band and suitable solvent. The strongest band free of interference from other sample components is usually chosen, but modern computer treatment of data will frequently allow deconvolution of overlapping spectra.

In general, UV quantitative measurements require calibration in the solvent chosen for the method. A simple calibration curve of concentration versus absorbance can be prepared from the standards. However, it is advisable to study all known components to determine interferences.

POTENTIAL PROBLEMS

When the spectroscopist is performing quantitative determinations that require a linear calibration curve, Beer's law must be applicable over the concentrations under investigation. When deviations exist in Beer's law at the concentrations under investigation, extrapolation from one concentration may not be truly representative of the system concentration. Concentration of some active species such as the

high nucleophilic amino functional aromatics used as epoxy cold-temperature catalysts may react with the surface of metal pigments, effectively removing them from the solution and yielding low results.

Another potential problem occurs because Beer's law is based on monochromatic light. The typical band pass of analytical instruments will depend on the technique being used to produce the monochromatic light. The use of prisms and slits can lead to an appreciably high band pass on the order of 10 to 20 nm. Instruments with holographic gratings and automatic peaking can be as low as 2 nm.

X-Ray Analysis

by A. Monroe Snider, Jr.[1]

X-RAY DIFFRACTION (XRD) and X-ray fluorescence spectrometry (XRFS) are powerful, well-established tools used by analytical chemists in many areas of technology. They have great utility in the coatings industry. In areas where they are applicable, they are frequently the quickest and easiest technique available. XRD is convenient for the identification of diverse crystalline solids encountered in paint research laboratories and production plants. It is particularly well suited for use in the identification and quantitative analysis of crystalline pigments and extenders, either when they are alone or present in paste or paint. XRFS is useful as a stand-alone technique for elemental analysis and as a complementary tool for use with other analytical techniques. X-ray spectrometers typically can analyze all elements with an atomic number of about 11 (sodium) and higher, but some units can reach as low as atomic number 5 (boron). XRFS can span the concentration range from parts per million to high percentages for most elements in liquid or solid samples. Dedicated XRFS units, much lower in cost than scanning spectrometers, can be set up to detect and quantify one or a few specific elements. Portable XRFS units are available for field investigations. The present section summarizes the principles and methodology of XRD and XRFS.

RADIATION SAFETY

Although operation of modern X-ray instruments involves little risk to the operator when proper safety practice is followed, it is imperative that the operator know and follow proper practice. Exposure to excessive quantities of X-radiation is injurious to health. Therefore, users should avoid exposing any part of their bodies, not only to the direct beam, but also to secondary or scattered radiation that occurs when an X-ray beam strikes or passes through any matter. It is strongly recommended that users check the degree of exposure by film badge or dosimeter carried on them. X-ray instruments should not be operated with safety interlocks, shielding, or other protective devices removed or deactivated. Before using the equipment, all persons designated or authorized to operate X-ray instrumentation or supervise its operation should have a full understanding of its nature and should also become familiar with established safe exposure factors by careful study of the American National Standards Institute Standard N43.2-1988, "Radiation Safety for X-ray Diffraction and Fluorescence Analysis Equipment" [*1*]. Inquiries should be made of state agencies about existing requirements.

X-RAY DIFFRACTION

Application

Types of Samples

X-ray diffraction is widely used for the analysis of analytes that are crystalline or polycrystalline solids, i.e., solids comprised of atoms or ions arranged in a three-dimensional lattice pattern [*2*]. The sample may be totally crystalline or may contain one or more crystalline components interspersed with noncrystalline material. Common types of materials analyzed include pigments and extenders (alone, in grind pastes, in liquid paints, or in dried paint chips), miscellaneous crystalline solids, and pretreatment on metal. X-ray diffraction also has important uses in the study of amorphous materials such as polymers and inorganic glasses [*2*]. In the case of scanning X-ray diffractometers, a flat surface of the specimen must be presented to the X-ray beam.

Types of Information Provided

X-ray diffraction analysis permits qualitative and quantitative analysis of crystalline components. It can indicate the degree of crystallinity, crystallite orientation, and long-range order in polymers. Long-range order in liquids has also been studied [*2*].

Range of Concentrations

As a rule, crystalline components can be analyzed by routine methods at concentrations ranging from 100% down to approximately 1 or 2%. However, the limit of detection varies widely with the identity of the analyte of interest, the number and identity of other components, the quality of the instrumentation used for analysis, and the instrument operating conditions. Analysis of components at concentrations as low as 0.01% has been reported [*3*].

Physical Principles

X-ray diffraction experiments are performed by irradiating a specimen of crystalline or polycrystalline material with a beam of X-rays of known wavelength and determining the angle 2θ between the incident beam and each diffracted beam of X-rays and measuring the intensity of each diffracted

[1]Senior research associate, PPG Industries, Inc., Research & Development Center, P.O. Box 11472, Harmarville, PA 15238.

Copyright© 1995 by ASTM International

beam. Diffraction occurs only at discrete angles defined by the Bragg equation [2,4,5].

$$n\lambda = 2d \sin \theta$$

where

n = a positive integer (usually one),
λ = the wavelength of the X-rays used,
d = the distance between layers of atoms of a set of lattice planes, and
θ = the angle between the incident X-ray beam and the lattice plane [5].

The wavelength of the X-rays is determined by the choice of the X-ray tube target material, usually copper, and is thus known. The wavelength of copper K_α radiation, the principal component of X-rays from a copper target, is 1.541 78 Å. It is common practice to use a crystal monochromator or absorption filter to prevent unwanted wavelengths of X-rays from contributing to the diffraction pattern. Angle θ is half of the diffraction angle 2θ that is determined experimentally. The distance between layers of atoms in a set can be calculated by using the Bragg equation. The distance, d, is determined by the diameter of atoms comprising the crystal, the three-dimensional arrangement of the atoms in the crystal, and the set of lattice planes in the crystal that produced the "reflection" of X-rays. Thus, crystallites of different compounds or different crystal modifications of a single compound will give different sets of d-spacings. Each crystalline phase will produce a unique X-ray diffraction pattern that can be used as a "fingerprint" for identification. Detailed discussions of the Bragg equation and the physical basis of X-ray diffraction are available in various treatises on X-ray diffraction, such as the classic work by Klug and Alexander [2].

Analysis by X-ray diffraction requires that a specimen be placed in the primary beam of a diffractometer and the diffraction angle and the intensity of each diffracted beam be measured. Diffractometers use either an electronic detector or photographic film to indicate the position of the diffracted beams of X-rays. Most diffraction units in industrial laboratories today use an electronic detector, usually a proportional counter. Figure 1 is a simplified diagram of a diffractometer. Here, the specimen is placed in a holder at the center of a goniometer system. A receiving slit and detector slowly sweep around an arc at a fixed distance from the center of the goniometer, facilitating determination of the intensity of X-rays scattered at each angle, 2θ, on the arc. While the detector moves through angle 2θ, the specimen rotates about the same axis through angle θ. A plot of the intensity of scattered radiation as a function of 2θ, a diffractogram or diffraction pattern, is thus produced. Figure 2 shows the diffraction pattern of the rutile form of titanium dioxide.

A relatively new variation of the electronic detector is the position-sensitive detector (PSD) that uses an arc-shaped solid state detector to sense both the position and intensity of the diffracted radiation [6,7]. The PSD is stationary during data collection, but may be moved to different locations on the goniometer circle, as required, so that its surface can intercept X-rays at all 2θ positions of interest. Compared to a conventional scanning unit, a PSD can markedly shorten the time required to collect data.

The oldest method for collection of diffraction patterns, photographic, is still useful today, with the Debye-Sherrer camera being the most commonly used camera [2]. The Debye-Sherrer camera (Fig. 3) uses a strip of film mounted on the inner surface of a cylindrical holder. The film records X-rays diffracted over a 2θ range of 360°. The d-spacing of arcs caused by exposure of the film to diffracted X-rays can be calculated from the position of the arcs on the film. Relative intensities of the diffracted X-ray beams can be evaluated by measuring the degree of darkening of the corresponding arcs on the film by an optical density measurement or by visual comparison to standards. Figure 4 shows the diffraction pattern of rutile TiO_2 recorded with a Debye-Sherrer camera.

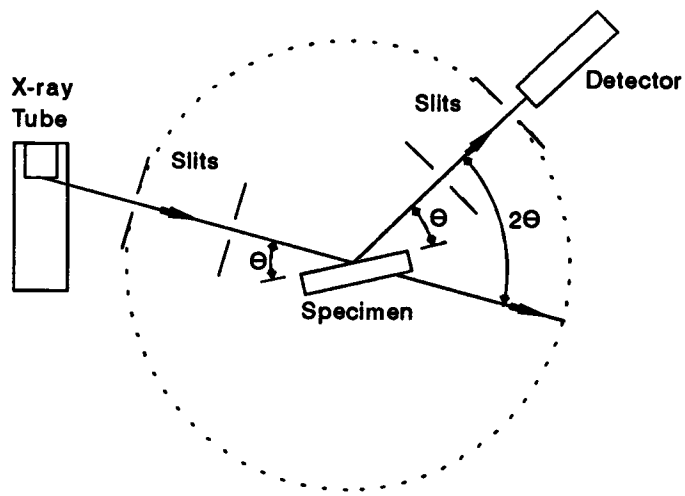

FIG. 1—X-ray diffraction goniometer system.

Experimental Procedure

Specimen Preparation

Specimens for X-ray diffraction can be any crystalline containing solid that can be mounted to permit collection of a diffraction pattern. For scanning diffraction units, the surface of the specimen should be flat and must be positioned in the focal plane of the instrument's X-ray optical system. The latter requirement can be met by mounting the specimen with its surface flush with the face of the specimen holder designed for the instrument. Failure to do so causes a systematic error in the observed 2θ angle and d-spacing of all peaks in the diffraction pattern. Figure 5 shows a photograph of specimen holders used in some commercial X-ray diffractometers.

Common types of samples encountered in the coatings industry and the recommended modes of mounting them in a scanning diffractometer are summarized in Table 1.

A Debye-Sherrer camera is useful for analysis in cases where there is too little sample for analysis using a conventional scanning diffraction unit. For small amounts of powder, the specimen is prepared by loading the powder into a thin-walled glass capillary or by mixing the powder with noncrystalline glue and rolling the mixture to form a filament. The capillary or filament after hardening is mounted in the center of the camera on a motor-driven rotating stub. Rotation presents a more nearly random orientation of crystallites to the incident X-ray beam. A single small chip or crystal may be analyzed by attaching it by glue to the end of a

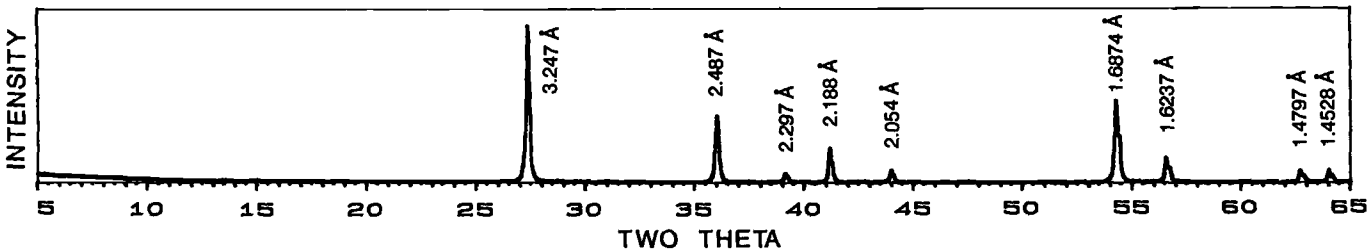

FIG. 2–X-ray diffraction pattern of rutile TiO_2 with the peaks labeled with the *d*-spacing of the corresponding sets of crystallographic planes.

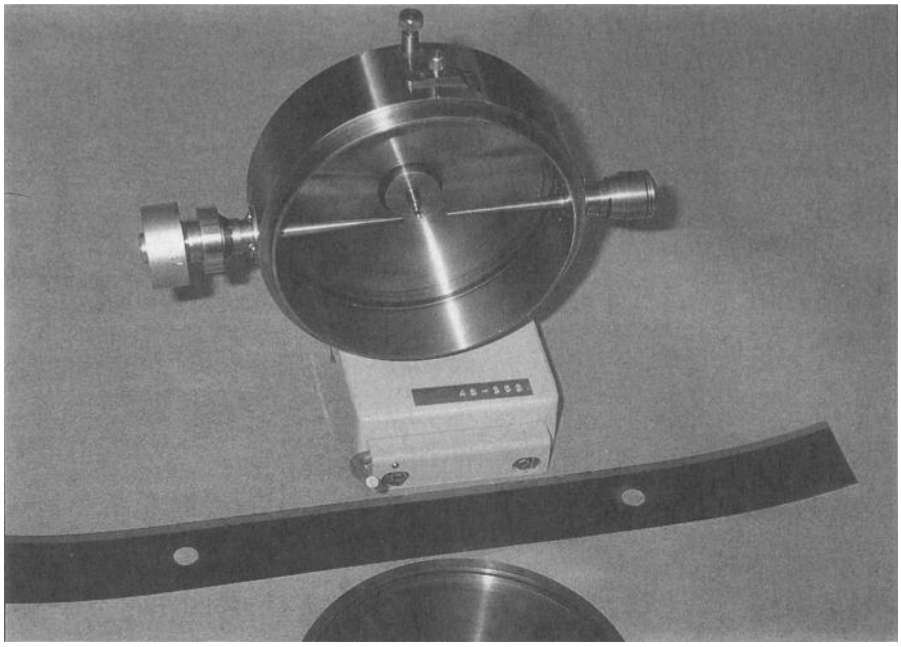

FIG. 3–Debye-Sherrer camera with the front cover removed displayed with a developed X-ray film.

glass capillary and exposing it to X-rays in the Debye-Sherrer camera. In Fig. 3, the capillary can be seen mounted along the axis at the center of the camera.

Specimens suitable for a Debye-Scherrer camera are equally suitable for XRD units equipped with a position-sensitive detector and a holder for capillary specimens.

A thin-film X-ray diffractometer, a variation of the scanning diffractometer, can be extremely useful in the analysis of thin films of crystalline coating or contaminant on flat surfaces [*8,9*]. They also give better results than conventional diffractometers when only a small amount of powder is available. Thin film units operate exactly as conventional scanning diffractometers except the surface of the specimen is irradiated with X-rays at a fixed but selectable grazing angle. In comparison to conventional X-ray diffraction analysis, this approach reduces the depth of penetration of the X-ray into

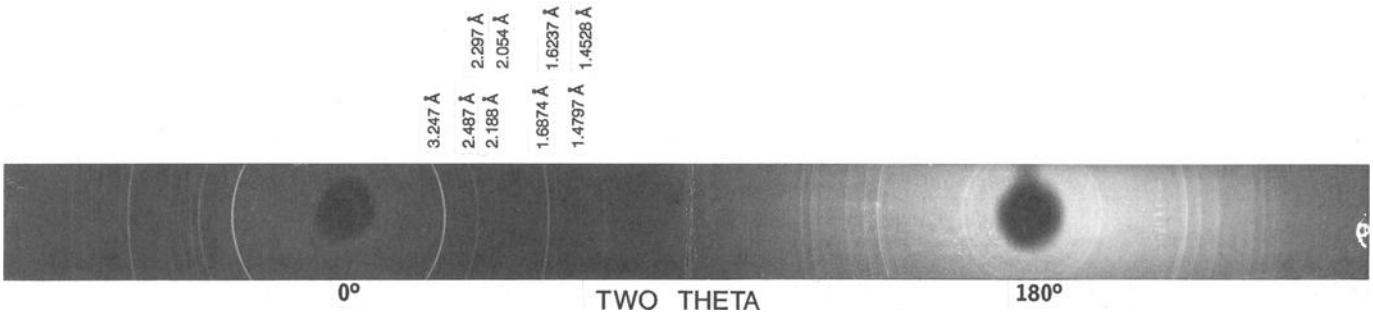

FIG. 4–Debye-Sherrer film with diffraction pattern of rutile TiO_2. The *d*-spacings of selected diffraction arcs are marked for comparison with peaks shown in Fig. 2.

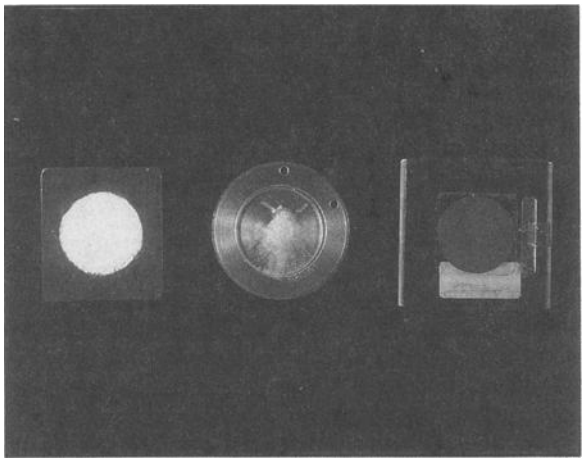

FIG. 5–Specimen holders for three common commercial X-ray diffractometers, each with a different type of specimen: (left) powder in a depression, (center) powder sprinkled on petroleum jelly smeared on a zero background quartz plate, and (right) disk cut from a drawdown of paint.

TABLE 1—Common samples and method of mounting for XRD analysis.

Sample	Method of Mounting
Powder	Put directly in holder or sprinkle on film of petroleum jelly or amorphous glue on zero background plate.
Liquid paint or grind paste	Prepare drawdown film on amorphous plastic sheet. Cut specimen to fit holder. Attach specimen to holder using double stick tape.
Paint chip	(1) Cut specimen to fit holder or (2) scrape off portion of interest, pulverize, and run as powder.
Paint on panel	Cut specimen to fit holder or cut to same dimensions as holder and run without holder.
Pretreatment on metal	Cut specimen to fit holder or cut to same dimensions as holder and run without holder.
Paint with low pigment content	Remove pigment from paint by centrifugation. Dry and grind the pigment plug. Mix the ground material. Run as powder.[a]
Suspension in liquid	Isolate solids from liquid by decantation, filtration, or centrifugation. Dry, grind, and mix. Run the resultant powder as described above.[a]
Sludge	(1) Run as drawdown on amorphous plastic sheet or (2) dry, grind, mix, and run as a powder.
Gel	(1) Run as smear on plastic sheet, (2) dissolve organic portion with solvent and then handle sample as suspension, or (3) ash and handle as powder.[b]

[a]*Caution:* The composition of the plug may be heterogeneous because of stratification of pigments during gravity settling or centrifuging.

[b]*Caution:* Ashing may change the crystalline composition of a sample by causing decomposition, vaporization, or transformation of phases that are present. Ashing at mild temperature, 450°C, in accordance with ASTM D 4451-85, Test Methods for Pigment Content of Paint by Low Temperature Furnace Ashing (450°C), may prevent or lessen the amount of change of crystalline components [23].

the specimen and enhances the strength of the signal from crystalline components on the surface [9].

Instrument Operation Conditions

Operating conditions should be based upon recommendations of the manufacturer of the X-ray diffraction unit, requirements of the analytical method being used, and practical laboratory considerations. As a general rule, X-ray tubes with copper targets are commonly operated with a potential of about 40 to 45 kV and a filament current of about 35 to 45 mA. If other factors are held constant, then higher power settings can be used to shorten analysis time, lower the limit of detection, and improve signal-to-noise ratio, but at the expense of shortened tube life. For routine, general-purpose analysis by scanning X-ray diffraction units, the common choice for slits used to define the dimensions of the X-ray beam illuminating the specimen and reaching the detector are as follows: 0.15° for the receiving slit and 1.0° for all other slits. If other factors are held constant, then larger slits can be used to shorten analysis time, lower the limit of detection, and improve signal-to-noise ratio, but at the expense of reduced ability to resolve closely spaced peaks. Conversely, smaller angle slits should be used if higher resolution is required. For analysis of unfamiliar paints, pigments, and other materials, diffraction patterns should be collected over a range scanning at least from 5 to 65° 2θ. Use of a shorter scan range may cause the omission of important diffraction peaks. However, scans spanning a narrow 2θ range may be satisfactory for routine tests based on peaks located within a chosen portion of the diffraction pattern. For routine qualitative and semiquantitative analysis, satisfactory results can be achieved with most step scanning instruments by progressing in steps of 0.02° 2θ, with 1.0 to 1.2 s per step. Longer count time may be required for quantitative analysis. In the case of older diffractometers with analog scanning motors, a scan rate of 1°/min is satisfactory for routine qualitative and semiquantitative analysis.

Qualitative Analysis

Interpretation of X-ray Diffraction Patterns

Preparation of d-Spacing Intensity Table—After the X-ray diffraction pattern of a test sample is recorded, the analyst must obtain a list of all diffraction peaks with their *d*-spacing and relative intensity. The peaks should be listed in descending order of *d*-spacing. The intensity is expressed as a percentage of the strongest peak, taken as 100. If the X-ray unit lacks data processing capability, then the analyst must read the 2θ of each peak from the pattern and calculate the *d*-spacings from the 2θ values of the peaks using the Bragg equation. Likewise, the height of each peak must be measured by hand and the relative intensity determined. However, *d*-spacing-intensity tables can be obtained automatically from diffraction units equipped with even the most basic computer capabilities.

General Comments—Identification of pigments, extenders, and other crystalline phases by X-ray diffraction is accomplished by matching the peaks of the diffraction pattern of a sample under analysis with the sets of diffraction peaks exhibited by reference samples of known composition [2,10,11]. X-ray diffraction provides no chemical information about a test sample other than the identification of each com-

ponent that is achieved when a full match of its set of peaks is found. Either manual or computer-assisted searches can be done. Manual methods rely on the numerical comparison of d-spacings and intensities of diffraction peaks. Recent computer search methods also begin by matching the d-spacings of peaks, but rely in part on the analyst to do visual matching of peaks on a video screen.

Several instrument manufacturers and after-market suppliers offer computerized search-match programs. Operated on personal computers, these programs use diffraction data files stored on compact disk or magnetic medium. The data files are available from the International Centre for Diffraction Data (ICDD), formerly known as the Joint Committee for Powder Diffraction Standards (JCPDS) [*12*]. Use of these computer programs and data files can greatly speed qualitative analysis [*13*].

Manual Search Procedures—Diffractionists who are experienced in the analysis of paints, but who do not have computerized search-match facilities, usually employ a qualitative analysis procedure that has the two following steps. First, the diffraction pattern is inspected for the presence of sets of peaks that are characteristic of commonly used pigments and extenders, or other phases suspected of being present. Sets of peaks found in the pattern that are suspected of resulting from common components are compared to the peaks on reference diffraction patterns. The comparison may be done directly by comparing diffraction patterns or indirectly by comparing the d-spacings and relative intensities calculated from reference patterns. Partial or even complete identification of components may be achieved by this procedure. Second, peaks that were not identified by the first approach are subjected to a systematic search using compilations of X-ray diffraction data, such as the Powder Diffraction File from ICDD. The first approach is most useful when the analyst, because of information available from other sources such as elemental analysis, the appearance, knowledge of the intended use of the paint, or experience, suspects the presence of certain crystalline components.

Figure 6 shows the X-ray diffraction patterns of several common paint pigments. For brevity, the term pigment will be used to mean both pigments and extenders. The pigments are readily distinguished from each other and from all other crystalline material by the positions of the peaks on the 2θ scale and by the relative intensities of the peaks. Since the diffraction pattern of each crystalline phase is unique, it may be used as a "fingerprint" for identification. The patterns in Fig. 6 were collected under identical conditions from powder specimens. Although some pigments originally gave patterns with greater peak heights, they are all plotted to about full scale for convenience.

Figure 7 shows diffraction patterns of dried paint films of two test paints of known composition. Each crystalline component in the paint film contributes its own set of peaks to the pattern, with the position and relative intensity unaltered by the other components. Resin and other noncrystalline components produce only a broad, weak hump in the baseline. Some crystalline components of the two paints represented by Fig. 7 can be identified by comparison with the diffractograms of individual pigments in Fig. 6.

Table 2 lists 37 pigments and extenders commonly used in paint, with the d-spacings and relative intensities of their five

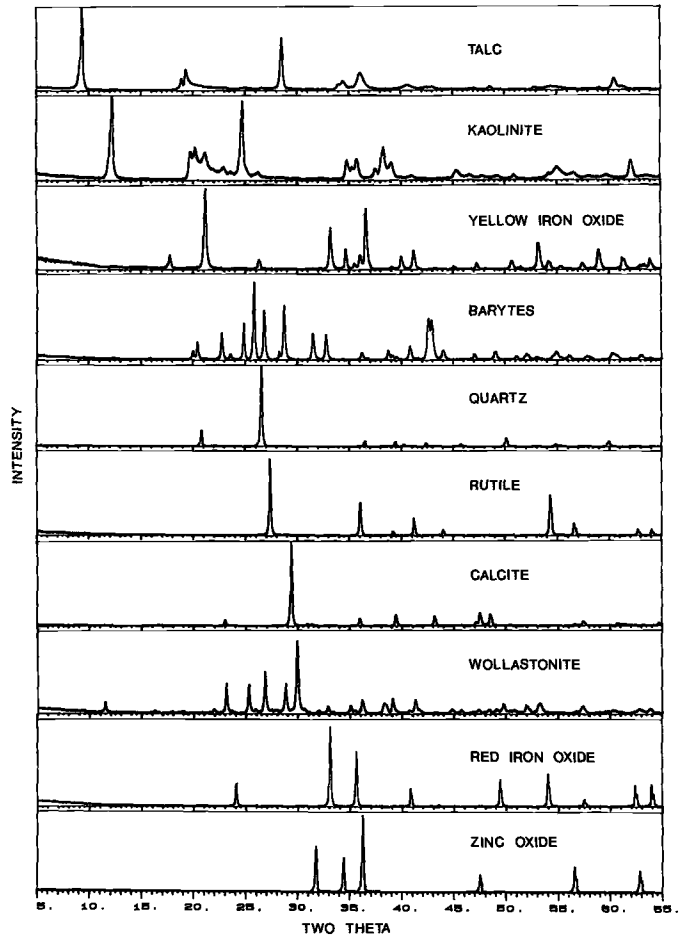

FIG. 6–X-ray diffraction patterns of several common pigments and extenders run as powder.

most intense diffraction peaks. This table, compiled from the Powder Diffraction File of ICDD, may aid the paint analyst in identifying common components. The pigments are listed in order of the d-spacing of the strongest peak. The d-spacing of the strongest peak is listed in the first column on the left. The next four strongest peaks of each phase are listed in decreasing order of their d-spacings. The subscripts state the relative intensity of each peak rounded off to the nearest integer, with the intensity of the strongest peak taken as 10 and represented by "x."

To use Table 2 in a systematic manner in interpreting a diffraction pattern, the analyst determines the d-spacing of the peaks at the high d-spacing end of the pattern of the sample under analysis and then searches the first column of Table 2 for apparent matches. When an apparent match is found for a peak, the pattern of the test sample is inspected for the presence of the remainder of the peaks listed in the same row of Table 1. The absence from the pattern of any one of the listed peaks is usually sufficient reason for rejection of the suspected component. However, in the case of materials consisting of platelet or acicular-shaped particles such as clays, mica, and aluminum flake, preferred orientation may greatly decrease the intensity of some diffraction peaks compared to the intensities listed in Table 2. If the pattern of the test sample has all the peaks listed for the candidate compo-

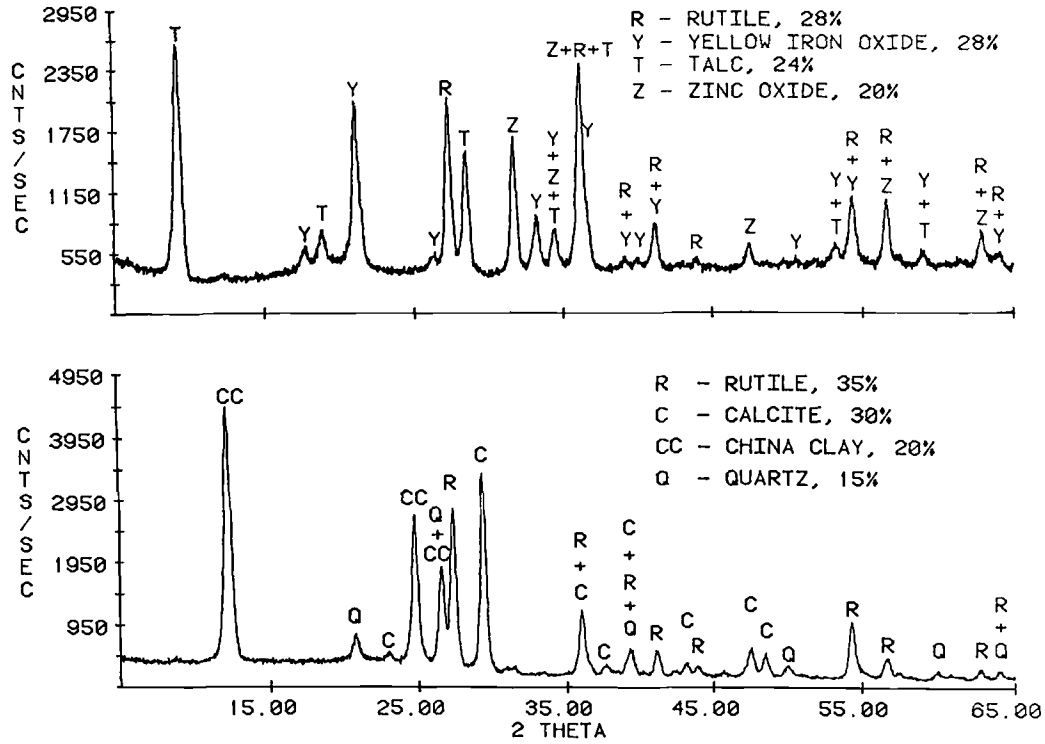

FIG. 7–X-ray diffraction patterns of drawdowns of two paints with the principal peaks of the constituent pigments labeled.

nent, then the analysts should note the ICDD file number listed for the phase in the last column. The file number may then be used to locate the full set of diffraction data provided by ICDD (and JCPDS) compilations. Using the ICDD data, all peaks attributed to the identified component may be marked on the pattern of the test sample. The identification process is then repeated with unassigned peaks in the pattern, working progressively from the peaks with the highest *d*-spacing, particularly the strongest ones, to the peaks with low *d*-spacing.

In an alternative use of Table 2, the analyst searches the list for crystalline phases that he suspects may be present in the test sample. If the strongest peaks listed in Table 2 for the suspected component are present in the diffraction pattern of the test sample, then the analyst notes the ICDD file number and proceeds as described in the previous paragraph.

The printed Alphabetical Index & Search Manual and its computer compact disk counterparts from ICDD provide an alphabetical listing by name of a large collection of crystalline phases, their formula, the *d*-spacing and relative intensity of the three strongest peaks, and their ICDD file number. These references are an extremely useful starting point in peak identification when the analyst knows or suspects the presence of certain phases in the test sample. If the three strongest peaks of a candidate are found in the pattern of a test sample, then the analyst should use the ICDD file number to locate the full set of diffraction data on the compact disk or in the equivalent printed volumes. For positive identification, all peaks listed for the candidate in the full data set must be present with appropriate intensity in the test pattern. However, the weaker peaks of a low-concentration component may be unobservable.

Peaks that remain unassigned after the information in Table 2 and the alphabetical files has been used must be identified by using the ICDD Powder Diffraction Files and either the Hanawalt or Fink search methods, or other search system. The Hanawalt method is based on the three strongest peaks in the diffraction pattern. The Fink method is based on the eight strongest diffraction peaks of each phase without use of intensity information. The Fink index lists each phase eight times with a cyclic permutation of the eight peaks. Instructions in the Hanawalt and Fink search manuals should be studied carefully before attempting to use either method [*12*]. Although still used in many laboratories, sale of Fink search manuals has been discontinued.

Computer-Assisted Searches—Analysts using computer programs for qualitative analysis must rely on instruction from the program supplier. In general, computer search routines provide a list of crystalline phases that have peaks that match, or approximately match, the 2θ positions of the peaks of the test sample. Unfortunately, since more than one phase, perhaps many, may have peaks at the same 2θ position as the test sample, a search-match program may suggest phases that are not actually present. "False hits" are especially common when the diffraction pattern of the test sample is complex. Recent computer search routines provide the opportunity for the analyst to include information about elemental content of the sample and a variety of additional physical and chemical data to exclude implausible candidates. They also permit the analyst to adjust the *d*-spacing range spanning each test sample peak to account for possible error in the *d*-spacings of test sample and reference data. The analyst can widen the *d*-spacing "search window" to reduce the possibility of missing a component of the test sample or

[a]Subscripts represent the relative intensity (rounded to the nearest integer) of the diffraction peaks of a phase with the most intense peak taken as 10 and represented by "x."

[b]Particles of this material frequently exhibit preferred orientation in paint films, thus causing the observed relative intensities to differ significantly from intensities listed in this table.

narrow the window to reduce the number of false hits. When analyzing "difficult samples," the analyst may benefit from comparing the results of searches run with a variety of search window widths. Some search routines assign a figure of merit to each candidate on the list based on similarity between data for the test sample and the candidate. Most programs permit the analyst to suggest candidates for consideration and exclude specific noncandidates. The analyst may draw on his knowledge of the origin of the sample and use Table 2, when appropriate, to suggest candidates. Visual matching on a video screen of the 2θ position and intensity of peaks of candidate components, represented by "sticks," with the position and intensity of actual diffraction peaks is a key part of computer-assisted analysis. All candidate components with "extra" peaks not found in the diffraction pattern of the test sample must be rejected unless there is reason to suspect that preferred orientation of the particles can account for the discrepancy. Candidates with badly mismatched peak intensities must be considered suspect except when preferred orientation could account for the discrepancy. Relative intensities are especially unreliable for mineral pigments, especially clays, mica, and silica. Complete analysis ideally requires that a set of crystalline components can be identified that can account for all peaks, both their position and intensity, observed in the diffraction pattern of the test sample.

Although computer search-match programs are valuable aides for interpretation of diffraction patterns, common programs that are presently available may suggest the presence of components that are absent and fail to show the presence of phases that are truly present. Therefore, results thus obtained should always be verified and, if necessary, corrected by the analyst.

Limitations—Qualitative analysis by X-ray diffraction has three principal limitations. First, only crystalline phases can be identified. Noncrystalline components must be identified by other means. Second, different substances can be encountered that have similar diffraction patterns, at least in part. Misidentification can occur when the sample contains several

crystalline phases producing a complex pattern and diffraction is the only technique being used for analysis. Examples of potentially confusing coincidences or near coincidences are the strongest peaks of red lead, quartz, and zinc sulfide, with *d*-spacings of 3.38, 3.34, and 3.31 Å, respectively, a secondary peak of barytes at 3.319 Å, and a strong peak of mica at 3.36 Å. The 3.247 Å peak of rutile may conceal the 3.260 Å peak of strontium chromate. The 3.446 peak of barytes may conceal the 3.452 Å peak of strontium chromate. Many other similar peaks can be found for common pigments in Table 2. Third, low concentration components may be overlooked, especially if they scatter X-rays weakly or if their strongest peaks are overlapped by major components. For example, small amounts of zinc oxide may be overlooked if its strongest peak at 2.476 Å is overlapped by a peak of rutile at 2.487 Å or talc at 2.476 Å, particularly when the latter phases are major components. Fourth, the relative intensity of peaks in the pattern of certain phases may differ significantly depending on their history, the degree of preferred orientation of the particles, the specimen preparation techniques, and the instrument used to collect the pattern. Anomalies especially arise from pigments that consist of platelet or acicular particles that exhibit preferred orientation and from clays that have been changed by chemical, thermal, or mechanical processing.

The speed and reliability of analyses can be greatly improved if information is available about what elements and functional groups are present in the sample. X-ray fluorescence and optical emission spectroscopy are convenient techniques for qualitative elemental analysis. Plasma emission, atomic fluorescence, and atomic absorption spectrometry can also be used for elemental analysis. Infrared spectroscopy can provide functional group information and, through spectral matching, may provide independent corroboration of pigment identification. Elemental analysis data are particularly useful in detecting and identifying crystalline components that are present at low concentrations. Elemental analysis and infrared spectroscopy results are useful for identifying noncrystalline pigments.

Quantitative Analysis

Theory of Quantitation

Quantitative analysis by X-ray diffraction is based on the principle that the intensity of a diffraction pattern of a crystalline substance is directly proportional to the concentration of that substance in the sample. This relationship and several complicating factors are discussed in detail by Klug and Alexander [*2*]. The intensity of X-rays diffracted from a given set of crystallographic planes in component *i* in a mixture is given by the equation

$$I_i = K_i' f_i / \mu$$

where

I_i = the intensity of diffracted X-rays,
K_i' = a constant that depends on both the nature of component *i* and the characteristics of the apparatus,
f_i = the volume fraction of component *i*, and
μ = the absorption coefficient of the mixture.

Since the absolute intensity I_i is influenced by the composition of the matrix, the absolute concentration of an analyte cannot be determined unless a calibration curve is established with an internal standard.

However, using the "matrix flushing" method described by Chung, the *relative* concentration of crystalline components in a mixture can be determined without knowledge of the absorption coefficient [*14,15*]. This approach is based on the fact that all components under analysis are in the same matrix and thus are equally influenced by X-ray absorption. The intensity of X-rays diffracted from a component *i* is given by the equation

$$I_i = k_i X_i$$

where

k_i = a constant that depends on component *i* and the apparatus, and
X_i = the mole fraction of component *i*.

The ratio of the intensity of X-rays diffracted from two components *i* and *R* is given by the equation

$$\frac{I_i}{I_R} = \frac{k_i}{k_R}\frac{X_i}{X_R}$$

where

k_R = a constant that depends on component *R* and the apparatus, and
X_R = the mole fraction of component *R*.

The constants k_i and k_R indicate the relative efficiency of two materials in diffracting X-rays from given sets of crystallographic planes into the detector of the diffractometer. The relative value of k_i and k_R can be determined from the equation

$$\frac{k_i}{k_R} = \frac{I_i}{I_R}$$

by measuring the intensity of X-rays diffracted from two crystalline components *i* and *R* in a 1:1 binary mixture. Peak area, rather than height, should be used to represent intensity since the former is less influenced by differences in particle-size distribution. Quantitative analysis of a multicomponent mixture requires that the identity of all components be known. One component is arbitrarily chosen as an internal reference, *R*. Binary 1:1 by weight mixtures are prepared with the reference component and each of the other components. The intensity ratio I_i/I_R of a peak, usually the strongest, of each component is then measured. The ratio of the intensities of the diffraction peaks defines the k_i/k_R of each pair of components. The ratio k_i/k_R is called a reference intensity ratio or RIR [*16–20*]. Corundum, the most commonly used reference material, is the basis of all RIR values given in ICDD Powder Diffraction Files. Davis, Smith, and coworkers published RIR values for some common materials, including several that are used as pigments or extenders in paint [*20,21*]. Published reference intensity ratios must be used with care since material other than corundum may have been used as the reference and intensity may have been measured as peak height instead of area.

PRACTICAL PROCEDURE FOR CALCULATING COMPOSITION

The relative weight percent of each crystalline components in a multicomponent mixture can be determined by the following procedure:

1. Determine the intensity of the diffraction peak chosen for quantitation of each component. (Integrated intensity based on peak area is recommended. Intensity may be expressed in counts per second, relative intensity compared to the most intense peak in the set, or any other consistent system.)
2. Determine the reference intensity (RIR) for every crystalline component in the sample if the information is not already available. (Once a RIR has been determined, it may be saved and used in future analyses conducted under the same experimental conditions.)
3. Divide the intensity of the chosen peak of each component by the corresponding RIR.
4. Normalize the set of quotients so that their sum is 100.
5. The normalized quotients correspond to the relative weight percent of each crystalline component.

Example:

The diffraction pattern of a sample indicated the presence of three components: rutile, quartz, and tan iron oxide. The analyst determined that the RIRs for these phases are:

3.20 for the 3.247 Å peak of rutile

2.96 for the 3.342 Å peak of quartz

2.32 for the 2.543 Å peak of tan iron oxide

The intensity of the corresponding peak for each component in the diffraction pattern of the test sample is:

Component	Intensity
Rutile	100.0
Quartz	19.1
Tan iron oxide	1.8

The data and calculated values may be organized as follows:

Component	Intensity	RIR	Quotient	Percent
Rutile	100.0	3.20	31.3	81.1
Quartz	19.1	2.96	6.45	16.8
Tan iron oxide	1.8	2.32	0.78	2.1

Two important points about quantitation by X-ray diffraction analysis should be noted. First, the results do not include noncrystalline components such as carbon black, amorphous silica, or highly processed clays. Second, the results do not represent percent by weight on either a dry film or a liquid paint basis.

The absolute weight percent of crystalline pigments and extenders can be determined by either:

1. Using a variation of the above method that includes an internal standard [*14,15,22*] added in known concentration to the paint.
2. Taking into account the total percent pigment in the paint if no amorphous pigment is present. The percent pigment in dry coating or water-reducible paint can be determined by ASTM Test Method for Pigment Content of Water Emulsion Paints by Low-Temperature Ashing (D 3723) [*25*]. The percent pigment in solvent-reducible paint can be determined by ASTM Method for Determination of Pigment Content of Solvent-Type Paints by High Speed Centrifuging (D 2698) or ASTM Test Method for Pigment Content of Solvent-Reducible Paints (D 2371) [*23*].

The accuracy and precision of quantitation by X-ray diffraction are strongly dependent on the number and type of crystalline components present, the accuracy of the reference intensity ratios used, the amount of preferred orientation of crystallites, and the instrument-operating conditions. Published studies reported that the "matrix flushing" method described above yielded results that agree with known composition within 4.2% relative for all components [*15*]. Standard deviations of about 0.4 and 5% have been reported for components comprising 90 and 5%, respectively, of three-part mixtures of NiO, α-Fe_2O_3, and Fe_2O_4 [*24*]. Smith et al. reported relative error ranging from 0 to 12% [*19*]. Dyakonov et al., in a study with seven laboratories, reported relative standard deviations of interlaboratory determinations ranging from 5 to 20%, but cited relative standard deviations of 60% for low-concentration components [*25*]. An approach for dealing with preferred orientation in mica has been suggested by Kamarchik and Ratliff [*26*].

Limitations

Quantitation of pigments by X-ray diffraction is sometimes handicapped by one or more of the following problems. First, the degree of crystalline regularity within particles of some pigments, especially silica and clays, may differ depending on the source and the nature of the processing that they have received. A factor contributing to variability of the apparent crystallinity is the amount of substitution of "foreign" ions in the crystalline lattice. An example is the substitution of magnesium for calcium in calcite and strontium for barium in barytes. Thus, a given amount of pigment in a test sample may diffract X-rays more or less strongly than the supposedly equivalent pigment sample used to establish the RIR. An article by Davis et al. provides a valuable listing of reference intensity ratios (*versus* corundum) for many common pigments and illustrates the variability of reference intensity ratios for pigments from different sources [*21*]. Second, pigments particles that are platelet or acicular in shape tend to assume preferred orientations in a paint film as the paint dries. If the extent of preferred orientation of the particles in the specimen and the reference specimen used to establish the RIR differs, then quantitation based on the RIR is incorrect. Mica and aluminum flakes commonly exhibit preferred orientation. Third, the strongest peaks normally used for quantitation may be overlapped by peaks of other components, thus requiring the use of weaker and less reliable peaks as the basis of quantitation.

Examples of X-ray Diffraction Analysis

Pigment Analysis

X-ray diffraction analysis is the most direct way to determine the identity and purity of pigments, whether in assessing the quality of pigments from established suppliers or in

evaluating pigment from potential new suppliers. Crystalline impurities contribute "extra" peaks to diffraction patterns, differences that may be readily seen in patterns of pigment powders alone or in grind pastes. X-ray analysis has long been established as the method of choice for determination of the amount of anatase in rutile [ASTM Test Method for Ratio of Anatase to Rutile in Titanium Dioxide Pigments by X-ray Diffraction (D 3720)] [*23*]. The widespread use of diffraction in the pigment industry attests to its utility in that field.

Questions concerning the identity or amount of pigments in paint can be more conveniently and definitively answered by X-ray diffraction than by any other technique. Visual comparison of diffraction patterns or, when necessary, quantitative analysis can be used to determine whether errors in pigment composition account for the difference in performance, color, or gloss of "good" and "bad" paint. Diffraction analysis is a basic tool that may be used to verify whether a paint that exhibits poor performance is the correct paint and comes from the correct supplier. The differences in the two patterns in Fig. 8, one for a good paint and one from a poorly performing suspect paint, coupled with differences in resin and solvent determined by other techniques, proved that the suspect paint was an unauthorized substitute.

Metal Pretreatment and Other Thin Coatings

X-ray diffraction can be used to determine the identity and amount of pretreatment on metal or, in general, crystalline coatings on substrate. Figure 9 shows the characteristic part of the diffraction patterns of two common types of pretreatment, hopeite [$Zn_3(PO_4)_2 \cdot 4H_2O$] and scholzite [$CaZn_2(PO_4)_2 \cdot 2H_2O$], on zinc-galvanized steel. Coating thickness or pretreatment weight can be determined by comparison of the intensity of one or more peaks of the species of interest with the same peaks exhibited by standard samples.

X-RAY FLUORESCENCE SPECTROSCOPY

Application

Types of Samples

X-ray fluorescence spectrometry is applicable to any liquid or solid that can be placed at the focal point of the X-ray optics system. Permissible specimen size differs widely with instrument type. Common commercial laboratory units can accept specimens as large as a cylinder about 4.0 cm in diameter and 2.5 cm in height to as small as 1 or 2 mg of powder. Some laboratory models can analyze specimens up to several centimeters in each dimension. There is no maximum size limit for bench top or portable units with hand-held X-ray probes.

Types of Information Provided

The most sophisticated and costly X-ray spectrometers can be used for qualitative and quantitative analysis of all elements in the atomic number range from 5 (boron) to 92 (uranium). Lower-cost instruments span fewer elements and offer less versatility.

Range of Concentrations

Analysis can be performed on elements ranging in concentration from 100% down to a few parts per million in favorable cases. The limit of detection differs widely with the

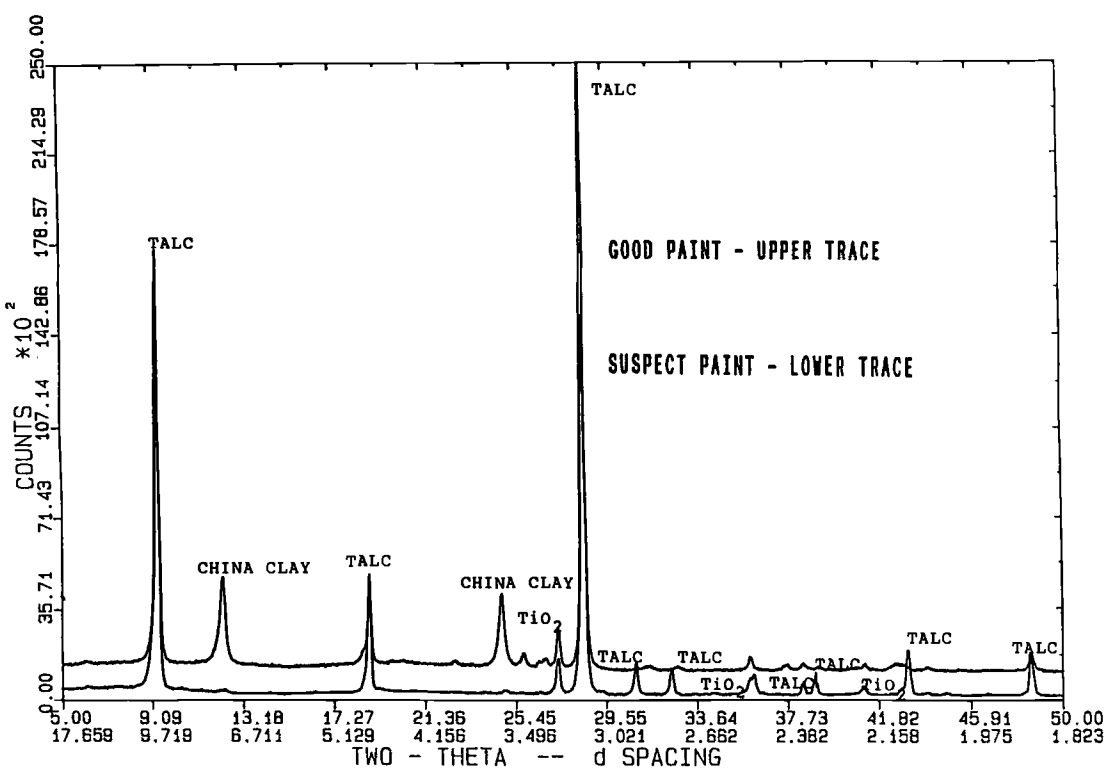

FIG. 8–X-ray diffraction patterns of drawdowns of two paints: one known to be good, one of suspect identity.

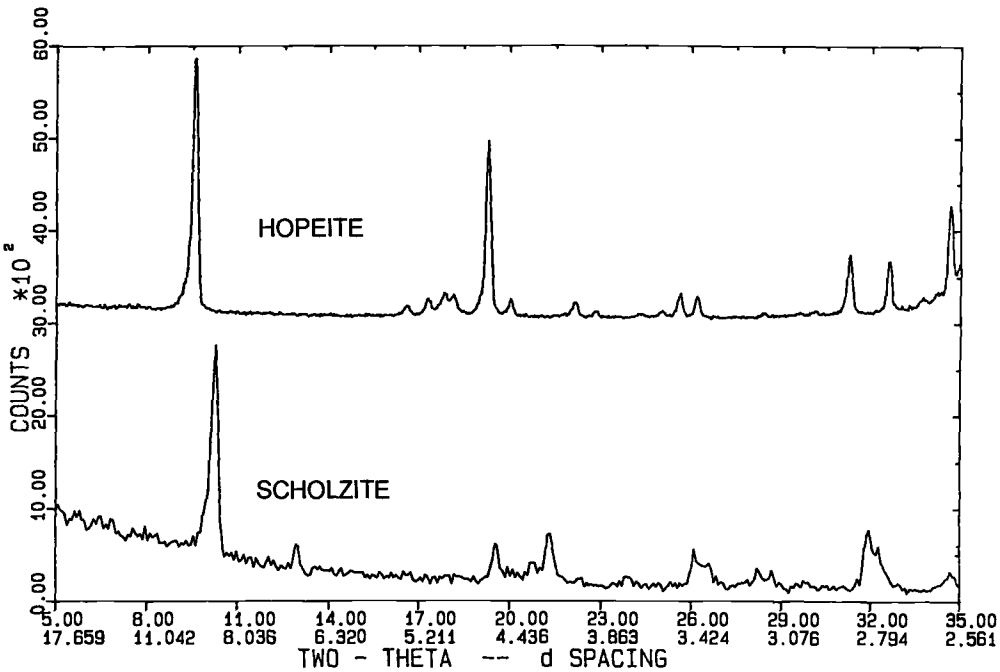

FIG. 9–X-ray diffraction patterns of hopeite and scholzite pretreatment on zinc-galvanized steel. (The principle peaks of zinc are beyond the right end of the pattern.)

model of spectrometer, the element of interest, and what other elements are present. The limit of detection rises rapidly with decreases in atomic number, especially below 11 (sodium).

Physical Basis

When X-ray photons of sufficient energy are directed onto a specimen, some photons are absorbed in a process that causes ejection of electrons from core atomic orbitals. The vacancies thus created in the inner orbitals are then filled by electrons from outer orbitals. The transitions of electrons from outer to inner orbitals are accompanied by the release of X-rays in a process called X-ray fluorescence [*27,28*]. The wavelengths of the fluorescent X-rays are greater than the wavelength of the incident X-rays. Of key importance in analysis is the fact that every element emits fluorescent X-rays at characteristic wavelengths. The spectra are plotted as intensity as a function of either 2θ angle (as in Fig. 10), wavelength, or photon energy (as in Fig. 11). Angle 2θ refers to the posi-

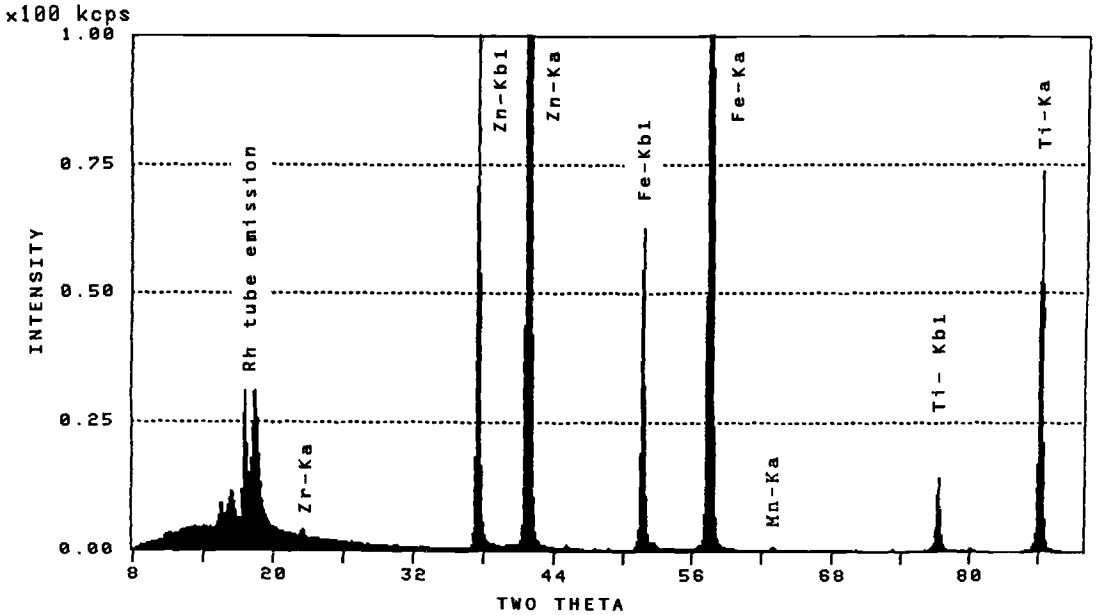

FIG. 10–Part of a WLD X-ray fluorescence spectrum of paint containing rutile, yellow iron oxide, talc, and zinc oxide.

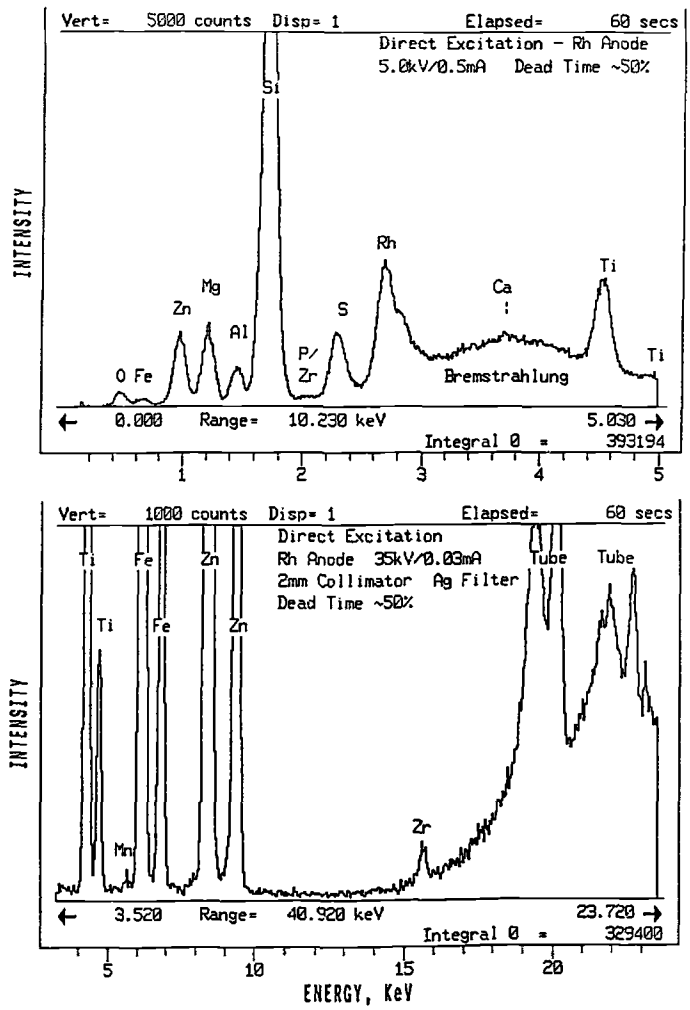

FIG. 11–X-ray fluorescence spectrum, recorded using an energy dispersive spectrometer, of the paint used for Fig. 10.

tion of the X-ray detector that moves at twice the angle of the diffraction crystal used in some instruments to separate different wavelengths to produce a spectrum.

Types of X-ray Fluorescence Spectrometers

Scanning

Scanning X-ray fluorescence spectrometers permit the acquisition of spectra spanning a broad wavelength or energy range. These spectrometers, usually floor-standing, are versatile instruments for both qualitative and quantitative analysis. Scanning spectrometers, most using X-rays from Coolidge-type tubes, can be further classified as either wavelength or energy dispersive.

Wavelength-dispersive (WLD) instruments produce a spectrum by using a crystal to diffract the fluorescent X-rays, a single wavelength at a time, onto a detector that measures their intensity. By rotating the crystal through an angle defined as θ as the detector moves around an arc through angle 2θ, only those X-rays that satisfy the Bragg equation reach the detector. The resultant spectrum is usually plotted as intensity as a function of 2θ angle, but could in principle be plotted as intensity as a function of wavelength. By use of several crystals, each effective for a certain span of wavelengths, a broad range of wavelengths can be scanned. Instruments based on energy-dispersive X-ray spectroscopy (EDXS) permit all wave lengths of the fluorescence to reach the detector simultaneously and use a pulse-height discriminator to electronically classify the energy of the X-ray photons that strike the detector.

Descriptions and comparisons of the two types of scanning spectrometers have been provided by Campbell [*29*]. Compared to EDXS units, the WLD spectrometers generally offer far superior resolution and lower limits of detection. EDXS instruments provide much faster acquisition of spectra and are usually lower in cost. Scanning spectrometers are convenient for qualitative elemental analysis and are broadly versatile for quantitative analysis [*30*].

Dedicated (Specialized Application)

Dedicated X-ray fluorescence spectrometers, available at much lower cost than the scanning spectrometers, permit quantitative analysis of a single element or a few selected elements. Most of the dedicated units, and all the lowest priced units, use a radioactive isotope instead of an X-ray tube as the source of radiation to excite the specimen [*31*]. In single element analyzers, the isotope source, detector composition, and operating conditions are chosen to give best performance for analysis of a specific element of interest. Dedicated X-ray spectrometers are typically small bench top units with simple operating procedures. They are well-suited for routine analysis [*30*].

On-line

Products and process materials may be analyzed on-line by specially adapted dedicated X-ray fluorescence units with remote analyzer heads [*32*]. The heads house the X-ray source and detector. Flow-through heads can be used for liquids. Fixed or moving heads can be used for moving sheet stock or other solid material. Bulk composition or the composition or thickness of a coating on a substrate can be determined by this method. The apparatus and methodology are custom-designed for each application.

Portable

Portable X-ray fluorescence units with self-contained power supplies and either single or multiple element capability are available for uses that require mobility. They are well-suited for rapid analysis in factory yards and in field studies [*33*].

Electron Beam Excited X-ray Spectroscopy

Spectroscopic analysis can be performed with X-rays generated by bombardment of a specimen with an electron beam, as in a scanning electron microscope (SEM) or an electron microprobe (EMP) [*27*]. The spectrum may be produced by either energy-dispersive or wavelength-dispersive means. SEM units, commonly equipped with energy-dispersive X-ray capabilities, are extremely useful tools for the study of surfaces and small features, especially defects such as craters, voids, pinholes, mars, and stains. In addition to providing images, such instruments can perform qualitative and quantitative elemental analysis. EMP units, usually equipped with both energy-dispersive and wavelength-dis-

persive capabilities, are used when the emphasis is on quantitation rather than imaging. Both SEM and EMP permit elemental analysis as point analysis, line scan, area analysis, or mapping. Present technology permits analysis of all elements with atomic number 4 (beryllium) and higher.

Experimental Procedures

Specimens may be any solid or liquid that can be presented to the X-ray beam. The size of the specimen holder of the spectrometer is the principal practical limitation. Sample preparation methods have been discussed by Bertin and Leyden [*27,34*]. Figure 12 shows two types of specimens.

Many of the recommendations given in Table 1 for X-ray diffraction also can be used to prepare specimens for qualitative analysis by X-ray fluoresence spectroscopy. However, the analyst is cautioned that the X-rays used for X-ray fluorescence spectroscopy are commonly more penetrating than those used for diffraction analysis. Unless care is taken, the fluorescence spectrum may show elements in the backing material used to support the intended specimen material. The analyst must either use a specimen that is sufficiently thick to prevent X-ray fluorescence from the backing from reaching the detector or use a backing (such as a metal-free polymer) that is free of conflicting elements. It is common practice to place liquid or powder in a disposable plastic cup, the bottom of which is covered with a thin plastic film that transmits X-rays. (Liquids and powder are most conveniently analyzed in spectrometers that irradiate the specimen from below. For instruments of the opposite configuration, the specimen cup must be filled so that there is no bubble when the cup is inverted in the analysis chamber.) Paint chips may be placed directly in the specimen cup, and drawdowns of paint on metal-free plastic sheets such as Mylar may be cut to fit the specimen holder.

For quantitation, powders may be pressed into disks in a binding agent such as orthoboric acid, granular cellulose, or graphite or cast as pellets after dissolution in molten flux such as lithium tetraborate or lithium metaborate. Ashing or extraction with acid or organic solvent is sometimes useful to remove analytes from bulky matrices, thus lowering the limit of detection and perhaps increasing analytical accuracy. Dissolution with acid or other solvent may make the sample more amenable to quantitation methods described under **Quantitative Analysis.** Detailed procedures for briquetting, fluxing, and ashing are available in the *Spex Handbook of Sample Preparation and Handling* [*35*]. Powders and liquids can be analyzed in disposable cups, as mentioned above. Disk-shaped specimens cut from solid samples may be handled in a similar manner. Bertin provides valuable information about specimen preparation [*27*].

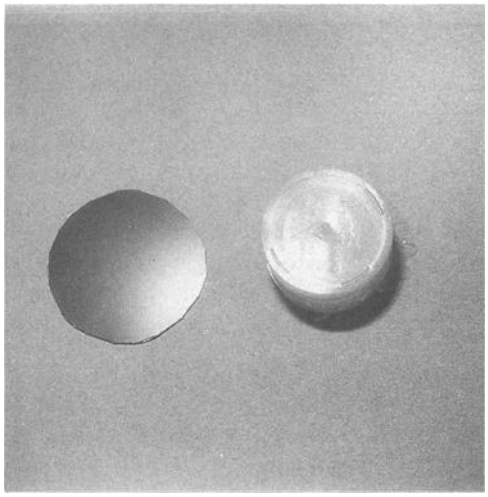

FIG. 12–Two examples of specimens: *left:* A disc cut from a painted steel aluminum; *right:* A plastic cup covered on the bottom with metal-free plastic film and on the top with a plastic cap. Suitable for liquids and powders.

Specimens are analyzed under vacuum whenever possible to minimize absorption of X-rays by the atmosphere in the analysis chamber. However, liquids and powders must be run under helium or air to prevent spatter. Portable analyzers and certain models of bench top units can operate without the specimen in vacuum or purge gas because of the short distance between the specimen and critical instrument parts.

Operating procedures differ widely with the make and model of X-ray spectrometer. Manufacturer instructions on safety and operation should be consulted.

Qualitative Analysis

Qualitative elemental analysis can be conveniently done using a scanning X-ray fluorescence unit. Elements in a specimen can be identified by the position of the peaks on the spectrum expressed as photon energy (kilovolts), 2θ angle, or wave length. Peak identification tables can be found in manuals provided by manufacturers of the spectrometers or in treatises on X-ray spectrometry [*27*]. Modern X-ray spectrometers have computer programs that can indicate what elements are present in a specimen. For instruction in use of these programs, the analyst should refer to the instrument operation manual.

Figure 10 shows part of an X-ray fluorescence survey spectrum (collected using a wavelength-dispersive instrument) of a drawdown of a tan paint, the same one used to produce the diffraction pattern in Fig. 7*a*. Note the corroborative nature of element content indicated in Fig. 10 and the identity of the pigments determined from the diffraction pattern in Fig. 7*a*. For comparison, Fig. 11 is an X-ray fluorescence survey spectrum, recorded by an energy-dispersive instrument, of the same sample.

Quantitative Analysis

General Principles

The principles of quantitative analysis by X-ray fluorescence spectrometry have been discussed in detail by many workers including Bertin [*27,28*]. The basic equations show that the intensity of the fluorescent X-rays is proportional to the amount of element that produced the X-rays, but is influenced by other factors such as the density and absorption coefficient of the specimen. Nevertheless, the linear proportionality between analyte concentration and fluorescence intensity shows that common analytical methods such as standard addition can be readily employed in X-ray spec-

trometry. Direct comparisons of concentration can also be made between samples that differ only in the amount of analyte of interest. Analyses by these simple methods can be done with small, low-cost, bench-top analyzers. Analysis of more than one element, especially in a matrix of variable composition, is best done with more sophisticated scanning spectrometers with suitable computers and software. Yet, some bench-top analyzers equipped with computers can determine the concentration of more than one element in matrices of variable composition. X-ray spectrometers must be programmed and calibrated by the analyst or the manufacturer for each analytical task before reliable quantitative analysis can be done. Recalibration must be done periodically.

Direct Comparison Method

Quantitation by direct comparison is done as follows. The analyst prepares or collects a set of three or more reference specimens that contain an element of interest at a range of known concentrations, but are otherwise essentially identical. Equal amounts of each specimen are placed in specimen cups or otherwise prepared for analysis. The analyst collects fluorescence intensity data for the element of interest from the set of samples and establishes a calibration plot of intensity *versus* concentration. Modern X-ray spectrometers with integrated computer capabilities can store the calibration plot for convenient use. When the spectrometer lacks computer capabilities, the analyst can construct the plot manually or use an external computer. Test samples of unknown composition are then run on the spectrometer under conditions identical with those used when the calibration samples were run. Intensity data from each test sample can be converted to concentration through use of either a manual or computer-stored calibration plot. To avoid extrapolation error because of unexpected plot curvature or other reasons, the range of concentration of the reference specimens should span the concentration of the specimens being analyzed. If the test specimen lies outside the range, then either the specimen should be diluted by a known amount to bring it "on scale" or the calibration plot should be extended with additional reference specimens. Operating instructions from the supplier of the spectrometer should be followed.

When applicable, direct comparison is usually the simplest and most convenient element quantitation method available. It can be done with even the simplest X-ray spectrometers. Most modern X-ray spectrometers can store several, perhaps many, calibration plots suitable for different applications.

Cautions: (1) If a specimen differs in matrix composition or physical state from the specimens used to establish the calibration plot, then the analytical results may be incorrect. Error can be large if the matrix of the test sample and the reference samples differ widely in absorptivity of X-rays. (2) The calibration curve may show a significant amount of curvature if the analyte and the matrix differ widely in absorptivity (e.g., tin in resin) and a wide range of concentrations is spanned. If the intensity *versus* concentration plots shows curvature, then either a polynomial fit must be used or another method of analysis must be employed. (3) Calibration plots tend to lose accuracy with time and must be replaced or corrected following manufacturer instructions.

Standard Addition Method

The method of standard addition can be used when no suitable reference samples are available to permit analysis by direct comparison. In this method, the analyst divides the test sample into at least three equal portions of known volume or weight. One of the divided specimens is retained for analysis with no further change. Each remaining specimen is "spiked" with the element of interest in a series of different known amounts. This method has convenient application only to liquids, and perhaps to powders, because of the need to mix uniformly the added component with the original material. The concentration of *added* analyte in each specimen is then calculated. The intensity of X-ray fluorescence of the analyte in each specimen is measured under identical conditions. The intensity of the analyte fluorescence signal is plotted as a function of added analyte concentration, as in Fig. 13. The data line of the graph is extrapolated to the point of interception (a negative number) on the concentration axis. The absolute value of the concentration intercept corresponds to the concentration of the original unspiked sample. Many modern X-ray spectrometers have computer programs that do the calculation.

Empirical Methods

The empirical methods require the use of a set of reference samples that span the concentration range of all elements of interest. All modern high-priced and most mid-price X-ray spectrometers can perform analyses using one or more variations of this approach when equipped with suitable software. The analyst must follow the instructions from the instrument supplier. Empirical methods are well suited for routine multielement analysis of large numbers of samples of the same type. A different program, with its own set of reference samples, must be established for each class of samples and choice of elements. High accuracy and precision are achievable when the reference samples properly represent the test samples.

Fundamental Parameter Methods

Fundamental parameter methods are set up by the analyst with a set of reference samples, each either a pure element or a simple compound with a high percentage of an element of interest. In general, all elements to be analyzed should be included in the setup. However, some instruments can interpolate the analytical response of omitted elements from similar elements that were included in the setup. Programs that permit analysis by one or more fundamental parameters methods can be purchased with most high-price and some mid-price instruments. The analyst must follow instructions from the instrument supplier. In principle, once a program is established, no further reference samples are needed. In practice, recalibration is needed when instrument repair, maintenance adjustments, or other factors change the instrument response. No standard samples, in the usual sense of the word, are needed for calibration. Fundamental parameters programs can be used to perform multielement quantitative or semiquantitative analysis of test samples of widely varied composition and unfamiliar nature. Accuracy varies with the task and the sophistication of the instrumentation and software.

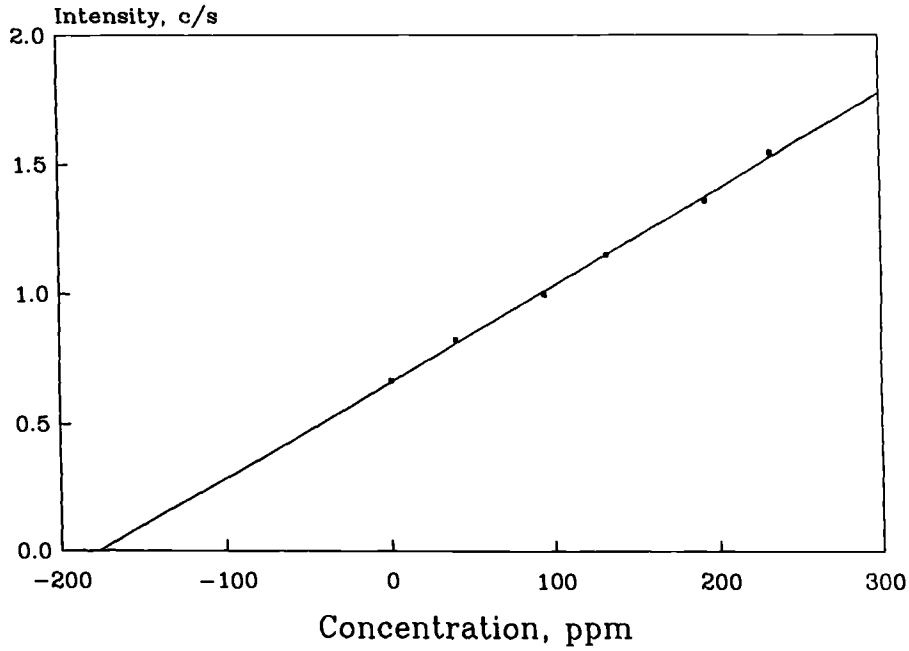

FIG. 13—A plot of the intensity of the sulfur K_α peak as a function of the concentration of sulfur in the analysis of an aqueous solution by a standard addition method.

Comparison to Other Techniques

In quantitative analysis of liquid samples, X-ray fluorescence spectrometry, compared to atomic absorption or plasma emission spectrometry, offers the advantage of being able to handle samples with (1) higher concentrations of analyte without use of large dilution factors and attendant inaccuracy, (2) matrices that are ill-suited for aspiration into nebulizers, and (3) elements that are not easily detected by flame or plasma photometric techniques.

Applications of X-ray Fluorescence Spectroscopy

Analysis of Elements in Solution

Figure 13 shows a plot of data used in the quantitation of sulfur in an acidic aqueous solution by a standard addition method. The sample resulted from flushing a steel panel retrieved from outdoor exposure with citric acid and then concentrating the solution by evaporation. This example illustrates a general-purpose method.

Surface Analysis

Foreign substances may sometimes be detected on surfaces by X-ray fluorescence spectroscopy, eliminating the need to resort to X-ray photoelectron spectroscopy and other "surface analysis" techniques. To be detectable, the contaminant must contain an element that is not present in significant amounts in the surface itself. Figure 14 shows a silicon peak in the high-resolution X-ray fluorescence scan of the surface of a piece of aluminum extrusion from which poorly adhering paint was peeled. Comparison of Figs. 14*a* and 14*b*, respectively, prove that washing the peeled surface with hexane significantly reduced the amount of silicon present. The elevated silicon signal on a substrate to which paint adhered poorly and the ready removal of the silicon material by hexane suggested the presence of silicone oil. This suspicion was confirmed using analysis by micro-infrared spectroscopy of residue left by evaporation of the hexane washings.

Detection of Bulk Contaminant

The low limit of detection of X-ray fluorescence spectroscopy makes it well suited for the detection of trace impurities, some of which may not be detectable by any other means. There is the tacit requirement that the contaminant contain an element that is not a normal component of the sample. Although small amounts of impurity may have no perceptible impact on the performance of a material, knowledge of the presence and amount of an impurity may be crucial in determining the cause of substandard performance. Table 3 summarizes data collected by X-ray fluorescence spectrometry in the investigation of a case in which silicone contamination was suspected as the cause of cratering exhibited by certain batches of water-borne paint. Quantitation was by a standard addition method. Although X-ray fluorescence spectrometry cannot distinguish between different silicon-bearing species, the higher level of silicon in batches of resin used in the crater-prone paint supports the suspicion that silicone caused the cratering. The data also suggest that a threshold concentration between 7 and 13 parts per million silicon in the resin is needed to produce cratering in the paint produced from it.

Quality Control

Dedicated X-ray fluorescence units that can determine the concentration of a single element have great utility in production plants for monitoring the composition of raw materials, intermediates, and products. One application is the monitoring of batches of paints to ensure compliance with federal regulations that limit lead content to no more than 600 parts per million based on nonvolatile content. A common tech-

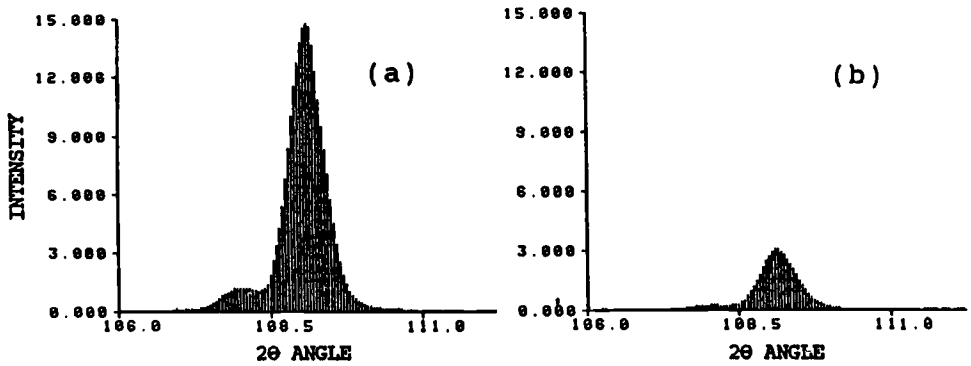

FIG. 14–The K_α peak of silicon on extruded aluminum from which poorly adhering paint has been peeled: (a) peeled only; (b) peeled and washed with hexane.

nique for determining lead content has been atomic absorption spectroscopy using ASTM Test Method for Low Concentrations of Lead, Cadmium, and Cobalt in Paint by Atomic Absorption Spectroscopy (D 3335) [*23*] or a similar method. X-ray fluorescence offers a quick alternative to atomic absorption spectroscopy, which may be too laborious and time-consuming for routine plant use. Lead content of a sample of paint can be determined by placing a drawdown or liquid specimen in the analysis chamber and directly reading either the content or signal count rate of lead. Dedicated X-ray fluorescence analyzers are available that give direct readout of concentration once a calibration curve has been established using samples of known concentration. The principal drawback of this method is the need for a separate calibration curve for every type of paint analyzed. Differences in the paint composition such as the type and amount of pigment can influence the intensity of the lead signal. In addition, interference from other elements such as bromine can produce large errors in apparent lead concentration.

Figure 15 is a plot of lead count rate from ten consecutive batches of paint measured with a dedicated X-ray fluorescence analyzer. The count rate that corresponds to 0.06% lead, the legal limit, is indicated by a horizontal line. To provide leeway for error, a lead limit of L_{max} (taking into account the precision of the method) may be chosen as the highest "passing" count rate. The dotted line represents L_{max}. Any sample that gives a count rate between L_{max} and the legal limit is considered suspect. Suspect batches of paint should be analyzed by ASTM Method D 3335 or other independent method, to determine the concentration of lead. Batches with unacceptable lead content may be scrapped or "blended-off."

TABLE 3—Concentration of silicone, determined by XRFS, in batches of resin used in batches of paint of known extent of cratering.

Extent of Cratering	Concentration of Silicon, ppm
None	3
None	4
None	7
Bad	13
Bad	13
Worst	40

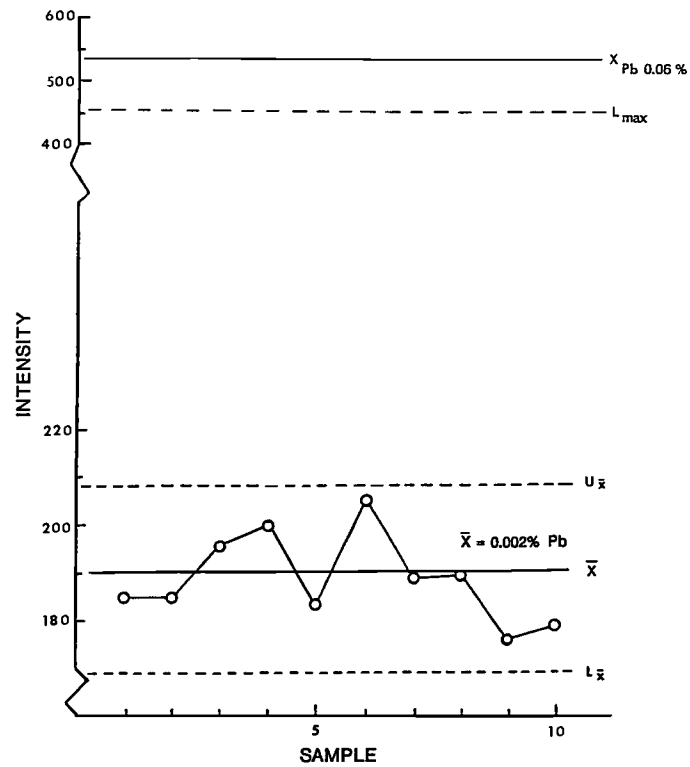

FIG. 15–A plot of the intensity of the lead signal for consecutive batches of latex paint as measured by a dedicated X-ray analyzer.

Dedicated X-ray analyzers have also been used to monitor the amount of rutile in batches of paint in production plants [*36*].

Guidance on the use of X-ray analyzers to determine the coating thickness is given in ASTM Standard Test Methods A 754-90, Coating Thickness by X-Ray Fluorescence [*37*], and B 568-90, Measurement of Coating Thickness by X-Ray Spectrometry [*38*].

Analysis in the Field

Concerns over the potential adverse health effects of lead in paint in residential buildings has prompted an interest in convenient, nondestructive methods of testing for lead. Fully portable X-ray analyzers that can detect lead in paint on walls

and other surfaces are commercially available. The analyzers can detect lead-containing paint beneath layers of lead-free paint, and some can provide direct readout of the amount of lead per unit area of paint surface [39]. The accuracy and precision are not well documented. The Department of Housing and Urban Development established a limit of 1.0 mg of lead per cm^2 of painted surface, a level detectable by portable analyzers.

Other uses of portable analyzers include determination of the weight of pretreatment on metal, the thickness of paint, and the concentration of key elements in samples at environmental cleanup sites.

SUMMARY

X-ray diffraction and X-ray fluorescence spectrometry, used alone or in combination, can provide valuable information about coatings, coating ingredients, impurities, and substrates. Sample preparation effort is minimal for both techniques. X-ray diffraction offers easy qualitative and quantitative analysis of crystalline materials in general and pigments in particular. X-ray fluorescence spectrometry is widely useful for qualitative analysis and, when suitable standards are used, for quantitative analysis. Attractive features of X-ray fluorescence spectrometry for quantitative analysis include its suitability for all elements except a few with lowest atomic number, applicability over a broad concentration range, tolerance of chemically reactive specimens, and applicability to samples of diverse physical states. Both X-ray diffraction and X-ray spectrometry are suitable for applications including basic research, product and process development, quality control, and practical problem solving. The area of greatest potential growth is the use of dedicated X-ray fluorescence spectrometers in production plants for quality control, particularly for on-line monitoring.

Part 16: Specifications

Paint and Coatings Specifications and Other Standards

78

by Wayne Ellis[1]

MANY ORGANIZATIONS THAT PURCHASE paint products in large volume for maintenance and construction projects require conformance to their respective specifications. Such organizations may be federal, state, and local government departments and agencies, large industries, public utilities, railroads, and universities.

Briefly, a specification is a precise statement of a set of requirements to be satisfied by a material, product, system, or service that indicates the procedures for determining whether each of the requirements is satisfied [*1*]. Paints and coatings used in industrial new construction may be specified in construction documents, while paints used in maintenance may be described in individual specifications of the owner organization. Finishes applied by large manufacturing industries are often specified by their engineering departments. Specifiers of large quantities of maintenance finishes, such as public utilities, transportation organizations, and government agencies (local, state, and federal), purchase on a specification basis. Purchase may be by competitive bidding.

SPECIFICATIONS CONSIDERATIONS

The Construction Specifications Institute (CSI) [*2*] says the following items should be considered in a project construction specification: scope, related sections, references, definitions, performance requirements, submittals, quality assurance, delivery-storage-handling, project conditions, and sequencing scheduling. Submittals cover paint product data and color samples. Material specifications in the ASTM format [*3*] generally include terminology, ordering information, chemical composition, physical and mechanical properties, performance requirements, sampling, test methods or analytical methods, inspection, packaging and marking, and sometimes quality assurance. While this chapter deals mainly with standard specifications, others such as standard test methods, standard guides, standard practices, and standard terminologies, are often referenced in construction coatings operations. They include, for example, Federal Test Method Standards, which are available from Defense Printing Service Detachment Office (DPSDO).

Some paint and coatings specifications (for example, for military use) require prequalification of the products described. Such prequalification is required when the time to conduct tests will exceed 30 days, or when quality conformance inspection would require special equipment not commonly available, or when the specification covers life survival or emergency life-saving equipment. The specifications for these products include the requirements for qualification, the qualification tests, and the name of the activity responsible for qualification. Products that are qualified are listed on qualified products lists.

International specifications and standards for paint and coatings may be of interest. For example, Canadian standard 1-GP-71, *Methods of Testing Paints and Pigments*, may be obtained from the Canadian General Standards Board (Ottawa, Canada K1A 1G6, 819/956-0425). ISO (International Organization for Standardization) standards, such as the ISO 9000 series on quality performance, may be ordered from ANSI, the American National Standards Institute (1430 Broadway, New York, NY 10018 (212/642-4900) or directly from ISO (1, rue de Varembé, Case Postale 56, CH-1211 Genève 20, Switzerland, Telephone +41 22 749 01 11).

SOURCES OF PAINT SPECIFICATIONS

Federal Government Sources

The U.S. Department of Defense (DOD) *Index of Specifications and Standards (DODISS)* indexes government standardization documents (military specifications, standards, and handbooks; federal specifications, standards, and commercial item descriptions; qualified products lists; and industry documents adopted for DOD use); as well as alphabetic, numeric, and Federal Supply Class (FSC) listings. The *DODISS* is available to civil agencies and private sector industry by subscription, as either hardcopy from the Government Printing Office, or as microfiche from the Defense Printing Service Detachment Office (DPSDO) at 700 Robbins Avenue, Building 4D, Philadelphia, PA 19111-5094. Individual government documents may be ordered, generally without charge, from DPSDO; by telephone 215/697-2667, by fax 215/697-2978, or by mail from the Standardization Documents Order Desk, same address as previously stated. Automatic distribution of standardization document also is provided by DPSDO by subscription for new or revised issues in requested FSCs.

and Materials (1916 Race Street, Philadelphia, PA 19103, 215/299-5585) has developed more than 800 standard test methods and practices concerned with paints and coatings. They include standard specifications for many paint raw materials, although not for commercial paints. These standards are published as Vols. 6.01 through 6.04 of the *Annual Book of ASTM Standards* and are available as separate standards.

AAMA, the American Architectural Manufacturers Association (Suite 310, 1540 East Dundee Road, Palatine, IL 60067, 708/202-1350), publishes specifications for organic coatings for aluminum. AASHTO, the American Association of State Highway and Transportation Officials (444 N. Capitol Street NW, Washington, DC 20001, 202/624-5800), has developed standards dealing with highway materials of construction, including paints. MFMA, the Maple Furniture Manufacturers Association (60 Revere Drive, Suite 500, Northbrook IL 60062, 708/480-9138), publishes specifications for finishes for wood floors and a list of conforming floor finish products.

NACE, the National Association of Corrosion Engineers (1440 South Creek Drive, Houston, TX 77084, 713/492-0535), has developed standards covering corrosion testing, selection of corrosion-resistant materials, and the use of coatings to reduce corrosion. SSPC, the Steel Structures Painting Council (4400 5th Avenue, Pittsburgh, PA 15213, 412/268-3326), has developed paint specifications and other standards for the preparation of metal surfaces for painting, painting systems, and paint application. CSI, the Construction Specifications Institute (601 Madison Street, Alexandria, VA 22314-1791, 703/684-0300), has prepared several *SpecGuides* as part of construction documentation covering the preparation of technical specifications for paints and painting.

Underwriters Laboratories Inc. (333 Pfingsten Road, Northbrook, IL 60062, 312/272-8800) is used to obtain UL listing, classification, and recognition. Testing sites are also located in California, North Carolina, and New York.

Nongovernment standards that have been adopted by the DOD and that are listed in the DODISS are issued by the Navy Publishing and Printing Service Office to DOD activities only [*4*].

Electronic Database Sources

A powerful database, the Construction Criteria Base (CCB), is available in compact disc format by subscription from the National Institute of Building Sciences (1201 L Street NW,

Suite 400, Washington, DC 20005, 202/289-7800). It includes the complete construction guide specifications of most federal government departments and agencies, as well as those of many nongovernment organizations. The model building codes also are accessible in CCB. It is a consolidated system that includes full copies of supporting documentation and the software needed to develop end-item contract specifications for projects, including:

- Applicable codes and regulations.
- Construction guide specifications, of major military departments and civil agencies.
- Design and estimating guidance documents.
- Materials, testing, and processing documents.
- Product data, available in full-color graphics.
- Built-in software for search and processing functions.

Accessible in the CCB are referenced military and federal specifications and standards, commercial item descriptions, together with referenced nongovernment specifications and other standards. These latter are included by agreements negotiated with the copyright owners. Subscription variations include read-only, or full print copy access.

Information Handling Services (IHS), (14 Inverness Way East, P.O. Box 1154, Englewood, CO 80150, 303/790-0600), is another general source for both government and industry specifications and other standards for coating materials. It provides direct access to current issues of referenced documents cited in guide specifications, including all military and federal specifications, qualified products lists, handbooks, and commercial item descriptions. International standards are also available, as are vendor catalog services. Subscriptions are available in microfilm cartridge or compact disc formats.

National Standards Association (NSA), (1200 Quince Orchard Blvd., Gaithersburg, MD 20878, 301/590-2300), provides an online index (DIALOG File 113) of all U.S. government and industry standards, specifications, and related documents, including cancelled military specifications and standards dating back to the early 1940s.

Library Sources

Some standardization documents, indexes, databases, and services listed above may be available in government, state, city, industry, university, or federal depository libraries.

Table 1 summarizes construction/coatings criteria sources, access, and types of information available [5].

tests on, 18–20
types, 16–18
waterproofing membranes, 18
Black box, 634–636
accelerated natural weathering, 638
Black panel thermometer, 633
Black pigments
carbonaceous pigments, 179
classification, 180
iron oxide blacks, 179
(*see also* Ceramic coatings)
Bleeding
artists' paints, 708
traffic marking materials, 743
Bleed test, colored organic pigments, 207
Blister formation, osmotic, 768
Block copolymer sealant, 735
Block resistance
architectural coatings, 704
artists' paints, 708–709
can coatings, 723
Blue-green pigments, 214
Blue pigments, 197–198
inorganic, 210–211
BN 8-4, 579
Boiling point, solvents, 137, 139–140
Bond strength, thermoplastic marking materials, 745
Bone blacks, 179
BON maroon, 192
BON reds, 192
Borates, inorganic anti-corrosive pigments, 240–241
Bourger-Beer law, 869
Bragg equation, 872
Bratt conductivity cell, 663–664
Breakthrough time, effects of molecular size and affinity, 401–402
Bridges, sealants, 737
Brightness, 507
Brightwell method, 428
Brinell Indentation Hardness Tester, 566
Brominated pyranthrone red, 194–195
Brookfield and Stormer viscometers, 683
Brookfield CAP 2000 viscometer, 363
Brookfield Digital Viscometer Model KU-1, 360
Brookfield Synchro-Lectric viscometer, 362–363
Brookfield viscometers, 362–363
Brown magnetite iron oxide, 212
Brown pigment, inorganic, 212
Brunauer-Emmett-Teller method, 313
Brush application, architectural coatings, 701–702
Brush drag, architectural coatings, 701–702
Brushing characteristics, artists' paints, 707–708
Brushouts, 485
BS 1006, 207
BS 2662, 207
BS 3900, 441–442, 504, 561
E1, 550
E4, 551
BTL Balanced Beam Mar Tester, 579–580
Buchholz Indentation Hardness Tester, 566
Bulk modulus, 573
Buoyancy-hydrometers, 297–298
Burgers model, 348–349
Butyl alcohols, 129
Butyl sealants, 735
BYK-Gardner cupping tester, 551–552

C

Cadmium mercury orange, 212
Cadmium orange, 212
Cadmium red, 210
Cadmium sulfide yellow, 211
Cadmium zinc yellow, 211
Caframo REAX 2 rotating mixer, 416–417
Calcium borosilicate, 243–244
Calcium carbonate, 176–177, 217
California, smog, 3–4
Camp abrasion tester, 529
Can, production processes, 717–720
can end preparation, 719
three-piece can, 718–719
two-piece can, 717–718
Can coatings, 717–723
industry, 717
tests

on cured surfaces, 721–723
on liquid paint, 720–721
ultraviolet cured, 719–720
Cantilever (beam) method, stress in organic coatings, 589–590
Capillary forces, 355
Capillary rise, 374
Capillary rise method, contact angle measurements, 378
Capillary viscometers, 363–364
Capillary waves, 377

pigment
analysis, 879–880
identification, 762–763
procedure for calculating composition, 879
qualitative analysis, 874–878
quantitative analysis, 878
specimen preparation, 872–874
thin film units, 873–874
X-ray fluorescence spectroscopy, 759, 880–887
application, 880–881, 885–887
bulk contaminant detection, 885
comparison to other techniques, 885
dedicated spectrometers, 882
direct comparison method, 884

electron beam excited X-ray spectroscopy, 882–883
empirical methods, 884
field analysis, 886–887
film thickness measurement, 438
fundamental parameter methods, 884
on-line units, 882
physical basis, 881–882
pigment identification, 762
portable units, 882
procedures, 883
qualitative analysis, 883
quality control, 885–886
quantitative analysis, 883–884
scanning, 882
standard addition method, 884–885
surface analysis, 885
X-ray microanalysis, scanning electron microscopy, 817–818
X-ray photoelectron spectroscopy coating failure analysis, 768, 778
X-ray scattering, particle-size measurements, 325
Xylenes, mixed, 126

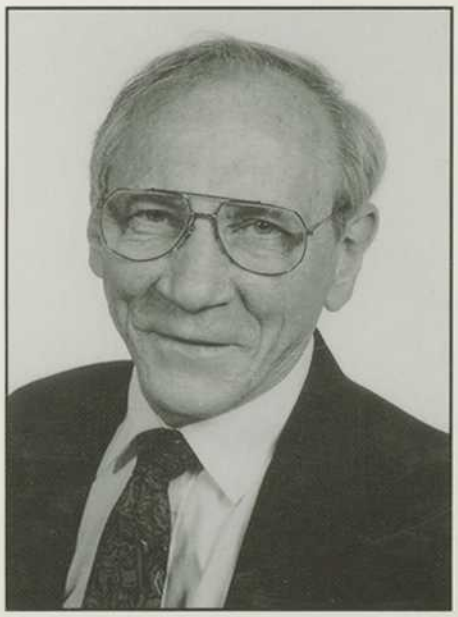
Y

Yellowing, artists' paints, 709
Yellowness indices, 462
Yellow pigments
inorganic, 211–212
(*see also* Colored organic pigments, yellows)
Yield behavior, practical aspects, 344
Yield stress
coating layers, 352
test methods, non-Newtonian behavior, 344
Young equation, 372
Young–Laplace equation, 373
Young's modulus, 564, 573

Z

Zabel test, 659
Zeeman effect, 786
Zinc
cathodic protection, 238
coating failure analysis, 778–779
in primers, 244
Zinc borate, 240–241
Zinc chromate, 211
Zinc hydroxy phosphite, 243
Zinc oxide, 244
Zinc phosphate, 242–243
Zinc pigment
grade classification, 224–225
properties, 224
Zinc potassium chromate, 241
Zinc tetraoxychromate, 241

About the Editor



Dr. Joseph V. Koleske is a Senior Consultant for Consolidated Research, Inc., in Charleston, West Virginia. He has served in this capacity for seven years. Prior to this position, he was a Corporate Research Fellow at Union Carbide Corporation in South Charleston, WV for 25 years. In his career, he has worked in the areas of material science; solution properties of polymers, fibers, and polyurethanes; and radiation-curable, powder, and high-solids coatings.

He is a member of ASTM and the Federation of Societies for Coatings Technology and serves on the Editorial Review Board of the ***Journal of Coatings Technology.***

Dr. Koleske received his B.S. degree from the University of Wisconsin-Madison and M.S. and Ph.D. degrees from the Institute of Paper Chemistry, Lawrence College, Appleton, Wisconsin.

He holds 87 U.S. patents in the above fields and is the author or coauthor of more than 90 journal articles and book chapters. Co-authored books include ***Alkylene Oxides and Their Polymers,*** Marcel Dekker Inc., New York, 1990; ***Poly(ethylene oxide)***, Academic Press, New York, 1976; ***Poly(vinyl chloride)***, Gordon & Breach, New York, 1969.
